In discussing the somewhat extensive subject of the degenerations of the liver it is obviously desirable first to determine what are the diseases that may fairly be considered as coming under that heading, and later to refer to their clinical aspects and diagnosis. On clinical grounds it may be well to divide the cases of degeneration of the liver cells into: (1) those that are primary or at least simultaneous with changes in the supporting and vascular tissues of the organ, including Kupffer's cells; and (2) those secondary to (a) gross disturbances of the vascular supply of the organ—for example, in portal thrombosis or cardiac failure; (b) inflammation or suppuration, as in abscess, pyelphlebitis, or cholangitis; and (c) biliary obstruction. There is not any distinction to be drawn between the pathological changes in these two groups, but it is to the first group that attention will be almost exclusively directed in the introduction to this discussion. They may be classified as (1) acute and subacute, and (2) chronic.

The primary acute degenerations of the liver cells may be clinically divided into the slight and the grave; the slight often transitory and without any obvious symptoms, though the recent tests for hepatic function may reveal insufficiency of the liver cells. That recovery may occur was proved experimentally by Whipple and Sperry,² who produced hyaline necrosis of the central two-thirds of the hepatic lobule by repeated chloroform anaesthesia for one to three hours on successive days. Acute degenerative changes may supervene in a previously damaged liver, as in cirrhosis or in the liver of chronic venous engorgement, and in this latter instance the change has been described as aseptic (Bolton³), as due to cytolytic ferments derived from the liver cells (Oertel⁴), or as bacterial (Mallory,⁵ Frothingham⁶).

The chronic degenerations of the liver include senile atrophy, fatty change, amyloidosis, cirrhosis, and the cirrhosis of haemochromatosis; the relation of primary carcinoma to degeneration of the liver will also be discussed.

ACUTE DEGENERATIONS OF THE LIVER.

Acute infectious and intoxications may produce partial or total degeneration of the lobules of the liver. Zonal necrosis of the hepatic lobule was studied by Opie⁷ in 1904; the peripheral zone is seldom affected as it is supplied by the portal vein and the hepatic artery, and poisons are prone to be swept on by the arterial blood into the intermediate zone, causing mid-zonal necrosis; out of 500 cases examined there were 4 only of peripheral necrosis, 3 being associated with puerperal eclampsia. Mallory,⁸ who previously described two forms of necrosis—focal and diffuse or central—found the latter to be specially connected with streptococcal infection; and more recently the central zone, which from its poor blood supply is the most vulnerable, has been found to be earliest and most affected in tetrachlorethane, trinitrotoluene, and arsonbenzol poisoning (Turnbull⁹). Combined necrosis of the middle and central zones is, as Opie pointed out, an early stage of the process that terminates as acute yellow atrophy.

Acute parenchymatous degeneration or cloudy swelling of the liver cells, such as occurs in various fevers, infections, and intoxications, is the effect of a process either less virulent generally or with less selective power to act on the liver. It may be the first sign of degeneration which subsequently shows fatty or necrotic change, or it may not proceed further and be followed by recovery of the liver cells. There are thus these three grades, or perhaps it would be safer to say three forms, of degenerative change. How far cloudy swelling is concerned in the production of symptoms in fevers and intoxications is an interesting question on which information is required and may be provided by functional tests, and it is possible that its importance has been overlooked in the past, even as regards the production of acidosis.

Acute and subacute hepatitis show in a varying degree, which may be regarded as depending on the nature of the causal agent, the attempts to repair the accompanying cellular degeneration—namely, cellular regeneration and proliferation of the interstitial connective tissue. It may be suggested that those forms of hepatitis that from the start are characterized by well-marked regeneration are less prone than the forms showing mainly degeneration to be followed by cirrhosis. Thus it is remarkable how very rarely cirrhosis can be ascribed to malarial hepatitis in which regeneration of the liver cells is a prominent feature. It is true that Jonesco and Poppel¹⁰ have recently described a malarial hepato-splenic cirrhosis, but they adopt Chauffard's¹¹ explanation that it is due to poisons derived from the spleen, a process analogous to Banti's disease and Egyptian spleno-megaly (Richards and Day¹²), in which hepatic cirrhosis eventually supervenes. It will be interesting to hear if cirrhosis is a sequel of spirochaetosis icterohaemorrhagica, in which well-marked regeneration of the liver cells may be present microscopically; at present there does not appear to be any evidence of this. On the other hand, Leonard Rogers¹³ has shown that cirrhosis follows kala-azar and amoebic dysentery, in both of which degenerative rather than regenerative changes are seen in the liver cells. Possibly the connective tissue proliferation, which Nathan¹⁴ argues serves a useful purpose as a nutrient medium for the liver cells, is only called into being when the liver cells fail to regenerate and proliferate without this help.

The grave acute degenerations of the liver provide the cases of the rather ill-defined clinical condition of icterus gravis, forms of which may be roughly catalogued as: (1) Acute yellow atrophy of inconstant or unknown aetiology, usually sporadic, and characterized by naked-eye atrophy of the organ, extensive necrosis, and subsequent autolysis of the liver cells. If not immediately fatal, it is succeeded by the process variously described as subacute atrophy, multiple nodular hyperplasia, acute cirrhosis, nodular hepatitis. (2) Due to known infections, such as streptococci, *Treponema pallidum*, *Leptospira* (*Spirochaeta*) *icterohaemorrhagica*, *Leptospira icteroides* of yellow fever, in which gross atrophy and autolysis are not in evidence. (3) Due to known poisons, which either produce severe degeneration with necrosis—such as tetrachlorethane, trinitrotoluene, and arsonbenzol (salvarsan) preparations—or well-marked fatty degeneration, as in phosphorus, chloroform, and iodoform poisoning. Some of these will be briefly passed in review.

Syphilis.

Syphilis in its early stage may produce a benign jaundice which is probably due to disordered action of the liver cells and not to intrahepatic and intralobular obstruction. But that this is the sole explanation may from the rarity of this

complication (0.3 per cent.) be questioned; possibly some other factor, such as an infection of so low a virulence that it would not damage a healthy liver, is able to exert this effect in an organ with its resistance already impaired. In exceptional instances, of which Parkes Weber¹⁷ collected 53 cases before the era of arsenobenzol compounds, the lesions of acute yellow atrophy are induced, and here again the question of the sole responsibility of syphilitic infection may be raised. Whether or not the *Treponema pallidum* is present in the liver still requires an answer.

Since the treatment of syphilis by arsenobenzol compounds has become general, the incidence of benign jaundice (0.56 per cent. among 39,377 military cases¹⁸) and of acute yellow atrophy has increased. The occurrence of such cases in groups and sometimes in association with epidemic jaundice or other infection (Stokes, Ruedemann, and Lemon¹⁹) in the neighbourhood has lent support to the natural suggestion that infection is the additional factor responsible for jaundice in syphilitic patients undergoing arsenobenzol treatment—an attractive but so far unproved explanation. The whole subject has been much discussed, and the Salvarsan Committee of the Medical Research Council has issued one report and has in the press another (Special Report Series, No. 66), which contains information on as yet unpublished work done by Mackenzie Wallis on functional tests—the laeculose tolerance and the blood lipase—showing that temporary hepatic insufficiency almost always follows a course of arsenobenzol injections. Spence and Broth²⁰ by the blood laeculose test found evidence of hepatic insufficiency in cases of benign jaundice following arsenobenzol treatment, and Vidal, Abrami, and Lancovescio²¹ obtained positive results in the cases following salvarsan treatment, both without jaundice, and more markedly in cases with jaundice, by their haemoclastic reaction, which, however, awaits further confirmation.

Spirochaetosis Ictero-haemorrhagica.

In spirochaetosis ictero-haemorrhagica the microscopical appearances show much variation, and jaundice, which is not an essential feature, does not correspond with the degree of structural change; it may indeed be extremely prominent in association with but slight microscopic change, and vice versa (Garnier and Reilly¹⁵). McNeo²² describes three groups of cases: (1) those with necrosis in the central zone of the liver; (2) those showing regenerative changes in the liver cells which are separated from each other and contain bile pigment, but have not undergone necrosis; (3) those with little change. The jaundice has been regarded as obstructive or as haemolytic (Basile²³), but Brink²⁴ and McNeo consider it to be due to disordered function of the liver cells. Spirochaetosis ictero-haemorrhagica is an example of the syndrome of hepato-renal insufficiency or of the cases otherwise described as acute nephritis with jaundice or hepato-nephritis, in which both organs are affected by the causal agent, and thus differs from cases in which the kidneys undergo degenerative changes from the intoxication due to grave hepatic lesions. The prognosis of cases of icterus gravis is in great measure determined by the functional activity of the kidneys, and this is particularly so in spirochaetosis ictero-haemorrhagica, in which grave symptoms may be due to uraemia. Garnier and Reilly¹⁵ indeed contrast the gravity of spirochaetosis ictero-haemorrhagica, which they regard as depending on renal insufficiency, with that of acute yellow atrophy, which is due to hepatic insufficiency.

Toxic Jaundice.

During the war 100,000 persons in this country worked in trinitrotoluene, and among them 404 cases of toxic jaundice were reported to the Home Office (O'Donovan²⁵); but after preventive measures were introduced, as the result of the late Benjamin Moore's²⁶ demonstration that the absorption of trinitrotoluene took place through the skin, the incidence of jaundice fell in a remarkable manner. The outbreak was fully investigated under the auspices of the Medical Research Committee, and two valuable reports^{27 28} were issued. A noteworthy point was the latency shown in the onset of jaundice—namely, the long interval that might elapse between the last exposure to the poison and the onset of jaundice, even up to nine months (E. E. Glynn); there was evidence to show that serious damage to the liver might occur without any symptoms (Panton²⁹). The causation of the hepatic changes—which, like those of tetrachlorethane and salvarsan poisoning, are much the same as those of acute yellow atrophy—has given rise to some discussion. Benjamin

Moore argued that trinitrotoluene first attacked the blood, and that from the resulting excessive metabolism of haemoglobin the liver became exhausted and underwent the grave degenerative lesions. Panton²⁹ disputed Moore's statement of constant blood destruction, and it may be added that if excessive haemolysis so exhausted the liver as to lead to grave lesions this should occur in pernicious and other forms of severe haemolytic anaemia. Though it was very difficult to induce the hepatic lesions in experimental animals by trinitrotoluene, the changes in the liver were regarded as due to the direct action of the poison on the hepatic cells. But from the comparative infrequency of toxic jaundice and from its tendency to occur in outbreaks the existence of some additional factor, such as a coliform infection, harmless or trivial in its effects on the healthy liver, but capable of producing grave changes in a liver with its resistance lowered by prolonged exposure to trinitrotoluene, has naturally been suggested. But no definite proof of this could be obtained. The position is exactly the same as regards the hepatic lesions seen after the administration of arsenobenzol compounds, and in both the factor of individual want of resistance on the part of the liver is a possible explanation.

On the histological evidence H. M. Turnbull³⁰ regarded the jaundice as obstructive and not haemolytic in nature, but he admitted that the escape of bile into the blood as the result of parenchymatous disintegration could not be excluded. Workers absorbing trinitrotoluene pass a chromogen, derived from trinitrotoluene in the urine, which is detected by Webster's test; but with the onset of toxic jaundice the chromogen disappears, and Dale³¹ shows that this azoxy compound is the most satisfactory method of eliminating trinitrotoluene from the body. So although a positive Webster test shows that the individual is absorbing trinitrotoluene its disappearance should be regarded as a danger signal of toxic effects.

Tetrachlorethane was employed early in the war as "dope" for rendering the wings of aeroplanes impervious to air and moisture, and in November, 1914, cases of toxic jaundice appeared. Up till July, 1916, when its use was given up, there were in all 70 cases of jaundice with 12 deaths (T. M. Legge³²). In 1913 a few cases had occurred in this country and in Germany. This form of toxic jaundice, specially investigated by Willcox, Spilsbury, and Legge³³ was due to the inhalation of the vapour of tetrachlorethane, and both experimentally and in man caused first fatty change in the liver, kidneys, and heart, and then extensive degeneration of the liver cells with diminution in the fat content, so that the lesions resemble those in trinitrotoluene poisoning. Willcox³⁴ draws attention to the insidious onset of symptoms, the comparatively long duration of the acute stage with deep jaundice (thus differing from acute yellow atrophy), the freedom from much fever (a distinction from infective jaundice), the absence of anaemia, and the well-marked jaundice.

Opie's³⁵ observation that whereas neither *Bacillus coli* nor chloroform alone produces acute degeneration and atrophy, this lesion may result from their combined action, has an important bearing both on the etiology and clinical aspects of icterus gravis and acute yellow atrophy. Thus it helps to explain the incidence of these manifestations when an anaesthetic is administered during the course of an acute intestinal or other infection. In this connexion the observations of E. A. Graham³⁶ that the resistance of the liver cells runs *pari passu* with their glycogen content has obviously a practical application: it has been shown experimentally by Davis and Whipple³⁷ that sugar given before anaesthesia protects the hepatic cells against damage by chloroform, and when given after anaesthesia enables the cells to recover rapidly, that proteins are much less effective in this respect, and that the administration of fats facilitates the changes in the liver cells. On these grounds sugars and carbohydrates should obviously be given before and after operations, proteins sparingly, and fats avoided.

Widespread, if not total, degeneration of the zones of the hepatic lobules without necrosis may be due to poisons such as alcohol, phosphorus, chloroform, and iodoform, and be followed by excessive fatty change. I have seen an intensely fatty liver weighing 10 lb. in an alcoholic woman. Leathes³⁸ has shown that this extensive accumulation of fat may occur rapidly; and it appears reasonable to regard degeneration of the cells as the cause of the failure of the normal desaturation of fat by the liver, and so of accumulation of fat in the liver. It must, however, be admitted that such pathological fatty accumulation may also be a chronic

condition—for example, in alcoholic and tuberculous patients—and so come in the later category; in determining this point the tests for hepatic efficiency should lead to certain knowledge. The detection by functional tests of the presence of degeneration and fatty changes in the liver before operation would obviously be of value in the prevention of further hepatic degeneration by forbidding chloroform anaesthesia and by emphasizing the need for the administration of sugar.

Clinical Manifestations.

The clinical manifestations of acute degenerations of the hepatic cells vary greatly; in the severe forms there may be jaundice, chloaemia, and other obvious signs of hepatic insufficiency—as in acute yellow atrophy and icterus gravis; on the other hand, in the slight cases jaundice may be absent, and it is only by means of tests for hepatic insufficiency that the existence of impaired function of the liver can be established. The clinical latency of acute degeneration of the liver cells is suggested by two events: (a) the occurrence of acute symptoms a considerable time after exposure to the responsible poisons, such as trinitrotoluene and arsenobenzol preparations; and (b) the evidence of hepatic insufficiency revealed by efficiency tests—the blood lactulose and the lipase tests—after courses of salvarsan. To explain why symptoms do not appear at once when acute degenerative changes have presumably occurred, it may reasonably be suggested that the initial degeneration is not sufficiently widespread to exhaust the compensatory power of the liver, and in support of this the well-known cases of subacute atrophy may be instanced.

The delayed occurrence of acute atrophy in persons removed from exposure to trinitrotoluene, or in patients weeks or months after the termination of a course of salvarsan, is a difficult problem; three explanations may be tentatively mentioned: (a) A bacterial or other poison derived from the intestine or elsewhere may attack the liver cells, which, being already damaged, are not able to offer effective resistance to a poison against which they have no acquired immunity. It appears probable that the influence of two poisons acting successively on the cells and tissues of the body has hardly received due attention, though Opie's work has thrown light on this subject. Stuart McDonald²⁹ suggested infection with organisms of the coli-typhoid group, acting on a liver damaged by syphilis and by salvarsan, as the additional factor responsible for the occurrence of the grave hepatic lesions following treatment by arsenobenzol compounds, but Turnbull's³⁰ histological examination of the livers in 8 cases did not lend any support to the view of bacterial infection. (b) Foulerton³¹ pointed out that chloroform, ether, and tetrachlorethane are fat solvents, and that three other substances which produce degenerative changes in the liver—phosphorus, dinitrobenzol, and trinitrotoluene—are readily soluble in fats. He suggests that these poisons become linked with the reserve fats in the subcutaneous and visceral adipose tissue, and when on an emergency these fats are mobilized in considerable quantities and carried to the liver to be desaturated and converted into available organic fat, these poisons pass to the liver in such quantities as to set up grave lesions in an already damaged organ. In conjunction with Heritson he found that arsenic is present in the largest quantity in those parts of the body that are richest in fat. (c) The action of the poison may be progressive, and finally the lesions may become so extensive that complete hepatic insufficiency results; Turnbull³⁰ considered that in the livers of arsenobenzol and trinitrotoluene poisoning there was strong evidence of the progressive action of the poison.

In degeneration of the liver the multiple functions of its cells are, at any rate from a clinical point of view, less impaired than might have been anticipated: indeed on this point our knowledge is probably more deficient than is generally recognized, and should be greatly extended by the wide employment of the recent tests for functional efficiency. But in connexion with these functional tests the share taken by other parts of the body, such as the pancreas and muscles, must be borne in mind. The most obvious defect is jaundice due to retention of bile pigment in the circulation as the result of disordered function of the liver cells, the bilirubin being shunted into the blood or lymph capillaries instead of into the bile capillaries. But even here we are not on sure ground, for it is no longer certain that the liver cells manufacture the bile pigment; Brulé⁶ argues that the liver cells merely pick out bile pigment and salts from the blood and excrete them; and it has been thought that bilirubin is manufactured by the vascular endothelium generally and by

Kupffer's cells in the liver (Lepelme³²; Hatiégau³³; C. M. and B. B. Jones²⁹) and then passed on to the liver cells, which, possibly after altering the bilirubin in some way, excrete it into the bile capillaries. It is thus possible that the liver cells modify the bilirubin in a manner analogous to their action on fats as described by Leathes.³² Dr. J. W. McNee has suggested to me that this hypothetical action of the liver cells may account for the form of bilirubin which gives the direct or immediate reaction with van den Bergh's diazo-test of the blood serum³⁴ (in mechanical or obstructive jaundice), and that the delayed or indirect reaction with van den Bergh's test is given by the form of bilirubin (in haemolytic and non-obstructive jaundice or Lepelme's functional jaundice) which has not undergone this modification by the liver cells.

Dissociated jaundice in which either bile pigment or bile salts, but not both, are retained in the blood stream as the result of disordered function of the liver illustrates the diverse, almost capricious, manner in which the degeneration of the liver cells may show itself. Here again we are reminded of the imperfect state of our knowledge, for although Grigaut³⁵ believes that the cholesterol yields cholic acid, and that functional disorder of the liver cells interferes with this transformation and so leads to an increased cholesterol content in the blood, the mode of formation of bile acids is far from established. Discussion may perhaps be directed to the view recently put forward by C. M. Jones²⁷ that the lowered haemoglobin content in the course of acute infections such as pneumonia, enteric, scarlet fever, and septicaemias, and also in chronic degenerative conditions such as cirrhosis, Banti's disease, and hepatitis, is not due to haemolysis but to failure of the liver to resynthesize the derivatives of bilirubin—namely, urobilinogen and urobilin—with the iron into haemoglobin, and that as a result there is an excess of bile pigments obtained by aspiration from the duodenum.

The manifold proteolytic functions of the liver cells depend upon a number of ferments, and, although little is known of those concerned with the metabolism of cystin, alkapton, and the porphyrins, it would seem that these ferments, whether they be confined to the liver or not, must be highly resistant, because the manifestations of cystinuria, alkaptonuria, and porphyrinuria, which Sir Archibald Garrod has happily called inborn errors of metabolism, are so rarely seen even in very grave and extensive degenerations of the liver cells. As a rare example, Simpson's³⁶ description of haematoporphyrin in the faeces of a case of malaria may be quoted. Non-diabetic acidosis is often associated with fatty liver—for example, in cyclical vomiting, pregnancy, appendicitis, cholecystitis, and delayed chloroform poisoning—because the ketone acids liberated in the deamination of the amino-acids are not oxidized. A question for discussion arises as to the causation of the general haemorrhages seen in grave degenerations of the liver; they may be due to diminution in the fibrinogen in the blood from damage to the liver cells, and in support of this there are observations showing that chloroform and phosphorus poisoning and cirrhosis are accompanied by a fall in the fibrinogen content and the coagulation power of the blood (Whipple, Gram³⁷). But the poisons or infections responsible for the hepatic degeneration, such as arsenobenzol preparations, may act as acute endotheliolytic agents, and so directly cause haemorrhages; or toxins absorbed from the intestines may, from failure of the liver to stop them, pass into the general circulation.

Prognosis.

The prognosis of cases in which recovery from clinically severe acute degeneration of the liver has occurred and in which the liver has presumably undergone permanent damage, such as subacute atrophy with cirrhosis and compensatory hyperplasia, is a subject on which more information is desirable; for trinitrotoluene poisoning must have left a legacy of many cases of this kind, and others will arise from time to time from non-fatal sporadic acute yellow atrophy and from the ill effects of salvarsan treatment. Ross and McMaster's³⁸ experimental work showing the great reserve power of the liver both in structural reparation and in function, and the knowledge that ordinary multilobular cirrhosis may become compensated and remain latent, make it probable that in favourable circumstances—namely, freedom from renewed intoxication and secondary infections—the outlook should be fairly good. M. Stewart³⁹ followed up 17 patients two to three years after recovery from toxic jaundice due to trinitrotoluene, and found that they all were in reasonably good health and had been free from any relapse of

judice, but that practically all of them suffered from certain amount of epigastric pain.

The treatment of acute degenerations of the liver, especially on the point of view of prophylaxis, by increasing the resistance of the liver cells by dietetic measures—namely, administration of
Davis and Whipple

CHRONIC DEGENERATIONS.

The *senile atrophy* of the liver with diminution in the size of the lobules and of the cells which contain granules of a so-called lipochrome pigment is not accompanied, as are most chronic degenerations of the liver cells, by hyperplasia of the interstitial tissues, possibly on account of the general loss of vitality of the whole organ.

Pathological fatty accumulation of the liver cells results in degeneration due to infective and toxic processes, and is accompanied by other evidence of impaired functional activity; thus Auld² found that blood pigment liberated in a spleen in haemolytic experiments was not stopped by liver cells showing fatty change, though Kupffer's cells were loaded with blood pigment. In normal conditions the blood contains a fat-splitting ferment—lipase—the amount being remarkably constant; in hepatic disease the blood lipase is decreased and it has therefore been thought that normally the liver inhibits the formation of lipase. Whipple found that blood lipase increased in experimental chloroform poisoning; he employs a test consisting in the addition of amyl butyrate to the blood serum as a means of estimating the functional efficiency of the liver. The frequent absence of jaundice in fatty livers shows that the function of biliary excretion is not necessarily affected in a severe manner to correspond with failure in its activity in fat metabolism.

Amyloid liver, which is an infiltration of the vascular network of the liver, is by definition not a degeneration; but it has as much claim to be mentioned here as the secondary liver, except that the pathological fatty infiltration is a secondary degeneration of the hepatic cells. In the amyloid liver the hepatic cells often show a secondary degenerative change, as evidenced by fat or atrophy, and it is therefore noteworthy that cirrhosis does not occur; possibly, as Nathack²⁰ suggested, this depends on impaired vitality of the connective tissues.

Cirrhosis.

Portal or multilobular cirrhosis is the result of attempts to repair the damage done by multiple focal degenerations of the cells in the peripheral and intermediate zones of the lobules. Though this process is usually spread over a long period of time, it is not always chronic, for in subacute atrophy and in poisoning by tetrachlorothane and trinitrofluorene the cirrhosis merits the description acute or subacute. Indeed, acute yellow atrophy and portal cirrhosis are the result of a process similar in nature, though differing markedly in their rate of progress, with transitional stages such as the subacute diffuse hepatitis described by Symmers.²¹ The cirrhosis in portal cirrhosis has usually been regarded in the light of cicatricial tissue and as devoid of any useful purpose; but the recent experimental work of Nathan,²² in implanting the omentum into the kidney and liver, suggests that young connective tissue, by providing the liver cells with a nutrient medium which is effective in proportion as it approaches the structure of the embryonic mesenchyma, favours their multiplication and compensatory hyperplasia. In this connexion it may be remembered that the newly formed connective tissue in hepatic cirrhosis is very freely supplied with blood vessels from the hepatic artery which is normally responsible for the nourishment of the hepatic parenchyma; in fact, there is in cirrhosis a much freer communication between the hepatic artery and the portal vein than normally (F. C. Herrick²³). The formation of connective tissue in hepatic cirrhosis, therefore, initiates a means of furthering compensatory hyperplasia, but, after stimulating the growth of hepatic cells, even to the formation of adenomas, the fibrous tissue, having accomplished its end, becomes old and no longer of any use; indeed, by cicatricial contraction it does harm, and thus is an example of a compensatory process that fails. The secondary changes succeeding the original degeneration of the hepatic cells in cirrhosis that have been mentioned so far are those of a compensatory nature, but their degeneration leads to the production of de-differentiated cells in which the property of active growth is developed at the expense of the higher functional powers. The bearing of such cells on the problem of tumour formation will be referred to later.

The factor of alcoholism in the production of multilobular cirrhosis, though it must still be regarded as important from its frequency and chronicity, is now recognized as one only of the conditions that may, directly or indirectly, produce focal degenerations followed by repair of the liver. Attention has recently been directed to the part played by syphilis in the aetiology of cirrhosis because the Wassermann reaction is so

in the subjects of that disease (Symmers,²⁴ Letenne,²⁵ Owen²⁶). It should be mentioned that as long ago as 1900 J. F. Payne²⁷ expressed his opinion that multilobular cirrhosis in children is due to syphilis, and this appears to be cases except those of Wilson's disease, for which Hall²⁸ who has the name "hepato-lobular" cirrhosis very probably acts as an

also, has been stated to be a cause of cirrhosis, especially by Roques and Cordier,²⁹ who regard the aetiology of cirrhosis as always tuberculous; but even if this latter view is correct, the infection of the peritoneum might be secondary to, and different from, that causing the degeneration of the liver cells. When focal degenerations in the liver occur as the result of infections and intoxication, hepatic cytolytic changes should be produced from absorption of their protein and a vicious circle result (Fleissinger³⁰). How far this may take place is open to considerable doubt. After repeated anaphylactic shock, Longcope³¹ found the livers of experimental animals to be cirrhotic as the result of fibrosis around the necrotic foci.

The glyco-genic function of the liver has for many years been tested by the examination of the urine after the ingestion of 100 grams of some form of sugar—such as cane, grape, or galactose—by the mouth; but now the laevulose tolerance test, which should not in health give rise to hyperglycaemia, has superseded tests in which the threshold of the kidney introduces a disturbing factor. Chausseard, Brodin, and Zizine³² find that active cirrhosis is characterized almost constantly by hyperglycaemia, and generally by the presence of bile salts and urobilin in the urine.

The excess of urobilinogen and urobilin in the urine of patients with cirrhosis has long been regarded as evidence of hepatic insufficiency. The mechanism of the formation of urobilinogen and urobilin has received a number of explanations, and recently the commonly accepted view—the entero-hepatic—has been attacked by Hooper and Whipple,³³ Brulé,³⁴ and C. M. Jones.³⁵ According to the entero-hepatic explanation urobilin is formed only in the intestine by the nascent hydrogen liberated as the result of bacterial activities, and the urobilin thus formed partly escapes as the stercobilin of the faeces and is partly absorbed and carried to the liver to be reconverted into bilirubin; but if the functional power of the liver cells is impaired, or if they are overworked by dealing with the blood pigment of excessive haemolysis, some of the urobilin passes into the blood and so into the urine. In place of this explanation it is now urged that there is an intrahepatic formation of urobilin from bilirubin, a valid argument in its favour being that duodenal aspiration—that is, above the intestinal level where bacterial activity would lead to the formation of urobilin—shows the presence of urobilin. Whipple³⁶ contends that there is no evidence of absorption of urobilin from the intestine. Increase in duodenal urobilin occurs in haemolysis, but is also found in cases of anaemia without any other evidence of haemolysis; and, as mentioned above, C. M. Jones,³⁷ following Wilbur and Addis,³⁸ suggests that from impaired function the liver fails to resynthesize the urobilin with iron into haemoglobin, and that hence there results an excess of urobilin in the duodenum and a deficiency of haemoglobin in the blood. This would account for the anaemia sometimes associated with portal cirrhosis when there is no evidence of loss of blood by the bowel, such as may be shown by the benzidine test for occult blood.

The pigmented cirrhotic liver of haemochromatosis—a subject discussed in the Section of Pathology and Bacteriology at the meeting of the British Medical Association last year (vide Dunn³⁹)—presents several features of interest in connexion with the degenerative diseases of the liver. In cirrhosis some degree of siderosis of the liver cells is common (Kretz,⁴⁰ Abbott⁴¹); and, in opposition to the old view that siderosis of haemolytic origin was the cause of cellular degeneration and cirrhosis, it has been argued by Potter and Milne,⁴² and, as the result of repeated transfusion of blood for months in rabbits, by Rous and Oliver,⁴³ that the primary

lesion in haemochromatosis is multilobular cirrhosis of the liver. That haemolysis is not responsible for the excess of haemosiderin was urged by Moltzer,⁴¹ G. Parker,⁴² Sprunt,⁴³ Garrod and his co-workers,⁴⁴ and on experimental grounds by Rous and Oliver, who showed that the distribution of iron in the body differs in haemolysis from that in haemochromatosis. But, nevertheless, the haemosiderin should be regarded as derived from the haemoglobin, though its origin from the iron-containing proteins of the cells of the body has been suggested by Mackenzie Wallis⁴⁵ and by Sprunt. It is now generally agreed that iron is retained in the body, especially in the liver, which is normally concerned with the storage of iron and the metabolism of blood pigment. The damaged liver cells are apparently unable to deal with the pigment, which therefore accumulates, with the result that further cell destruction and secondary cirrhosis follow. But the question arises whether the haemosiderin collects first in the liver cells or in Kupffer's cells, which are said to be the main repositories of the pigment (W. G. MacCollum). It may be noted that the cirrhotic liver of haemochromatosis is remarkable for the presence of endarteritis, and that there is a close relation between the vessels and Kupffer's cells. The connexion between injury of the cells of the body and the presence of haemosiderin was noted by Potter and Milne and by Garrod as regards the cutaneous distribution which is on the exposed parts, and by Rous and Oliver in the viscera and atheromatous areas of arteries; but there must be some special factor concerned, for visceral and other lesions are common in the absence of siderosis.

The origin of the pancreatic changes, which when advanced are responsible for the terminal stage of bronzed diabetes, is worthy of discussion; the pancreatic fibrosis is still regarded as secondary to the haemochromatosis, whereas the hepatic cirrhosis is considered to be primary. But as some degree of pancreatitis is commonly associated with hepatic cirrhosis, it might logically be urged that this favours the incidence of siderosis, though, as in the case of the liver, the siderosis leads to a secondary and superadded fibrosis—a vicious circle. The sex incidence of haemochromatosis is remarkable: for two cases only (Abbott,¹ Roberts⁴⁶) have been reported in women out of about 80 recorded cases, Roberts's case showing glycosuria. In this respect it corresponds with primary carcinoma in a cirrhotic liver—another, possibly degenerative, sequel of cirrhosis; out of my 52 collective cases of primary carcinoma in a cirrhotic liver 47 were in males; cirrhosis is of course more frequent in males than in females, but the proportion is probably not so high as 3 to 1, whereas the proportion in primary carcinoma arising in a cirrhotic liver is 10 to 1; and in haemochromatosis 40 to 1.

As ordinary multilobular cirrhosis may be followed by primary carcinoma it is not surprising to find that the same sequence of events may occur in connexion with the cirrhotic liver of haemochromatosis, and indeed appears to be rather unduly frequent; Lochlein⁴⁷ collected three such cases in 1907, and at the Pathological Section of the British Medical Association meeting last year Maxwell Telling⁴⁸ and Matthew Stewart⁴⁹ referred to two cases that occurred at Leeds and were detected at necropsy only.

The amount of iron retained in the body is enormous and may amount to 40 grams, or eight times the normal quantity (5 grams according to Muir and Dunn⁵⁰); and the liver, which normally contains 20 cg., has been found to have 100 times this quantity. There is some evidence that this is due to diminished excretion by the kidneys and intestines (C. P. Howard and Stevens,⁵¹ McClure⁵²); but this retention is not absolute. Although Garrod¹⁷ reported absence of iron in the urine, faeces, and bile, Rous⁵³ described the presence of haemosiderin in the urine as a diagnostic sign of haemochromatosis. A relative retention of iron over a long period would suffice to lead to the enormous accumulation mentioned above.

The clinical features of the complete disease, bronzed diabetes—namely, the peculiar bronzing differing in some respects from that of Addison's disease, especially in avoiding the oral mucous membrane, the enlarged liver with occasionally prominence of the left lobe, and the enlarged spleen and the glycosuria—were regarded by Potter and Milne as a chain of circumstances which is rarely completed rather than as a definite symptom complex. Garrod,¹⁷ who also inclines to the view that it is not a definite disease, brings out the distinctive features of the pigmentation—namely, its occurrence on parts

exposed to the air and light rather than to pressure and irritation, thus showing a resemblance to the pigmentation he has recently described in porphyriurias, and its superior claim to the adjective "bronzed" as compared with that of Addison's disease and of chronic arsenical poisoning. He refers to the somnolence and asthenia as the results of the cirrhosis rather than as due to diabetes. From pigmentation of the ductless glands pluriglandular insufficiency and disappearance of the secondary sex characteristics have been described (Claude and Sourdel⁵⁴). The blood shows hyperglycaemia but no anaemia. Skiagraphically the liver does not show any increased opacity (Shattock⁵⁵), so x rays do not help in the diagnosis.

Diagnosis.—The association of glycosuria, hepatic cirrhosis, and cutaneous bronzing makes recognition easy; but glycosuria is usually a late event. In cases of cirrhosis with cutaneous pigmentation examination of a piece of skin may clinch the diagnosis by showing the presence of haemosiderin microchemically, and the discovery of the pigment in the urine has a similar significance; but negative results with these tests are not of any value.

Primary Carcinoma.

Primary carcinoma of the liver is not usually regarded in the light of a degenerative process, but as the result of a proliferation which has run riot. Primary carcinoma following cirrhosis is the form of hepatic new growth in which degeneration would appear to be most likely to play a part, for here progressive degeneration is known to occur and to be followed by compensatory hyperplasia of the liver cells; but according to Muir⁵⁶ the most reasonable explanation is that of Orth—namely, that for some unknown reason the proliferation oversteps the normal and takes on the autonomous character of a neoplasm. Thus carcinoma has been regarded as a regenerative process in which the de-differentiated cells have taken over the power to invade and destroy other cells (Brodens⁵⁷). But the view that degeneration is the primary step in carcinoma deserves consideration; from the study of senescence in dogs Goodpasture⁵⁸ concludes that degeneration, besides leading to the death of some cells, is followed by de-differentiation of others which become simpler in structure and function and recover their earlier power of growth, so that metaplasia and neoplasia are accidents of commencing old age. Oertel⁵⁹ also regards the transformation of degenerating into carcinoma cells as a phenomenon of senescence and due to disturbances in the nucleus-plasma relations, specifically the loss of nuclear chromosomes. He argues that of the two groups of chromosomes those with higher functions disappear while those concerned with growth survive, and that hence there develops a race of cells lacking the differentiation of normal cells but endowed with vegetative and reproductive process.

POINTS FOR DISCUSSION.

The extensive subject of degenerative diseases of the liver raises many interesting questions, of which the following are a few only.

1. The tests for functional efficiency of the liver; their scope, limitations, and results, especially in slight and latent degenerations of the liver.
2. Is the jaundice occasionally seen in early syphilis, in syphilitic patients after arsenobenzol treatment, and the jaundice of munition workers due to an additional factor—namely, infection—or does it merely depend on inherent weakness of the liver?
3. What is the explanation of the delayed onset of symptoms in persons previously exposed to the action of poisons such as trinitrotoluene and arsenobenzol preparations?
4. In degenerative diseases of the liver is jaundice due to (a) failure of the damaged cells to remove from the blood bilirubin formed elsewhere, or (b) do the liver cells, as the result of disordered function, shunt the bile pigment into the lymph or blood capillaries instead of into the biliary capillaries?
5. Is anaemia in hepatic degeneration due to failure of the liver cells to resynthesize urobilin and iron into haemoglobin?
6. The intrahepatic formation of urobilin.
7. How far is the incidence of cirrhosis after hepatitis accompanied by degeneration of the liver cells obviated by concomitant hyperplasia of the liver cells?

8. Is the interstitial hyperplasia in cirrhosis initially a noncellular process?
9. The value of haemosiderinuria in the diagnosis of haemochromatosis.
10. The relation of primary carcinoma of the liver to a previous degeneration and de-differentiation of the liver cells.

DISCUSSION.

Professor HUGH MACLEAN (St. Thomas's Hospital, London) said: Sir Humphry Rolleston has given us such an excellent and concise summary of the present position of liver pathology that I think little remains to be added. Personally, I should like to say something in connexion with liver tests, and more particularly with regard to the new laevulose test. Every investigator who tries to evolve tests for liver deficiency is always confronted with the difficulty that the functions of the liver are not really understood, and consequently it is not easy to suggest suitable methods. The two tests of which I have had most experience are the lipase test and the modern laevulose test. In my opinion the lipase test is, on the whole, not very satisfactory, as it cannot be relied upon to indicate the slightest derangements of liver activity. In certain cases it is useful, but on the whole not very helpful except in gross cases. With regard to the laevulose test, I should like to give its history very shortly, so as to clear up certain possible misunderstandings. The modern laevulose test was first used at St. Thomas's Hospital over three years ago by MacLean and de Wesselow, and afterwards by Spence and Brett; it was based on an observation made by the former observers, which was published in the *Quarterly Journal of Medicine* in January, 1921. This observation was to the effect that whereas all the ordinary sugars such as glucose, cane sugar, lactose, maltose, and galactose, when ingested raised the concentration of sugar in the blood, this did not happen when laevulose was given. Thus, if 50 grams of glucose were given to a healthy person, the blood sugar concentration was increased in the first half-hour or so from the usual 0.1 per cent. to about 0.15 or 0.17 per cent. From this maximum point the concentration began to decrease, and in about one and a half hours the blood sugar had returned to its normal value. When, however, 50 grams of laevulose were given, and the blood sugar was estimated at half-hourly intervals as before, no rise was found to take place. The effects of the two sugars on a healthy subject might be represented graphically by a distinct curve for glucose, and by a straight line for laevulose. From various considerations it was known that this lack of power on the part of laevulose to raise the blood sugar depended on an intact liver, for it was found that in patients suffering from a definite lesion of the liver the laevulose acted more or less like glucose and caused a marked increase in the blood sugar concentration. The modern laevulose test is therefore based on two facts: (1) laevulose, when given by mouth in doses of from 30 to 50 grams, does not raise the blood sugar in healthy subjects with an intact liver; (2) when the liver is defective it is not able to prevent laevulose from entering the blood stream, and so a rise in blood sugar concentration follows the ingestion of this sugar.

I should like to point out that laevulose and nearly all the other sugars have from time to time been used as liver tests, and that laevulose has been specially employed by Strauss. Now Strauss just gave a dose of laevulose and afterwards tested the urine for the presence of sugar. If the urine gave a sugar reaction the fact was taken as indicating liver involvement. It hardly seems necessary for me to point out that the modern laevulose test described has no connexion whatever with Strauss's test, except that in both cases laevulose is used. To say that the tests are in any way similar betrays an entire ignorance of the fundamental basis of the modern laevulose test. One might as well say that two entirely different surgical operations were the same because, in both cases, the surgeon used the same scalpel. A very slight experience of Strauss's test shows that it is of little value. This is fully explained in the light of the results of the modern test. Strauss's test could only give reliable results in gross cases where the renal threshold for laevulose had been exceeded. It is quite common, however, to find a marked sugar reaction with this test in patients in whom the liver is quite efficient, as indicated by the modern laevulose test and by the clinical condition. On the other hand, in many cases of obvious liver involvement no indication whatever of the condition is obtained by Strauss's test. It is quite impossible to enter into the reasons for these discrepancies here, but so marked are these anomalies that the test has long ago fallen into disrepute. The modern laevulose test is based not on Strauss's work, but on the observation already described, that when the liver was intact laevulose would not raise the blood sugar concentration. The test resulted directly from this observation, and until this essential fact was established the blood sugar method could

from Eight
Research

not be utilized as its results could not be interpreted. Further, it seems certain that in many cases the apparent positive results with Strauss's test were much more intimately associated with impurities in the laevulose than with any liver deficiency.

With regard to the prevention of toxic jaundice after the administration of arsenobenzol, it would appear, from the results of observations made by Colonel Harrison at St. Thomas's Hospital, that the ingestion of some sugar before the injection of the drug was of material benefit in warding off such attacks. In a set of patients receiving sugar before injection there were only two or three cases of jaundice after treatment, while in another set not receiving sugar there were nearly fifty cases. Whether or not a larger experience will justify these results must of course depend on future observations.

Dr. C. M. Wilson (London) said that hepatic insufficiency might be betrayed either by obvious signs or symptoms, such as jaundice, or in the absence of these by laboratory tests demonstrating the latent insufficiency. Clinicians required a test which would apprise them of impaired function of the liver when there were no symptoms to warn them of that impairment, or at any rate before such symptoms appeared. They needed, for example, not so much a test which would tell them the exact extent of the damage that chloroform administered as an anaesthetic had done to the liver, or even the date when that damage had been repaired, but rather one that would veto chloroform as an anaesthetic by warning them of hepatic insufficiency, just as glycosuria arrested the hand of the surgeon. Had we up to the present any such test of liver efficiency? He did not wish to belittle the value of the work done in that field, nor was he blind to the light that by means of these tests was being directed on the multiple functions of the liver cells; but for the moment he was concerned to question whether they possessed any test of liver efficiency sufficiently delicate to tell them what they wanted to know at a time when it was most needed—namely, before the advent of signs and symptoms revealed the nature of the trouble. He would be content in his contribution to that discussion to attempt to find some answer to that question. If he appeared unduly cautious they might, perhaps, agree with him that in chemical pathology at the present time, in its application to clinical work, a conservative view was not without value.

To obtain some idea of the comparative value of such tests, their scope and limitations, he had taken thirty apparently normal male students of practically the same age and carried out on them tests of hepatic efficiency by five methods—the estimation of the lipase and cholesterol of the blood, the laevulose tolerance test, the nitrogen distribution of the blood, and the haemoclastic crisis. Starting from that basis—and in the present confusion in the literature it was necessary to begin by establishing the normal—the same tests were applied to all abnormal conditions of the liver that came under his observation. An investigation of that nature was a laborious undertaking requiring many months for its completion, and he could only furnish them with tentative conclusions. Moreover, the time at his disposal in that discussion robbed these conclusions of their supporting facts, leaving them in the air as a few bald and isolated statements. He would once more remind them that they were seeking for a test whose warning preceded the onset of symptoms. In the course of that discussion a claim had been made that the lipase test satisfied these requirements. This test depended on the increase in certain diseases of the liver of the fat-splitting ferment lipase, which was normally present in the blood. In the thirty students used as controls the figure varied between 0.1 and 0.32. But when the test was applied to diseases of the liver it was found, as Whipple maintained in 1913, that the figure rose only when there was actual necrosis of liver cells. It provided information in certain diseases of the liver, but it did so only when that information had been already furnished by clinical means. The test had little or no value in unmasking a latent inefficiency. And this applied to some of the other tests.

He concluded provisionally that, with the possible exception of the laevulose tolerance test, the only test which gave an early warning of hepatic insufficiency was that described by Widal as the haemoclastic crisis. Under that rather forbidding name was concealed a test disarming in its simplicity. The haemoclastic crisis depended on the fact that the normal digestion leucocytosis was replaced by a leucopenia when the liver was diseased. A white cell count was taken before the

patient's breakfast, seven ounces of milk were then drunk, and another count made twenty minutes after the milk. Of thirty normal students more than half showed a rise in the second count of 3,000 or upwards, while only two failed to show a rise of less than 1,000, so that the individual error in the count was not a factor. In two of the thirty the rise was delayed till forty minutes after taking the milk, so that it was advisable to do three counts if the second showed no rise, but commonly only two counts were necessary. In diseases of the liver there was an invariable fall in the second count. The question in this test appeared to be not whether it was positive in the early phases of diseases of the liver, but rather in how many other conditions a fall of the leucocytes followed drinking milk. Since Widal's observation, a certain amount of work had been recorded in Continental journals, recently summarized in *Medical Science*. The haemoclastic crisis was found not only in obvious diseases of the liver, such as carcinoma, but also in the course of certain infections wherein the liver was apparently affected. But it occurred, too, in diseases where the existence of hepatic involvement was either unsuspected or, at any rate, rested on mere speculation. Widal, for example, had found a positive result in asthma and in his (the speaker's) experience the most marked reaction occurred in that malady. He (Dr. Wilson) had also performed the test on 19 epileptics, 18 of whom gave a positive result. It was premature as yet to affirm that the test supplied what they wanted, but from many observations made during the past few months he could testify to its value and to the interesting possibilities that the test opened up. Perhaps the notes of two cases would illustrate in what direction we might look to this test for assistance.

CASE I.

A stout, red-faced countryman attended his out-patient department in May, complaining of epigastric pains. It was not easy to obtain any information through the protecting muscles of the abdominal wall, but he was surprised to find the haemoclastic crisis. The other tests of hepatic insufficiency to which reference had been made failed to support the evidence of the haemoclastic crisis. The physician to whose wards he was admitted could find no cause for the pain, and after a fortnight's observation the man was discharged. The pain, however, continued, and his faith in the test was restored by the reappearance of the man some weeks later with jaundice. The lipase had now risen to 0.65. Laparotomy in July revealed a malignant mass in the region of the pancreas and a smaller tumour in the neighbourhood of the gall bladder.

In this case the test had met the requirements he had put before them in that it furnished information of value in diagnosis before the nature of the illness had been demonstrated by signs and symptoms.

CASE II.

A man of 38 for many months had suffered from a vague malaise. Easily exhausted, he would wake on one or two mornings in the week with a headache and a yellow fur on the tongue. The headache was not severe, and passed off in the course of the morning. He himself ascribed his condition to being "liverish." On the mornings that the patient had a headache he showed the haemoclastic crisis, but on the other mornings he behaved as a normal individual, and showed a digestion leucocytosis. Counts were made on fourteen consecutive mornings. His condition sensibly improved if meat was excluded from his diet. The observation opened up an interesting field of inquiry into a condition which was common and hitherto of obscure causation. Did the liver, acting as a defensive barrier, prove inefficient on the mornings when the haemoclastic crisis occurred?

At that point he was checked by the recollection of his plea for caution, from which he had, perhaps, been temporarily seduced by the interesting possibilities of this test. Real progress lay, not in the application of the test to clinical work, but in the correct interpretation of its meaning and mechanism.

Dr. J. C. Spence (London) said: My contribution to the discussion will be limited to a brief description of the laevulose test for liver efficiency, and of its value in the investigation of certain diseases of the liver. I shall dwell more particularly on results I have obtained in cases of catarrhal jaundice. Thereby I shall be able to illustrate how this test can be used as a new experimental method of approach to the further study of liver diseases. I hope to be able to show that the results I obtained in catarrhal jaundice justify me in including this disease among those implied in the title of this discussion—namely, as a true degenerative disease of the liver.

Professor Maclean has already dealt with the principle of the test and the details of the method to be employed in its

use. There is no difficulty in carrying it out, and accurate results can be readily obtained by anyone familiar with one of the newer and more accurate methods of blood sugar examination; 30 to 50 grams of laevulose, according to the weight of the patient, should be given after four to five hours' fasting. These amounts in a normal person will cause no rise in blood sugar. If the liver's efficiency be impaired in any way the sugar brought to it after absorption from the alimentary canal will not be stored in the liver, but will pass through the organ to appear in the systemic circulation, and a rise in the blood sugar content of the blood will result. The height and length of the blood sugar curve, which portrays this rise, will be in proportion to the degree of hepatic inefficiency present. When using the test the possibility of diabetes mellitus must first be excluded, as this disease gives blood sugar curves similar to those of extreme hepatic inefficiency.

[Dr. Sponce then showed charts which illustrated results he had obtained in normal people in cases of toxic salvarsan jaundice of various degrees of severity, and in cases of obstructive jaundice due to impaction of a stone in the common bile duct.

Fig. 1 illustrated the result in a normal person. After 40 grams of laevulose there was no appreciable rise in blood sugar. The results obtained in various diseases of the liver he classified as moderate, severe, and extreme degrees of liver inefficiency, according to the height of the curve.

Fig. 2 indicated a moderate degree of liver inefficiency in a case of toxic salvarsan jaundice. After 50 grams of laevulose the blood sugar percentage varied from 0.090 to 0.126 after half an hour, to 0.148 after 1 hour, to 0.137 after 1½ hours, and to 0.112 after 2 hours.

Fig. 3 showed a severe degree of liver inefficiency in a man who developed jaundice after an injection of N.A.B. After 50 grams of laevulose the blood sugar percentage varied from 0.125 to 0.137 after half an hour, to 0.192 after 1 hour, and to 0.154 after 1½ hours. In this case the rise of blood sugar was higher and more prolonged than in the former.

Fig. 5 showed the result in an extreme case of liver inefficiency. The blood sugar percentage was 0.117, 0.159 after half an hour, 0.241 after 1 hour, 0.161 after 1½ hours, 0.192 after 2 hours, and 0.181 after 2½ hours. This was a significant result in an important case, and required more detailed comment. It was a case of a man, aged 57, who developed jaundice after two courses of silver salvarsan. The test was carried out in the third week after the appearance of the jaundice. At that time his symptoms suggested only an attack of moderate severity, with a correspondingly good prognosis. The result of the test led to suspicion of a greater degree of liver damage than the clinical manifestations showed. These suspicions were confirmed. Two days later the patient passed into a condition of cholaemia and died. *Post-mortem* examination revealed extreme toxic necrosis of the liver.]

In applying the test to these cases of salvarsan jaundice my experience has led me to formulate this working rule: If the laevulose test produces a blood sugar rise of 50 mg. per 100 c.cm. (for example, from 0.110 to 0.160 per cent.) which does not fall to the normal level within one and a half hours, the case must be regarded as serious and requiring the most careful treatment, however slight the other clinical manifestations may be. The following result represents the findings in a typical case of pure obstructive jaundice, due to the impaction of a stone in the common bile duct. After 50 grams of laevulose the blood sugar levels were 0.110 per cent., 0.116 per cent., 0.133 per cent., and 0.120 per cent. This indicates only a slight degree of liver inefficiency, in spite of the fact that the patient was very deeply jaundiced. By contrasting the results of the test in typical conditions of toxicæmia or in the hepatic jaundice with those of obstructive jaundice, it will help us to approach the problems of other diseases the pathology of which is not so clear. Catarrhal jaundice is such a disease, for the reason that the opportunities for *post mortem* examinations are so rare.

The results of the laevulose test in cases of catarrhal jaundice which I investigated, showed that a very severe degree of liver inefficiency was present at an early stage of the disease before marked jaundice was present. The recovery of hepatic efficiency in these cases was very rapid, and in some cases was very evident before the jaundice reached its height. Taking into account these two facts, that there is marked hepatic inefficiency during the first few days of the disease, and that this inefficiency, as shown by the laevulose test, is much greater than that usually found in pure extrahepatic obstructive jaundice, it is reasonable to believe that the actual pathological change is one affecting primarily the liver cell, and probably of the nature of a hepatitis. This view, that catarrhal jaundice is an affection of the liver tissue of the nature of a hepatitis, and not an inflammatory obstruction of the common bile duct, is supported by two clinical phenomena which are almost constantly

associated with it. These phenomena are the enlargement of the liver and spleen. In some cases the liver reaches the umbilicus, and the spleen is palpable well below the costal margin. This enlargement of the liver is present early in the disease, when, as I have shown, the liver inefficiency is at its height. This early enlargement of the liver is well illustrated in those cases which are often admitted to children's hospitals with a history of fever, vomiting, and drowsiness. Clinical examination reveals only an enlarged liver, and the presence of acetone bodies in the urine. *Pauca de mieu* the diagnosis of "acidosis" is made. A few days later jaundice develops, and the diagnosis is now changed to one of catarrhal jaundice. In these cases, at any rate, the enlargement of the liver precedes the appearance of the jaundice, and would confirm the view I have put forward that the condition is probably a hepatitis.

In conclusion, I can but comment on some aspects of the scope and value of the laevulose test. Its chief value is that its results are quantitative. It measures something, whether it be total hepatic efficiency or merely the ability of the liver to store carbohydrates. This being so, its main use will be as a new experimental method with which to approach the problems of liver diseases. Without being as yet in a position to give you a definitive opinion of the comparative value of this test with van den Bergh's test, and Widal's "haemolysis crisis" test, I hold at present the view that its results give more direct evidence of the condition of hepatic efficiency than do either of these other tests, from which the evidence obtained is largely circumstantial. The laevulose test is of clinical value in controlling the administration of salvarsan. By its routine use between the successive courses of treatment a latent damage of the liver can be revealed. Further treatment could then be modified according to the results of the test. It is a useful aid in the differential diagnosis of toxicæmia from obstructive jaundice if it be remembered that very mild cases of the former and very extreme degrees of the latter are likely to give anomalous results. Its ultimate scope has yet to be determined. But it will serve a most useful purpose if, after having added a little to our knowledge, it follows the law of evolution, which affects all clinical methods, and is replaced by a still better test of liver function.

Dr. J. W. McKee (University College Hospital, London) said: Sir Humphry Rolleston, in opening the subject set down for consideration to-day, has indicated its scope and suggested some lines along which discussion might be profitable. Some of them will be fully dealt with by those who have specially worked on such parts of the subject, and for this reason I have thought it best to take up briefly some rather general but fundamental questions which influence greatly the study of degenerations of the liver, but which are less likely to be covered by other speakers.

Let me begin by saying that, to understand the various kinds of damage which may affect the liver, it is obviously essential to know the structure of the normal organ. It seems, in a way, extraordinary to have to admit that the fine relationships of the structures forming the liver lobule are by no means completely worked out. Our main lack of knowledge is concerned with the intimate connexions between the blood capillaries of the portal vein, the polygonal cells, and the finest bile capillaries. We do not know for certain, although it is commonly inferred, whether any substance, in passing from the vascular capillaries to the bile ducts, must pass through the protoplasm of the polygonal cell. Yet for a complete understanding of the normal and abnormal metabolism of bile pigment such knowledge is essential. The accepted views of the structure of the liver lobule mostly date from the old days of gelatin-carmino injections, some of the best and most widely quoted of which were carried out by Lionel Beale in London as far back as 1856. It is easy to inject and trace the vascular capillaries, but impossible to inject the blindly commencing capillaries. All I wish to say here is that I have repeated such injection experiments and made use of other more modern methods of staining, and am unable to confirm some of the descriptions which have crept into most textbooks of normal histology. We do not know whether all the glandular cells of the liver lobule have the same function or if they all act together. Various observers have described in some of the lower animals two distinct types of cell within the same lobule, differing in size and in the characters of the contained granules. In a bat, known as *Rhinolophus hipposideros*, the difference is stated by Oppel to be very obvious

indeed, collections of large clear cells lying amidst groups of smaller, coarsely granular cells. I have in the past two years examined sections from a wide variety of mammalian, avian, and reptilian livers obtained from the London Zoological Gardens, but have never seen more than minor and easily explained differences in the types of cell.

With regard to the functions of one element of the cellular structure of the liver lobule, our knowledge has greatly increased, chiefly as a result of experimental work. This knowledge is of great importance in connexion with the interpretation of the results and signs of many hepatic diseases. I refer of course to the so-called star cells of von Kupffer, large endothelial cells which lie along the walls of the vascular capillaries. In birds these cells form an almost complete lining to the capillaries of the outer part of the liver lobule. In man they appear less numerous. The great importance of these endothelial cells in the metabolism of bile pigment has now been fully recognized, and it seems improbable that the polygonal glandular cells of the liver are concerned in bile pigment metabolism, except in a secondary way. In birds, where the Kupffer cells are extremely numerous, the whole process of bile pigment formation can be watched under favourable experimental conditions. If, for example, blood destruction be induced experimentally in birds, the Kupffer cells may be seen to contain at one and the same time, (a) red blood corpuscles in process of disintegration, (b) bile pigment, which in birds is the bright green biliverdin, and (c) the iron-containing part of the haemoglobin molecule—haemosiderin—which gives the characteristic blue reaction with potassium ferrocyanide and dilute hydrochloric acid. Under such circumstances I have never seen anything suggesting bile pigment within the polygonal liver cells, but only in the Kupffer cells, and again in the bile capillaries. I have stated that in birds the Kupffer cells in the liver are much more numerous than in man, and I have published work in favour of the view that in man the great development of the spleen as an organ must be taken into account. I believe that the endothelial cells of the spleen have in man taken on part of the same function as the Kupffer cells in the liver. In birds the spleen is relatively very much smaller than in man when compared with the liver. This view of a combined action of the endothelial cells of the spleen and Kupffer cells of the liver in the metabolism of bile pigment has now received wide recognition on the Continent, and is fully accepted in a large monograph recently published by Eppinger and others, who deal with the group of diseases such as acholuric jaundice, etc., under the title of "The Liver-Spleen Diseases" (*Die Hepatosplenischen Erkrankungen*).

Briefly put, the views which I at present tentatively hold with regard to the metabolism of bile pigment are as follows—these are not original views, and have been supported in whole or in part by others: I believe that in man bile pigment is normally formed in the endothelial cells of the spleen and liver (Kupffer cells), and probably (although this is unproved) passes through the glandular cell to reach the bile capillary. Sir Humphry Rolleston has spoken of a possible explanation of the two kinds of bilirubin described by van den Bergh on the supposition that the pigment is modified in some way in its passage through the polygonal cell of the liver. If the liver cell be damaged or degenerated, the bile pigment, formed in the endothelial cells, may not be taken up by the polygonal cells, with the result that the bilirubin passes on into the blood with the ultimate production of one variety of clinical jaundice. The production of bile pigment by the endothelial cells is probably one of the last functions to cease in hepatic degenerations, and—for example, in acute yellow atrophy of the liver—the vascular capillaries may appear intact when the polygonal cells are largely necrosed.

I may now summarize briefly my ideas concerning the occurrence of jaundice in acute diseases of the liver. If the view I have put forward with regard to the functions of the endothelial cells of liver and spleen be correct, then it would appear possible for icterus to arise under three sets of circumstances:

1. Where there is direct obstruction to the outflow of bile—for example, gall stones blocking the common bile duct.

2. Where there has been increased haemolysis in the body and an excess of bile pigment is formed in the endothelial cells. This excess may be more than the liver cells can deal with, and the excess passes into the blood and may result in icterus—for example, acholuric jaundice, icterus neonatorum, the "latent icterus" of pernicious anaemia, etc. Such an

icterus might be expected to be of light degree and symptomless.

3. Where the glandular cells of the liver are damaged, while the endothelial cells continue to functionate normally. In such circumstances one must suppose the liver cells unable to take up in whole or in part the bilirubin offered to them, which therefore has to pass on along the blood capillaries into the circulation—for example, the toxic jaundice of typhoid fever and pneumonia, associated with cloudy swelling of the liver cells; so-called catarrhal jaundice, with acute hepatitis; "late" or delayed jaundice after salvarsan, etc.

In cases like acute yellow atrophy, where in addition to necrosis of many cells the whole liver lobule is finally disorganized, the exact mechanism and type of the icterus is less easy to suggest, and may probably vary at different stages of the disease.

Turning now to some other points in connexion with acute degenerative lesions of the liver. It is evident that far too much attention has been paid to the presence of visible jaundice as a diagnostic sign of acute hepatic disease. It is here that functional tests may be of value in indicating hepatic derangement in the absence of jaundice, especially if the results of the tests can be correlated with the symptoms and signs in the patient. It is not difficult to imagine that different parts of the manifold functions of the liver may be deranged in different ways and at different times without jaundice appearing at all. This has indeed been recognized to occur in one form of "dissociated jaundice"; and since the recognition of bile pigments in the serum has been made much more delicate by the methods of van den Bergh, we know that latent icterus may be present which is unrecognizable in the skin. Further, a study of the clinical features, and later of the histology, of cases of spirochaetal jaundice, has shown me that it is impossible to correlate the intensity of icterus with the extent of the hepatic damage. Sir Humphry Rolleston has referred to some of my results in this connexion. I have described three types of hepatic lesion in cases of this disease, all showing icterus of moderate severity: those with little histological evidence of damage at all, those in which the cells of the lobule are dislocated and individual cells are necrosed, and those in which there is intense necrosis of the central part of the lobules. In passing I may state that I regard the second type of lesion, which I have seen in other acute hepatic inflammations, as exactly corresponding to the desquamation and necrosis of individual cells seen, for example, in the renal tubules in acute nephritis.

I would like to refer very briefly to another type of hepatic degeneration—the so-called fatty degeneration which is seen so well in phosphorus poisoning. Munk has published work on fatty degeneration, especially of the renal epithelium in cases of "large white kidney," which appears to have a direct bearing on this form of hepatic lesion. Munk would place fatty degeneration as a reaction of the cell to damage, which is greater in severity than that producing cloudy swelling, but less severe and slower in action than that causing actual cellular necrosis. Such a view would bring fatty degeneration into line with other types of degeneration of the liver, the reaction of the damaged cells ranging from cloudy swelling right up to complete necrosis. It is well known that the lesion of acute yellow atrophy is easily distinguished from, for example, phosphorus poisoning by the almost complete absence of fatty degeneration of cells, the essential lesion in the first-named disease being cellular necrosis.

Professor ROBERT MUIR, after stating his appreciation of the very valuable contribution given by Sir Humphry Rolleston to the whole subject, first referred to certain points in the pathology of jaundice. The lesions concerned in its production might be distinguished as affecting (a) the bile ducts, (b) the liver cells, and (c) the blood and extrahepatic tissues. Jaundice due to biliary obstruction was, of course, well understood, but he thought that a lesion essentially obstructive, in the sense that the bile was formed but could not be got rid of, might be located in the liver cells themselves. In some cases of acute toxic jaundice lasting some time, small granules of bile pigment might be found in the liver cells, and this seemed to indicate that the bile pigment was being abundantly formed but could not be passed on to the biliary channels. It was conceivable that such lesions as partial necrosis, dislocation of liver cells, and even marked swelling of the parenchyma, might produce this result. The term "obstructive" should thus be taken in a wider sense than

was usually done. With regard to haematogenous jaundice there were two main questions, which were often not sufficiently distinguished by those who used the term. The first was, Could bile pigment be produced by the cells of other tissues than the liver? The second, Did this extrahepatic formation of pigment ever occur to such an extent as to lead to jaundice when the condition of the liver was normal? The first question could, of course, now be definitely answered in the affirmative—in fact, it appeared to be a common property of cells to be able to split haemoglobin into a moiety of the bilirubin type and an iron-containing moiety. To the second question, he considered a definite answer could not yet be given. It seemed doubtful whether a haematogenous jaundice in the strict sense—that was to say, with normally functioning liver cells—had been produced in experimental conditions. His observations in conditions of haemolysis led him to believe that the haemoglobin was split up within the liver cells as well as in the Kupffer cells, and that the latter, to judge from the amount of haemosiderin within them, played a smaller part in the human subject than in many of the lower animals.

With regard to cirrhosis, the all-important question concerned the etiology, and with regard to this our knowledge was very defective. Classifications might be made on an anatomical or on an otiological basis, but they did not correspond. The hob-nail liver, for example, was often produced by other causes than alcohol, whilst alcohol seemed to produce various types of cirrhosis. Cases of atypical cirrhosis seemed to him to be more frequent in recent years than formerly. In cirrhosis generally the essential factor appeared to be toxic action, with twofold effect: on the one hand, leading to degeneration and disintegration of the liver cells, and, on the other, stimulating overgrowth of the connective tissue—neither of these could be said to produce the other. He did not agree with the suggestion put forward that the interstitial overgrowth was to be regarded as a beneficial process, leading to hyperplasia of the liver cells. It seemed rather to be a case either of simple repair following damage, or of reaction to a slight irritant; and hyperplasia of liver cells occurred to a remarkable degree without any interstitial change—in fact, whenever there was any functional call for it. In regard to haemochromatosis he had practically nothing to add to what he had already published with Professor Shaw Dunn. He considered that there was no doubt that the cirrhosis of the liver preceded the deposition of pigment, and his observations also showed that a similar sequence of events might obtain in the case of the pancreas. He had no experience in detecting haemosiderin granules in the urine in the disease. The method, however, should be tried, as, apart from this and the pigmentation of the skin, there was no means, so far as he knew, of diagnosing haemochromatosis during life. As to the origin of cancer in cirrhotic livers, he maintained his former view that the malignant proliferation was a sequel of the hyperplastic proliferation. Microscopical examination showed that, although de-differentiated cells were present, the cancer cells did not take origin from these, but from the large actively functioning liver cells of the hyperplastic foci.

Sir WILLIAM WILLCOX (Medical Adviser to the Home Office), in continuing the discussion, said:

Toxioplhyllactic Function of the Liver.

A very important function of the liver which has not been sufficiently recognized is its protective function against exogenous poisons. This property of the liver is exhibited markedly when chemical poisons are taken into the system whether by the mouth or by the blood stream; all that is necessary is for the poison to be absorbed into the blood stream so that it passes by it to the liver. The liver has the property of acting like a sponge retention filter and absorbing the chemical poison. It is thus seen that in almost every fatal case of chemical poisoning the bulk of the absorbed poison is found in the liver if death occurs within a few days. Thus, in the case of arsenical poisoning, if the poison—arsenicous oxide, for example—is taken by the mouth, after absorption by the gastro-intestinal tract the poison is carried to the liver and a great part is retained there. Again, if the arsenical preparation such as one of the arsenobenzol derivatives be given intravenously and death occurs within a few days, a large proportion of the poison will be found in the liver. Exactly the same rule holds good for metallic poisons such as mercury or lead, and for organic poisons such as chloroform, phenol, trinitrotoluene,

etc. In the case of the alkaloidal poisons this property of the liver is particularly well exhibited, for in fatal cases the greater part of the absorbed poison is found in the liver. In the case of morphine poisoning it has been shown that the liver has the power of retaining a large proportion of the absorbed alkaloid, and the excretion of this absorbed morphine takes place from the liver into the stomach. It is probable that a similar action of the liver occurs in the case of other alkaloidal poisons. This protective function of the liver against exogenous poisons should, I think, be called the "toxioplhyllactic function" of the liver.

It cannot be claimed that the liver stands alone in possessing a toxioplhyllactic function, for it is well known that both the spleen and kidneys, and probably the other tissues of the body, have the power of retaining absorbed poisons, but to a much less extent than the liver. The liver in the exercise of its toxioplhyllactic function suffers often serious damage, and this is shown by the degeneration to which its cells are subject, such as the cloudy swelling and the more advanced condition of fatty degeneration following the effect of these absorbed poisons. In many cases the liver may truly be said to have laid down its life in its endeavour to protect the body from the action of exogenous poisons. For example, in phosphorus poisoning the liver cells may become almost entirely destroyed, and in cases of acute fatal poisoning by salvarsan, tetrachlorethane, trinitrotoluene, etc., such extensive fatty degeneration of the liver cells is found that it is quite clear that the normal function of the liver in the body metabolism must have been destroyed, and in such cases the real mode of death is an auto-intoxication due to loss of liver function, rather than a direct action of the poison in question. It is not only in the case of chemical poisons that the toxioplhyllactic function of the liver is exercised. Exactly the same result follows, though in different degree, the poisons produced by bacterial or protozoal organisms, or auto-intoxications. The liver are therefore shown from the

1. Chemical poisons, such as tetrachlorethane, trinitrotoluene, dinitrobenzene, dinitrophenol, arsenobenzol derivatives; inorganic arsenic and antimony compounds, phosphorus, arseniuretted hydrogen, phosphoretted hydrogen, chloroform, phenyl hydrazine, tolyleno diamine, and many others.
2. Bacterial poisons, such as the toxins produced in enteric and paratyphoid fevers, typhus fever, influenza, pneumonia, streptococcal infections, etc.
3. Protozoal poisons, such as the toxins produced in syphilis, yellow fever, spirochaetosis, icterohaemorrhagica, kala-azar, amoebic dysentery, malaria, etc.
4. Auto-intoxications, such as the changes in the liver found in uraemia, recurrent vomiting, etc.

The Time Factor in Toxic Degenerative Conditions.

The time factor has not, I think, received the attention it deserves in considering the degenerative conditions resulting from the action of toxins. This was well shown in the fatal cases of tetrachlorethane poisoning described in my Lettersonian lectures, 1919. In some of the acute cases an extensive degeneration of the liver occurred followed by death within a few days. In one fatal case the illness was prolonged over many weeks, and symptoms of ascites and portal obstruction supervened before death. Dr. Spilsbury found, on post-mortem examination in this case, marked fibrosis of the liver in addition to fatty degeneration of its cells, the fibrosis, in which he termed "replacement fibrosis," having occurred in the areas of the liver in which the cells had undergone necrosis from the effects of the poison. In another case which was seen by me several times ascites and portal obstruction followed the attack of tetrachlorethane jaundice. Paracentesis was performed on the patient twice and he made a complete recovery. Two fatal cases of acute fatty degeneration of the liver due to alcohol have been investigated by me in which the liver was very enlarged and yellow, the cells showing very marked fatty degeneration, exactly as is seen in fatal cases of delayed chloroform poisoning. These cases of acute alcoholic fatty degeneration of the liver are rare, but they are very interesting as showing that in some cases alcohol may act as an intense liver poison like chloroform, phosphorus, etc. It appears that the common form of multi-lobular cirrhosis usually associated with alcohol is brought about by the comparatively slow action of alcohol in causing degeneration in certain parts only of the lobule of the liver, and the destroyed cells become replaced by fibrous tissue, giving the characteristic histological picture of portal cirrhosis. Under this view the two cases of tetrachlorethane poisoning which developed cirrhosis would be comparable

with the condition resulting from the more prolonged and less intense action of the poison alcohol.

The question has been raised as to whether the jaundice resulting from chemical poisons such as tetrachlorethane, trinitrotoluene, arsenobenzol compounds, etc., may not be really due to some bacterial poisoning rather than to the direct action of the chemical poison. It has been said that only a relatively small proportion of cases of jaundice occurred amongst the workers in the two first-named poisons, and that if the poison had been the cause of the jaundice a higher jaundice incidence would have been expected. I think that the best answer to this question is the clinical evidence. In 1914 I personally examined a large number of the workers exposed to tetrachlorethane vapour, and a large proportion of these were suffering from toxic symptoms, such as anorexia, morning sickness, general malaise, headache, etc., a group of symptoms often called "toxic gastritis." Jaundice was the result of long continuance of these symptoms, and hence occurred in a comparatively few cases, since most of those suffering from early symptoms gave up work for a time, thus preventing the occurrence of jaundice. Dr. W. J. O'Donovan, who very carefully investigated clinically the workers exposed to trinitrotoluene, found that a considerable proportion suffered from "toxic gastritis," though the jaundice cases were comparatively few. The condition is exactly comparable to the effects of alcohol, since, as everyone knows, symptoms of "toxic gastritis" occur for a long period before the definite clinical symptoms of cirrhosis, with possibly jaundice. In the case of the arsenobenzol compounds, symptoms of "toxic gastritis" usually occur during the twenty-four hours following the administration of the drug. These are probably due to impaired hepatic function, and the evidence of fatty degeneration of the liver cells in the autopsy fatal cases is sufficiently conclusive in all three poisons. It appears to me that there is no doubt that the toxic jaundice resulting from the action of chemical poisons is due to the direct effect of the poison on the liver, and that bacterial influences are unimportant.

Delayed Jaundice following Salvarsan Poisoning.

It has been suggested that the delayed jaundice occurring after salvarsan poisoning is due to retention of arsenic in the body, and that this retained arsenic only acts on the liver at a considerable period after its administration. It is well known that in trinitrotoluene poisoning jaundice may occur many months after exposure to the poison has ceased. In two cases the period was over nine months. It is also known that in the jaundice cases following trinitrotoluene the urine was found free from trinitrotoluene during the jaundice attack. It is quite clear that the jaundice resulting from trinitrotoluene was due to the liver cell damage (hepatitis) consequent on the trinitrotoluene exposure, and that when the jaundice was present the trinitrotoluene was not at that time exerting its effects. The jaundice was the sequence of the toxic action of the poison on the liver. In the case of arsenobenzol jaundice exactly the same explanation holds good. After a single arsenobenzol administration the urine is after three weeks found free from arsenic, but no doubt some arsenic is deposited in the hair, nails, and epidermal tissues. The liver is then comparatively free from arsenic and the minute amount present cannot have any detrimental effect. The toxic effect of arsenobenzol on the liver occurs within a few days of its administration and if several doses are given there is a summation of toxic effects. These give rise to a degeneration of the liver cells and consequent liver changes which may be included under the term "hepatitis." It is the "hepatitis" resulting from the administration of doses of arsenobenzol compounds which gives rise to jaundice, and, just as in the case of trinitrotoluene poisoning, this jaundice may be delayed for months. In no cases of delayed arsenobenzol jaundice have amounts of arsenic been found in the liver which could at that time have been causing harm to the liver. The small amount of arsenic found in the liver in delayed arsenobenzol jaundice where a prolonged course of the drug has been given are accounted for by the deposition of the arsenic in the epidermic tissues and the gradual absorption therefrom of slight amounts of arsenic which could not of themselves be toxic.

Catarrhal Jaundice.

Dr. Spence, in his most interesting contribution, has pointed out that in catarrhal jaundice there is for a few days definite evidence of impairment of hepatic function, as shown by the laevulose test. I have no doubt that "catarrhal jaundice," as seen in peace time, is exactly the same condition as the

"epidemic catarrhal jaundice" which occurred during the war, and which was described by me in the Lettsomian lectures, 1919. The enlargement of the liver and spleen occurs in both of these conditions and the symptoms are identical. The jaundice is due to pathological changes in the liver itself, probably arising from a bacterial infection. The degeneration of the liver cells in catarrhal jaundice may, as in some cases recorded by me, be of such severity as to cause death from auto intoxication and atrophy of the liver; this only occurred in about 0.4 per cent. of the cases of "epidemic catarrhal jaundice" seen in Mesopotamia in 1917. It would be expected that if catarrhal jaundice is hepatic in type it would show a definite impairment of hepatic function, and Dr. Spence's confirmation of this is of great value.

The differential diagnosis between catarrhal jaundice and arsenobenzol jaundice can, however, be clearly made. In arsenobenzol jaundice there is a history of the administration of the drug; there is absence of splenic enlargement; the enlargement of the liver is not always so uniform as it is in catarrhal jaundice—thus the right lobe may be relatively more enlarged than the left in salvarsan jaundice. In both kinds of jaundice the liver diminishes in size considerably during the continuance of the jaundice, but the diminution is usually more marked in the case of arsenobenzol jaundice. In arsenobenzol jaundice the laevulose test for hepatic function remains negative for a longer period, while in catarrhal jaundice Dr. Spence has found that the test only remains negative for about three days. The absolute differentiation is shown by the presence of arsenic in the urine, the hair, and the nails in the case of arsenobenzol jaundice. It is important that in the analysis a reliable method for the detection of arsenic should be employed, such as the electrolytic Marsh-Berzelius test, the organic matter being destroyed by treatment with arsenic-free sulphuric and nitric acids.

Professor M. J. STEWART (Leeds) made the following contribution to the discussion:

Toxic Jaundice due to Trinitrotoluene.

In the discussion on atrophy of the liver at the Cambridge meeting two years ago, brief reference was made to the after-history of a series of cases of toxic jaundice due to trinitrotoluene. The result of that investigation was so striking, as showing the remarkable powers of recovery of the liver from what must have been, in some of the cases at least, a very severe destructive lesion, that I felt that the result of a further "follow up" might be of interest in connexion with the present discussion. Within the past fortnight, therefore, I have obtained information about all of the 17 cases in that series, and I have personally seen 13 of them. They had all suffered with toxic jaundice during 1916 or in the early part of 1917, so that a period of from five to six years has now elapsed since their illnesses. Twelve patients, including 3 who were dangerously ill (one with a red cell count of less than a million), and 5 others who were deeply jaundiced, are now in excellent health. Five of them have married, of whom four have borne children (one, one, two, and three respectively) without trouble or difficulty of any kind. Only 3 of the twelve now complain of occasional attacks of epigastric pain, although two years ago nearly all of them had this symptom. Of the remaining 5 cases in this series, 2 appear to be really ill—one with gastric ulcer, for which she has already had an operation, the other with severe epigastric pain after food, and occasional vomiting. Neither is at present incapacitated, and the latter especially is well nourished. The other 3 patients are full of complaints, but give a rather unconvincing and incoherent account of their symptoms. Their attitude rather suggests a vague hope of further compensation. No single patient has had any return of jaundice, and none of them have ascites. On the whole I think it may be said that so far as ordinary signs and symptoms are concerned, none of these 17 patients appeared to have suffered from hepatic inadequacy. That a number of them had atrophy of the liver is beyond doubt. At the time of their illness 3 of them appeared, symptomatically, to have the disease in as severe a form as several of those who died, and half of them were deeply jaundiced. No doubt in such cases the liver is now the seat of an irregularly distributed fibrosis, but the after-histories given above suggest that this is a strictly limited and non-progressive lesion, probably a pure replacement fibrosis. It is equally clear that sufficient regenerative hyperplasia of the undestroyed liver tissue has

taken place to render the organ functionally sound. In due time, no doubt, old cases of T.N.T. jaundice will come to the *post-mortem* room, and opportunity will be afforded for studying the anatomy of the healed lesion.

The Cirrhosis of Haemochromatosis.

As Sir Humphry Rolleston has mentioned in his opening paper, one of the many unsettled problems in connexion with haemochromatosis is the relation to one another of the two chief hepatic lesions, siderosis and cirrhosis. The older view, which, however, is still held by many, is that the siderosis is the cause of the cirrhosis. A number of recent writers believe, on the contrary, that degeneration and cirrhosis constitute the primary lesion, and that deposition of haemosiderin occurs in consequence of this. A third group takes the view that "neither factor is causative of the other, and presumably the two are due to some third unrecognized cause" (Dunn). In connexion with this problem there is one aspect of the disease on which I think sufficient stress has not been laid; I refer to its chronicity. The observations of Muir and Dunn, Howard and Stevens, and others have shown that in well-marked haemochromatosis the total amount of iron stored up in the liver and other organs is simply enormous, requiring for its deposition many years at the ordinary dietetic rate of iron intake; Howard and Stevens even suggest forty years as the possible length of time in their case. Now it seems to me unlikely that such a state of affairs could be initiated, and continued, by a degenerative and cirrhotic condition of the liver, whereas a primary siderosis, lasting many years, might very well be the starting point ultimately of the degenerative hepatic changes. From an examination of seven cases of haemochromatosis met with in the *post-mortem* room, and illustrating various stages of the disease, I have endeavoured to ascertain whether or not there was any correspondence between the amount of hepatic siderosis and the degree of cirrhosis. The result may be shown in tabular form:

Cases of Haemochromatosis (all men).

Case.	Age.	Amount of Hepatic Siderosis (Microscopically Estimated).	Amount of Free Iron (Percentage of Dry Weight).	Degree of Cirrhosis (Microscopically Estimated).
1	49	+++	3.78	+++
2	71	+++	2.98	+++
3	51	++	—	+
4	51	++	1.75	++
5	44	++	—	+
6	52	+++	4.5	+++
7	63	+++	3.6	+++

Cases 1 and 2 had primary cancer of the liver.

The result of this examination is to show that the two processes, on the whole, keep pace with one another, but that, if anything, the cirrhosis tends to lag behind the pigmentary deposition. A notable point emerging from this study is that haemosiderin may exist in large amount in liver cells which, apart from the presence of the pigment, appear quite healthy, with large, well-stained nuclei.

Carcinoma of Liver in Cirrhosis and Haemochromatosis.

In a series of 6,000 *post-mortem* examinations made during the past twelve years at the Leeds General Infirmary there were in all 8 cases of primary carcinoma of the liver, an incidence of 0.13 per cent. In 4 cases the tumour or tumours originated in a cirrhotic liver, and in 2 others in an organ which was the seat of haemochromatosis as well. In all there were 149 cases of portal cirrhosis in the series, and the incidence in this group is thus no less than 4 per cent. So far as cancer in haemochromatosis is concerned, I know of three published cases (Rudfleisch, Lohlein, and Achard and Loblanck) and one unpublished (Dunn), in addition to the two mentioned above. Inasmuch, therefore, as the number of recorded cases of haemochromatosis must now be well over 100, it looks as if the incidence of carcinoma in this disease is no higher than in portal cirrhosis generally.

Professor STUART McDONALD (Newcastle-upon-Tyne) said: I very much regret that I have been unable to hear the whole of the papers given in this discussion owing to my having to

take part in the proceedings of another Section. I have had the opportunity, however, of reading Sir Humphry Rolleston's opening paper and am particularly interested in what he said in regard to the grave acute degenerations of the liver which may occur in syphilis and particularly in syphilitic cases treated by arsenobenzol compounds. I am particularly obliged for the opportunity of pointing out a slight error which Sir Humphry Rolleston has inadvertently made with regard to my views on this subject. In a paper which I wrote in the beginning of 1918, and which was published in the *BRITISH MEDICAL JOURNAL* (1918, i, p. 76), dealing with a group of cases of acute liver atrophy in syphilitic patients under salvarsan treatment, I arrived at some general conclusions with regard to the etiology of the condition. In that paper I made certain suggestions which have attracted some attention, and which have been referred to in the recent report of the Salvarsan Committee of the Medical Research Council (Special Report Series, No. 66). The subject is an extremely difficult and obscure one, and the Committee have been unable to come to any definite conclusion as to the exact part played by salvarsan in the production of acute yellow atrophy. From the evidence they present there can, I think, be little doubt that salvarsan accounts for the increased incidence of jaundice in syphilitic patients under treatment by modern methods. Arising out of my paper referred to above, investigations were conducted in Newcastle on this point, and I am at liberty to state that Dr. R. A. Bolam, who was primarily responsible for the clinical side of the investigation, is also convinced as to the relationship of the jaundice to the salvarsan administration. His opinion may be stated thus:

"In the ordinary course of treatment of syphilis by salvarsan compounds a number of cases of jaundice occur towards the end of the course or within two or three months after its completion. This raises the incidence of jaundice in syphilis considerably beyond what was observed in pre-salvarsan days. If a more intensive course be given, the percentage of jaundice cases rises still higher."

In the case of acute liver necrosis, however, the direct relationship cannot be made out so clearly, and the exact etiology of the condition still remains obscure. The Salvarsan Committee's final conclusion includes a statement "that the poisonous action is possibly dependent for its occurrence on the presence of adjuvant circumstances of a nature as yet unknown." There must be something to account for the extreme rarity of the condition. Considering the thousands of cases of syphilis which have been treated by salvarsan compounds the total number of cases of so-called acute yellow atrophy is extremely small. I have suggested the possibility that the condition only occurs when several factors are working together. It is well known that acute liver necrosis occurred in syphilitic patients in pre-salvarsan days and it appears to me that the syphilitic toxin is an important factor in the process. We know, of course, that certain other toxic agents—as, for example, trinitrotoluene, and possibly certain metabolic poisons—may induce a similar or closely related change in the liver. We are not concerned with these agents in this particular group of cases, but for practical purposes we may fairly, I think, take the syphilitic toxin, and the arsenic, and possibly mercurial factors as constant. I have suggested that the typical phenomena of acute yellow atrophy only appear when still another factor, bacterial infection, acts in conjunction with some or all of the others. In the particular group of cases I described I did obtain evidence of bacterial invasion. Admittedly the evidence is incomplete, as it was only obtained *post mortem*, but I am similar observations have been made elsewhere, and I am still convinced that in the cases I referred to bacterial infection did play a part in the process. The Salvarsan Committee points out very fairly that in certain cases, or groups of cases, there is a certain amount of evidence, apart from the actual bacteriological findings, that infection may be an important factor. I am of opinion that no final conclusion is likely to be arrived at without experimental work, and I intend to continue my investigations on those lines.

Sir ARCHIBALD GARROD, in summing up the discussion, referred to the observations of Hermann Strauss, published some years ago, upon the effect of diseases of the liver in lowering tolerance for laevulose as evidenced by the occurrence of alimentary laevulosis after comparatively small doses of that sugar.

DISCUSSION ON THE PROGNOSIS AND TREATMENT OF CHRONIC RENAL DISEASE.

OPENING PAPER BY

HUGH MACLEAN, M.D., D.Sc., M.R.C.P.,

Professor of Medicine, University of London, St. Thomas's Hospital.

EVERY medical man interested in the pathology of the renal system will probably agree that the subject of chronic renal disease presents problems that are as difficult and obscure as any arising in the whole field of clinical medicine. Many of our older views of kidney disease have gradually changed in the light of modern knowledge, and we can now obtain a very good idea as to the general state of the renal efficiency in any given patient, but the problem of prognosis, and particularly that of treatment, still bristles with innumerable difficulties.

Much has been published recently on the various aspects of renal disease, but I do not propose to enumerate the different opinions expressed, since this would take too long, and at best could only be a summary of very diverse views and conclusions. Instead of this I propose to give you certain conclusions, based chiefly on the results of a large scale experiment carried out on patients obtaining pensions for no arthritis from the Ministry of Pensions. In 1919 an arrangement was made with the Ministry by which all patients in one of the London areas should be carefully examined at intervals, and the results obtained from time to time noted for comparison. This investigation was made possible by the Medical Research Council, which was good enough to furnish the necessary equipment and cards. This experiment has now gone on for three years, and it is hoped that it will ultimately furnish data on which the principles of prognosis may be established with some accuracy. Already many interesting points have come to light, but it will, of course, take several years before the full fruits of this investigation can be obtained. Already over 17,000 complete examinations have been carried out and the results tabulated, while several patients have been under observation for nearly four years.

Before passing on to a detailed discussion of prognosis and treatment, it is necessary to give a short account of the different varieties of chronic renal disease. In this connexion I wish to make it quite clear that I do not intend to enter into the problem of the histological appearances of the kidney in renal disease. This is largely of academic interest and has little or no bearing on either of the points under discussion to-day. In spite of the activity that has so frequently been exhibited in endeavouring to elucidate this aspect of the problem of renal disease, it is still impossible to forecast the exact histological condition that will be found *post-mortem* in any case of chronic nephritis. In reality the pathological findings are of little clinical importance, for what we have to deal with is not dead histology but living function. It matters little what the microscopic or macroscopic appearances of the organ may be, for, whatever the nature of the *post-mortem* changes ultimately found, they all operate during life in one direction, and give rise to a more or less impaired efficiency of the renal system with all its detrimental consequences.

Looking at the problem from the biochemical point of view, I think all observers are now generally agreed that two distinct types of chronic renal disease are encountered. In the first type to be described the chief symptom is marked oedema, and frequently no other important manifestation is present. The accumulation of fluid in the system is often so great that the internal organs of the chest and abdomen are waterlogged, and unless relief is afforded the patient dies from what may be described as drowning. Sometimes a certain degree of cardiac and general weakness is also present, and the patient may occasionally succumb from cardiac failure and general asthenia.

The Hydræmic Type of Nephritis.

On investigating such a case by the usual biochemical tests no evidence of renal inefficiency is found, with the exception that chlorides are either absent or deficient. The amount of urine passed is small, and it always contains excessive amounts of protein, and frequently large numbers of hyaline and other casts, but there is little or no evidence of cardio-vascular changes. Examination of the blood shows no retention of nitrogenous bodies; the percentage of urea

and other nitrogenous urinary constituents is normal, or even above the average, and the urea concentration test shows that the kidney is capable of concentrating urea nearly if not quite as well as in the normal subject. Shortly, in such a case there is no evidence whatever of any defect on the part of the renal system in eliminating the waste products of nitrogenous metabolism; the only apparent failure is in the excretion of salt and water. Because of the marked retention of water in these patients I have on former occasions referred to this type of case as the hydræmic variety of chronic nephritis; in a general way the condition corresponds to the textbook description of chronic parenchymatous nephritis, but it is really more a subacute than a chronic condition, for in a comparatively short time either the oedema clears up or the patient succumbs.

The Azotæmic Type of Chronic Nephritis.

This type of chronic nephritis is quite different in its manifestations from the hydræmic variety just described, and is characterized by a defect on the part of the renal tissue in the elimination of nitrogenous waste products. Salt and water are excreted quite well; indeed, the amount of urine passed is often excessive. In typical advanced cases, examination of the blood shows an increase in the urea and other nitrogenous bodies such as uric acid and creatinin. The normal power of the kidney to secrete a urine containing a much higher concentration of urea and other bodies than exists in the blood plasma is markedly interfered with, so that instead of concentrating urea in the urine to an extent 70 to 100 times that present in the blood the concentration is much lower and the urine may not contain more than 10 times or less the urea in the blood. The urea concentration test gives low figures, and frequently the diastatic value is also low. This condition is often associated with cardio-vascular changes, which may be very marked. Generally, albuminuria is not very extensive; indeed no protein at all may be passed. Large numbers of casts are often present, but, on the other hand, it may be impossible to detect any casts even in carefully centrifuged specimens. Since the principal result of this type of chronic disease is an interference with the normal power of the kidney to excrete nitrogenous bodies, it may be referred to as the azotæmic type. This is the condition which is always present in real chronic renal disease and it corresponds with the usual textbook heading of chronic interstitial nephritis.

Mixed Types of Chronic Nephritis.

The above brief description of the two types of renal disease refers to typical cases. Not infrequently the two types may be manifest in the same patient, when marked oedema and retention of fluid will be associated with a more or less definite inability on the part of the kidney to excrete nitrogenous bodies and to concentrate urea and other substances. This combination frequently gives rise to a very grave clinical condition, and often terminates fatally.

Briefly, the chief points which characterize the different types may be summarized as follows:

<i>Hydræmic Type.</i>	<i>Azotæmic Type.</i>	<i>Mixed Type.</i>
Marked retention of fluid in tissues; severe oedema, etc.	No oedema.	Oedema may be well marked.
No retention of nitrogenous products.	Tendency to retention of nitrogenous products.	Retention of nitrogenous bodies.
Retention of salt and water.	No retention of salt and water.	Retention of salt and water.
Little evidence of cardio-vascular changes.	Cardio-vascular changes tend to be well marked.	Cardio-vascular changes may be marked.

Indications on which Prognosis is Based.

The prognosis in any case of chronic nephritis depends chiefly on three factors: (1) the general clinical condition of the patient; (2) the physical state of the cardio-vascular system; (3) the results of biochemical tests.

With regard to the clinical condition it is unnecessary to say much here, since the main symptoms of chronic nephritis are well recognized. General weakness, loss of flesh, severe headaches, vomiting and gastro-intestinal symptoms, twitching of the muscles, convulsions, mental phenomena, and other uræmic manifestations are, if at all well pronounced, sure evidence of a grave condition which indicates a bad prognosis. It is, of course, well understood that even very definite uræmic manifestations—such as convulsions, for instance—are

not necessarily associated with an immediately fatal issue, and sometimes patients recover temporarily and live for several months, or perhaps a year or more, after these attacks. In my experience, however, no patients in whom the above symptoms were well pronounced lived for any considerable time. Further, in all cases the prognosis is markedly influenced by the state of the cardio-vascular system. This will be fully discussed later.

With regard to renal tests it may at once be said that they afford much more definite evidence of the renal state of affairs than is indicated by the clinical condition. Indeed, it is not uncommon to have patients bordering on fatal uraemia who show practically no clinical symptoms whatever, and who are quite unaware that they are suffering from any serious disease. Such patients always show quite definite evidence of the true condition when subjected to renal tests. So marked is the contrast between the clinical condition and the results of tests in some patients that at first one hesitated to accept the grave indications of the tests. Unfortunately, however, in the great majority of cases the result belied the clinical condition, and very soon definite symptoms appeared, terminating in the death of the patient. As the result of observing a large number of patients suffering from nephritis I now take the view that in cases where the clinical condition is not in accordance with the results of tests the clinical condition should not be considered very seriously. I am aware that this view is not accepted by all observers, but on inquiry it will generally be found that the upholders of the clinical condition as against the results of renal tests are generally individuals who have had little or no personal experience of modern methods of renal investigation.

Methods of Examination for Renal Efficiency.

Whatever tests an observer makes use of, it is important that he should adopt some definite system and apply this in all cases. This is the only means by which familiarity with the results of renal tests can be obtained, and by no other method is it possible to arrive at a correct interpretation of these results. At St. Thomas's Hospital we make use of the following scheme; it is easily carried out, and, in my opinion, furnishes all the information required in the great majority of renal patients. In each subject the following points are investigated:

- A. General condition and symptoms.
- B. Cardio-vascular condition: Blood pressure; position of apex beat; nature of second aortic sound; condition of peripheral arteries.
- C. Renal tests: (1) Blood urea estimation. (2) Examination of urine for protein, casts, blood, leucocytes, etc. (3) Urea concentration factor. (4) Urea concentration test. (5) Diastatic test.*

The Part Played by Renal Tests in Prognosis.

Before proceeding to a discussion of the importance of the cardio-vascular condition in prognosis, it will simplify matters if the interpretation of the renal tests referred to is now described. In chronic renal disease the results of blood examination, taken in conjunction with the urea concentration test, furnish perhaps the most useful knowledge as to the condition present.

Examination of the Blood.

The estimation of the so called non-protein nitrogen of the blood is of very great value, but since the blood urea is more easily estimated than the total nitrogenous products the content of the blood in urea is frequently relied on in renal investigations. This estimation gives, in the great majority of cases, all the information required, but it must be understood that the normal variations of blood urea are comparatively large and depend to a great extent on the nature of the food. In the healthy normal individual on ordinary diet the figure for blood urea should lie somewhere in the region of from 20 to 40 mg. per 100 c.cm. blood. In elderly people, however, it is not uncommon to find 50 mg. or even more, without any definite evidence of renal disease apart from the normal senile changes. While one might be justified in taking a serious view in the case of a young patient, aged say 20 years, whose blood contained 60 mg. urea per 100 c.cm., a similar urea content in a patient of 75 years, and taking a similar diet, would have an entirely different significance. It is impossible to give exact figures, since the blood urea content varies so much as the result of different factors; but in general it may be said that the older the patient the more

liable he is to have an increased blood urea content, and for practical purposes the blood urea concentration of the average normal individual on ordinary diet may be taken as ranging from about 15 mg. per 100 c.cm. in the young adult to 60 mg. or so in individuals over 70 years of age. When we get beyond this amount, the condition is undoubtedly abnormal, but any conclusions drawn from blood urea examinations must be considered in relation to age and diet. A persistent high urea content of over 60 mg. per 100 c.cm. in a young man, or a somewhat higher content in an elderly man, is of grave significance, as it indicates that probably about three-quarters of the renal tissue is not functioning.

It is most important to note that no prognostic significance can be attached to a single blood urea estimation, unless other tests and the clinical symptoms present indicate that the condition is really a chronic one, for temporary increases of the blood urea are by no means uncommon in patients suffering from very slight degrees of nephritis, and even in cardiac and other cases where there is no reason to suspect the presence of nephritis at all. Persistent high blood urea, however, is a most important feature, and is of much significance in enabling us to form an opinion as to the gravity of the condition. In chronic diseases the increased urea is practically always accompanied by some increase in the uric acid and creatinin of the blood as well, and when these substances are found to be definitely raised the outlook is certainly bad. An increase of blood urea, without a corresponding increase in the total non-protein nitrogen, is not necessarily of much importance, but it is rarely, if ever, that a definite increase in urea concentration is found in chronic nephritis without a corresponding increase in the uric acid and creatinin. In certain non-renal conditions this may occur, but even then it is unnecessary to estimate anything but the urea, for the true aspect of the case can be ascertained by combining the result of this test with that found by means of the urea concentration factor and the urea concentration test now to be described.

Urea Concentration Factor.

One of the chief functions of the kidney is to excrete the waste products of the blood in a concentrated form in the urine. A normal kidney has to deal, on the one side, with blood containing, say, 20 mg. urea per 100 c.cm.; while, on the other side, it secretes a urine containing perhaps 1,600 mg. urea per 100 c.cm. Thus in the formation of urine it concentrates the blood urea 80 times, and it is this power of concentrating that is referred to as the urea concentration factor. In disease this power of concentration is frequently very much diminished, the extent depending, of course, on the gravity of the lesion. In chronic nephritis of moderate severity the urea concentration factor may amount only to 30 or 40, while in severe cases it may be as low as 5 or even lower. Generally speaking, when this factor is below 10 the outlook is grave. The urea concentration factor should always be estimated in patients in whom a blood urea estimation is made by taking a sample of urine immediately after taking the blood and estimating the urea in both blood and urine. The result obtained from the fraction

$$\frac{\text{Milligrams of urea in urine per 100 c.cm.}}{\text{Milligrams of urea in blood per 100 c.cm.}}$$

gives the urea concentration factor.

This factor is of very great value in correcting our interpretation of certain cases in which the blood urea is high. If the urea concentration factor is also fairly high—or, in other words, if the urine contains a high percentage of urea (say 2.5 or so)—it is very improbable that the kidneys are inefficient, and the high blood urea is probably dependent on some accidental condition rather than on renal changes.

Urea Concentration Test.

This test was introduced by Maclean and de Wesselow a few years ago, and is based on the principle of ascertaining the power of the kidney to concentrate urea in the urine. The when an excessive supply is present in the blood. The patient, after emptying his bladder, receives 15 grams urea dissolved in a few ounces of water. Urine is collected at the end of each hour for two or three hours and the urea content estimated. Generally the urine passed at the end of the second hour shows a higher concentration than that of the first hour, and this sample is usually taken for the urea estimation. The lower urea content of the first hour's urine is due to diuresis set up by the urea; this diuresis generally passes over during the first hour, but may continue so as to

*For a full description of these tests see *Modern Methods in the Diagnosis and Treatment of Renal Disease*. Constable and Co., London.

influence the result of the second hour's urino. In such cases the urino passed after the third hour should be taken. The total amount of urino excreted should not exceed 120 c.cm. during the hour in which the urino taken for the urea estimation is passed. It is important to note that this test depends on concentration of urea alone and not on the amount of urea passed during a given period or other irrelevant points. It is necessary to emphasize this, as the principle of the test has been completely misunderstood and mixed up with other tests in quarters where, perhaps, such confusion might hardly be expected to prevail.

If after the ingestion of 15 grams urea the patient passes a sample of urine containing over 2 per cent. urea, the renal condition is fairly good; if the concentration is 2.5 per cent. or over, experience indicates that the kidney may be accepted as being quite efficient. In the absence of diuresis, concentrations of 1.5 per cent. or so indicate a moderately severe condition, but where the concentration is only 1 per cent. or less the outlook is grave.

Diastatic Test.

This test has been much utilized in the investigation of renal disease, but its results are somewhat erratic and its interpretation frequently difficult. The test depends on the fact that normally a certain amount of diastase is secreted from the blood into the urine, the amount passed being dependent on the integrity of the kidney. Expressed quite empirically, the urine of a normal individual generally contains from 6 to 20 units of diastase. When the kidneys are diseased the amount of diastase in the urine is reduced, and may be represented by a value of 1 or even less. In short, the lower the diastatic value the more intense the pathological changes in the kidney are likely to be. The test is useful but too erratic to be of much value by itself; in conjunction with other tests it is sometimes helpful.

In the absence of marked cardio-vascular lesions the interpretation of these tests and their bearing on prognosis may be summarized as follows. When severe cardio-vascular manifestations are present in addition to the nephritis the prognosis is correspondingly worse.

Blood Examination.

When the blood urea is persistently much over 50 milligrams per 100 c.cm. in a young adult, or 60 milligrams in an elderly subject, the prognosis is not hopeful, provided the other tests give similar indications. The possibility of increased blood urea as the result of a temporary exacerbation grafted on to a chronic nephritis must not be lost sight of, and various other causes of increased blood urea, quite apart from kidney lesions, must be remembered. In cases of high urea content there is generally an increase in inorganic blood phosphates, and such a combination is of serious import. Indeed, it would seem that the retention of phosphates is in some way connected with the onset of uraemia, so that phosphate retention must be considered as a serious indication. Progressive increase of blood urea concentration is also a most unfavourable omen.

Urea Concentration Factor.

When this is low the outlook is very grave. When it gets to the region of 2 or 3 the case is hopeless and life cannot be long sustained. Whatever the concentration of the blood urea the prognosis is good if the urea percentage in the urine is high.

Urea Concentration Test.

When the blood urea is high it is unnecessary to do this test as sufficient urea is already present in the blood, and all that is required is to estimate the urea concentration in a specimen of urine. Even if 15 grams urea be given in such a case no increase in urinary urea is obtained. When the blood urea is normal the pathological condition is naturally less severe, but the extent of the lesion can generally be indicated by the results of this test. If the urea percentage when using this test is over 2 or 2.5 the kidneys are quite efficient to carry out their functions. If much lower prognosis is more serious.

Diastatic Test.

In severe renal lesions the diastatic value will probably be less than 5, but little importance can be attached to this test alone in any given case.

Importance of Cardio-vascular Condition in Prognosis.

The state of the heart and arteries is of very great importance in helping us to forecast the probable course of chronic

nephritis of the ordinary azotaemic variety. The opinion is widely held at present that arterial sclerosis and other vascular manifestations are generally associated with marked deficiency of the kidney, and that many of the symptoms exhibited by patients with high blood pressure are largely dependent on the renal condition. Thus it is generally assumed that a patient who shows definite cardio-vascular changes combined with slight albuminuria, and perhaps the passage of a few casts, is almost necessarily suffering from more or less grave nephritis; indeed, the tendency is to regard the cardio-vascular changes as essentially secondary to the kidney lesion. This undoubtedly is the correct view to take in many cases, but there is now sufficient evidence to prove quite conclusively that in many patients with high blood pressure and other cardio-vascular changes the kidneys may be but slightly if at all affected. The more one investigates these cases the more apparent does it become that there is no necessarily close relationship, in all cases, between the condition of the kidney and the condition of the cardio-vascular system. In many patients suffering from chronic nephritis the cardio-vascular changes undoubtedly become more marked as the renal defect progresses; there are, however, many subjects who show but little evidence of marked cardio-vascular changes, but in whom the renal system is hopelessly inefficient. Conversely, it is not uncommon to find patients with very marked cardio-vascular changes in whom but little evidence of renal disease can be ascertained. These points must always be taken into consideration in estimating prognosis, for, in a general way, apart from such accidents as cerebral haemorrhage, the outlook in a patient with high blood pressure is not so bad if the kidneys are efficient. Indeed, such patients may enjoy comparatively good health for many years, even with a blood pressure as high as 200 mm. mercury or even more. This observation explains the curious cases one occasionally finds quoted in the literature, in which a history of high blood pressure of 250 or over, frequently associated with retinitis and other eye changes, was not incompatible with the enjoyment of fairly good health for several years. In such patients the kidneys were undoubtedly effective, at least during the earlier stages of the condition; in some instances the so-called uraemic manifestations which were said to be the cause of death were nothing more than the

direct results of cardio-vascular degeneration and could not be regarded as evidence of death from renal disease. High blood pressure, when associated with definite and advanced renal changes, may be regarded as hopeless. In Table I are given the results obtained in a series of 15 patients with high blood pressure and vascular changes, in whom renal efficiency tests showed definitely that the kidneys were but little affected and quite efficient to perform their ordinary functions. In the majority of these patients there was a history of acute nephritis some years before. In spite of the high blood pressure and other changes present, the prognosis in such cases is much more hopeful than it would be if the renal system were badly involved.

That there are some grave cases of nephritis in which the cardio-vascular system is not involved to any appreciable extent is seen from the results given in Table II. Here, as the figures show, the renal efficiency in many cases was hopelessly bad and the prognosis about as grave as could be.

TABLE II.—Patients with very Defective Kidneys, but no Blood-Pressure Changes.

No.	Duration of Disease.	Blood Pressure.	Condition of Arteries.	Blood Urea per 100 c.cm.	Urea Concentration Test.	D. Value.	Condition of Urine.
1	6 yrs.	160	Good	Mg. 194	0.85	1	Large numbers of hyaline, granular, and epithelial casts. Much protein.
2	4 yrs.	150	Good	200	0.9	1	Casts of all kinds exceedingly numerous. Much protein
3	Uncertain	125	Good	240	0.9	2	Protein and casts in abundance. Some leucocytes.
4	Uncertain	145	Fair	303	0.7	—	Fair amount protein. Hyaline and epithelial casts.

Note.—The position of the apex beat was normal in Cases 1, 3, and 4; in Case 2 it was just inside the nipple line in the fifth space. The second aortic sound was normal in all four cases.

It is no doubt true that slight renal involvement associated with marked cardio-vascular changes is not more common than the converse—marked renal involvement with little or no cardio-vascular changes. Usually, of course, chronic nephritis is accompanied by some involvement of the cardio-vascular system, but this is not necessarily very marked, and varies considerably in extent. Types of marked involvement of both cardio-vascular and renal systems are given in Table III.

TABLE III.—Patients showing Well-marked Vascular and Renal Lesions.

No.	Date of Examination.	Duration of illness.	Blood Pressure.	Blood Urea per 100 c.cm.	Urea Concentration Test.	D. Value.	Condition of Urine.
1	2.9.21	12 yrs.	218	Mg. —	1.1	1	Much protein; numerous casts of all kinds.
2	5.17.21	7 yrs.	184	—	1.3	5	Fair amount of protein; many epithelial casts.
3	6.8.21	6 yrs.	173	60	1.1	6	Very large amount of protein; numerous casts.
4	7.2.22	4 yrs.	280	—	0.9	2	Protein in fair amount. Numerous epithelial and granular casts.
5	8.4.22	5 yrs.	258	—	1.0	4	Very large amount of protein with very numerous casts.
6	6.4.22	6 yrs.	250	95	1.2	4	Protein moderate; epithelial and hyaline casts.
7	10.10.21	Uncertain	246	210	0.7	1	Fair amount of protein; very many casts of all kinds.
8	29.5.21	7 yrs.	230	—	0.6	2	Much protein; fair number of epithelial and granular casts.
9	31.3.22	11 yrs.	200	—	1.0	1	Protein abundant; fair number of casts.
10	7.10.21	Uncertain	280	92	1.2	5	Moderate amount of protein; few epithelial casts.

* These patients died.

Some General Observations.

In the majority of renal patients suffering from chronic interstitial nephritis (azotaemic nephritis) it is not very difficult to arrive at a fairly accurate prognosis when the method of examination suggested is carried out; this is more especially the case when the patient is under observation for

some time. In severe conditions the clinical symptoms alone will often indicate that the end cannot be far distant. Probably it is true that chronic renal patients with marked eye changes, such as retinitis and haemorrhage, do not as a rule live more than one or two years, but there certainly are many exceptions. When, however, we consider very carefully the state of the cardio-vascular system and the results of renal tests, there is very seldom any great difficulty in arriving at a definite conclusion as to the condition existing at the time of examination. On the other hand, it is not so easy, in some cases, to estimate the probable rate of progress of the disease, and frequently this can only be done by repeated examinations at intervals. Again, the liability of contracting an acute attack of nephritis must always be considered, but cannot of course be foreseen, and to this extent we must always be working in the dark.

The following results (Table IV) obtained from patients with varying degrees of nephritis illustrate some of these points:

TABLE IV.

No.	Blood Pressure (Systolic).	Blood Urea per 100 c.cm.	Urea Concentration Test.	Urea Concentration Test.	Condition of Urine.	Opinion of Case.
1	210	Mg. 116	8	0.9	Much protein; epithelial and granular casts.	Condition serious; prognosis very bad.
2	200	38	60	3.1	Protein small amount; few epithelial casts.	Kidneys good; prognosis good as regards renal condition.
3	160	20	50	2.8	Fair amount of protein; few hyaline casts.	Condition fairly good; prognosis quite hopeful.

Note.—The arteries were thickened in Case 1, and slightly so in Case 2; in Case 3 they were normal. In Case 1 the apex beat was in the left nipple line, fifth space; in Cases 2 and 3 it was in the normal position.

Prognosis in Surgical Operations.

Not infrequently the question of operation arises in the case of patients who happen to be suffering from some degree of chronic nephritis. In all such patients renal tests on the lines just indicated should be carried out, when it will generally be quite possible to say whether or not the renal lesion precludes operative interference. If there is no increased blood urea, and the result of the urea concentration test is good, it may be stated with some certainty that the renal condition does not contraindicate operation. This is a very large subject which it is impossible to discuss more fully here, but it may be said that experience shows that extraordinarily accurate forecasts can be made.

Frequently after operations on the genito-urinary organs, or after other major abdominal operations, the patient does very well for a few days, and then passes into a condition which is frequently associated with serious symptoms, and is variously labelled as "peritonitis," "acute post anaesthetic dilatation of the stomach," "delayed shock," "paralysis of the intestine," etc. It is hardly recognized that the majority of these cases appear to be of a uraemic nature, and generally clear up if the kidneys are moderately efficient. In conjunction with Dr. J. Jones I have made a considerable number of observations on this type of case, but as a full report will shortly appear it is unnecessary to discuss the matter further at this stage.

Treatment of Chronic Nephritis.

The detailed treatment of chronic nephritis requires little comment; it really resolves itself into the treatment of symptoms and is carried out by the use of the ordinary well-known remedies, with slight variations depending on the particular fancy of the medical practitioner. In all cases the general régime is important. Warm clothing, hot baths, careful attention to the bowels, avoidance of exposure to cold and wet, and, if possible, residence in a warm climate, are factors which no doubt frequently result in prolonging life. Unfortunately, it is often difficult or impossible for the patient to avail himself of all these measures. When he can do so nobody will, I think, deny that they are likely to prove helpful. The chief interest, however, in the treatment of chronic renal disease revolves round the question of diet, and nearly all medical men are careful to give very stringent injunctions as to the nature and amount of the

food which the nephritic patient may eat. In discussing this problem it is necessary to remember that the two forms of disease already mentioned—the hydraemic or chronic parenchymatous form and the azotaemic or chronic interstitial form—present rather different problems, and must be dealt with separately.

Diet in Chronic Interstitial or Azotaemic Type.

The usually accepted diet for chronic interstitial nephritis is one in which the protein constituent is low. The view adopted is that the renal system being the chief means by which waste nitrogenous products are eliminated, those products should be reduced to the minimum in order to spare the kidneys. This conception, no doubt, contains a germ of truth, but it was formulated in other days when our conceptions of protein metabolism and of renal activity were very different from what they are to-day. Really it is quite an open question whether protein in itself is at all detrimental even in cases of advanced renal disease. I am at present carrying out experiments in connexion with this problem, but the subject is a difficult one from the experimental standpoint. It is quite certain that even complete withdrawal of protein from the diet in cases of advanced lesions associated with uraemia does not influence the uraemic manifestations. It is frequently not difficult by the use of a carbohydrate diet to reduce the blood urea and non-protein nitrogen in a uraemic patient to well below the normal value, but this does not influence the uraemia. Until our information on this subject is largely increased it will, no doubt, be wise to restrict the amount of protein consumed when treating advanced cases. On the other hand, it is important to bear in mind that the ordinary healthy individual requires protein in order to maintain health, and that the minimum amount necessary seems to be about one gram per kilogram of body weight. When this amount is materially reduced the individual suffers sooner or later. It would, therefore, seem best to allow this amount of protein in all but advanced cases. In patients with slight or only moderately severe lesions, it seems best to give a diet containing a fair amount of protein, and the present custom of putting such patients on slops containing but a minimum of protein is to be deprecated. Many such patients suffer more from treatment than from the renal condition. When, therefore, the renal tests show that the kidney lesion is not severe, much benefit is frequently derived from an increase of protein food. On the whole, there is little doubt that the dietetic treatment of the milder forms of interstitial nephritis is at present too strict, and the patients do much better on a more liberal ration. In every case before putting a patient on any form of restricted diet the condition of the kidneys should be carefully ascertained, for sometimes the presence of a little albuminuria is the sole condition that can be found. In such patients dietetic treatment is superfluous, and frequently does harm. In the more severe types of disease it is probably advisable to limit the protein, but even here a fair amount should be given. It must be remembered that the body will itself supply waste products from its own tissues when little or no protein is given as food, so that it is impossible to eliminate altogether the work of the kidneys in excreting waste products.

Diet in Hydraemic or Parenchymatous Nephritis.

As already indicated, there is no retention of nitrogenous waste products in this variety of disease, and no apparent difficulty on the part of the renal system in excreting these products. Theoretically, therefore, there is no need to restrict protein. Since a large amount of protein is generally lost in the urine, an additional reason for the giving of protein is supplied. Practically it is found that a large protein diet is generally more effective than any other measure in clearing up the oedema and in helping to restore the patient to comparative comfort. This type of disease constitutes a phase which is essentially of moderate duration, for under favourable conditions it tends to pass into what is usually a mild form of interstitial nephritis. It may, however, pass into a very severe form of the interstitial variety, and in such cases the prognosis is grave. Until this condition—representing the chronic interstitial type of nephritis—supervenes, the ascites and oedema persist. Epstein and others have shown that the best method to get rid of the excess of tissue fluid is to give large amounts of protein in the diet. There is no doubt that large protein ingestion gives wonderful results in many cases, and this method should be adopted with all patients suffering from typical hydraemic nephritis without any azotaemia. Sometimes the elimination of salt from the diet has a

marked beneficial effect, but generally this alone is not sufficient; combined with high protein diet it is very often helpful. The exact mechanism by which protein acts in clearing up the oedema is not quite understood, but the increase of blood urea which naturally follows the increased protein ration is probably the chief factor on which this favourable result depends. The urea acts as a diuretic and so causes an increased flow of urine. In proof of this it is frequently found that daily dosage with 15 to 30 grams of urea for a few weeks will clear up very obstinate cases. In short, the best treatment for hydraemic nephritis is a large salt-free protein diet, accompanied at first with some urea given by mouth. This should be combined with rest in bed, hot-air baths, and free action of the bowels.

Decapsulation of Kidneys in Hydraemic Nephritis.

This is the type of case in which decapsulation of the kidneys is frequently attended with an improvement of the condition. While the results of this treatment are by no means uniform, it does seem that many patients suffering from obstinate hydraemic nephritis are greatly benefited by this procedure. The symptoms appear to suggest that the renal channels are blocked up with debris and swollen cells so that fluid can pass with difficulty, and so it is easy to understand how relief of this tension might give good results. Personally I have not had much experience of this treatment, but what I have seen suggests that in hydraemic nephritis operative procedures of this nature will play a much larger part in the future than has been the case in the past.

Though the discussion of the treatment of chronic nephritis is necessarily somewhat curtailed, we must face the fact that at present there is no specific treatment for this condition, and much work must still be done before we can be at all certain of the best means of combating this insidious lesion, and, if possible, preventing its advance.

DISCUSSION.

Dr. JOHN D. COMRIE (Edinburgh) said: One should not lose sight entirely, I think, of certain old and simple methods of testing the condition of the kidneys. The absolute amount of albumin that a nephritic patient passes is no criterion whatever of the state of kidney inefficiency, for the leak may be of a merely functional character, even when it is pronounced in degree; and on the other hand the kidneys are often very much damaged in structure and in efficiency when a mere trace of albumin appears in the urine. Nevertheless, if a case of parenchymatous nephritis be under continual observation and treatment, and if the albumin be carefully estimated every day, a useful indication as to prognosis is obtained, so that if a progressive diminution is noted the sign, *ceteris paribus*, is favourable. Again, the question as to how the patient secretes water—or in other words the maintenance of the normal proportion between the amounts of day urine and of night urine—is of much importance. This is an indication mainly, I think, of the state of the cardiovascular system as regards hypertrophy and sclerosis. Various methods have been suggested by Leathes,¹ John,² etc., for carrying out this test, but the most satisfactory in my opinion is to measure the quantity of night urine (9 p.m. to 7 a.m.) in one collection, and the day urine in seven two hourly (7 a.m. to 9 p.m.) collections. Normally the total night urine is not greater than any one of the two-hourly day urine samples, which show also considerable fluctuation. In the nephritic with marked arterio-sclerosis there is "fixation" of the rate of excretion, the two-hourly excretion tending to be more and more the same by day and night as the condition becomes progressively worse. This rule, as shown by Boyd and Malcolm Smith,³ is not, however, always true, especially in cases of severe nephritis with little arterio-sclerosis, and thus the test is not of value in all cases. The same unreliability attends the estimation of the rate of secretion of chlorides, of potassium iodide, and of some other easily soluble substances, whose amount is a function of the water excretion. The amount of pancreatic diastase excreted in the urine I have also found to be so variable as to be often unreliable.

The three tests upon which I place most reliance are: (1) the estimation of blood urea; (2) the urinary urea concentration test; (3) the excretion of phenolsulphonc-phthalein. Any one test is liable to have fallacies, and the kidneys may give a fair reaction with one while being less

³ *BRITISH MEDICAL JOURNAL*, 1921, ii, p. 428.

efficient with the others, so that these tests form useful mutual controls.

1. The estimation of blood urea is simply carried out by the urease method. One must be sure that the ferment used is active, and for the same reason one must be careful not to raise the temperature of incubation above 110° F. Any rise above 50 mg. per 100 c.cm. of blood indicates a marked urea retention; and if it be permanently over 100 the case is almost invariably a serious one; in bad cases of acute uraemia it may reach two or three times that amount and death is then very likely. A negative result is not, however, proof of normal renal efficiency, since persons with marked nephritis often have a normal blood urea of 30 mg. or thereabout. This applies to cases of subacute diffuse nephritis, or hydræmic nephritis, with a special tendency to dropsy. In such cases the patient may throughout the whole course of the disease show no accumulation of urea in the blood. This fact is particularly important to bear in mind in cases where the estimation of blood urea is used as a test for the capacity of the patient to undergo a severe surgical operation. The blood urea is also a valuable dietetic indication. These dropsical patients with low blood urea are benefited by a diet containing protein foods of easy digestibility—for example, mutton, chicken, and fish—while cases of the azotæmic type, with raised blood urea, should be kept for long periods on a milk and carbohydrate diet.

2. The urinary urea concentration test is the simplest test to carry out, and affords a very good general indication of the renal efficiency. It is carried out by administering 15 grams of urea in 200 c.cm. of water, and estimating the percentage of urea in the second hour's specimen of urine. A percentage of 3.5 or over indicates a normal renal function; over 2 per cent. it is compatible with a fair degree of health; and persisting below 2 per cent. in spite of treatment it is very unsatisfactory. Persisting below 1 per cent. it is a sign of impending death. It is often noticed that the diuresis caused by the urea produces a low reading, and I would suggest a correction as follows for the watery state of the urine produced by this hydrodynamic response of the kidney. The usual amount of urine passed after the urea test, in the second hour, is about 150 c.cm., and the reading could be corrected to that amount by the following formula—

$$C = U \times \frac{Q}{150}$$

where C is the concentration expressed in terms of the average quantity of urine passed in the second hour after the test, Q the actual quantity passed, and U the percentage of urea found in this. For example, if the patient passes 250 c.cm. in the second hour and this is found to contain 2 per cent. of urea, then

$$C = 2 \times \frac{250}{150} = 3.3 \text{ per cent.,}$$

that is, the figure corrected for the watery diuresis. Otherwise, if the quantity of urine is much above or below 150 c.cm., one must simply discard the test and try it again next day.

3. The phenolsulphonephthalein test has been used by the writer constantly for the past twelve years, and he regards it as the best, though not the simplest, individual test. It has certain requirements and fallacies. In the first place, one must measure very accurately for intramuscular injection 1 c.cm. of the phenolsulphonephthalein solution (containing 6 mg. of pigment). The urine must be completely voided for the two-hourly samples, and rendered strongly alkaline by 10 c.cm. of 10 or 15 per cent. caustic soda. The pigment of the urine, and especially the presence of blood, constitute considerable fallacies unless care be exercised. These can be avoided by filtration and the use of a suitable optical filter introduced below the prism of the colorimeter, as shown in the following table, which gives the average of a number of observations:

	Greenish-yellow Diabetic Urine.	Dark Brown Clear Urine.	Urine Smoky from Blood.
Actual percentage of phenolsulphonephthalein present	50%	50%	50%
Reading unfiltered	59%	70%	55%
Reading when filtered and colour screen used	53%	53%	52%
Reading when shaken with charcoal and filtered	—	—	45%
Reading after shaking with lead acetate and filtering	0	0	0

* *Edu. Med. Journ.*, February, 1922, p. 35.

The most correct reading is thus obtained by filtering the urine through a fine filter paper and using an optical colour screen. The excretion of this substance should take place chiefly in the first hour, and the amounts of the two hours should total at least 70 per cent.; excretion of 50 per cent. is compatible with recovery under treatment; 30 per cent. is low, but life may proceed on a low plane of vitality; an excretion below 20 per cent. is bad, and if it persists much below this figure death usually ensues within a few months.

Dr. J. O'BRYEN SMITH (Bristol) said: I wish to confine my remarks to the prognosis and treatment in chronic parenchymatous nephritis. All textbooks agree that this is one of the most unfavourable and rapidly fatal forms of nephritis. Jeauselmo in his recent work, *Maladies des Reins*, says: "Death takes place in from three to twelve months, and is often hastened by cardio-pulmonary or intestinal complications, septic infections, cachexia, and emaciation." The question I wish to ask is: Is there such a condition as pure chronic parenchymatous nephritis (large white kidney), and, if there be, is the prognosis so invariably unfavourable as is generally accepted? By chronic parenchymatous nephritis is generally meant a tubular nephritis accompanied by much oedema, deficient excretion of salt, diminished quantity of urine of high specific gravity, much albumin, numerous casts, but in which uraemia is uncommon, the blood pressure is not raised, ocular symptoms are rare, and, most important of all, the renal efficiency is fair. My clinical experience has been that if such a condition as tubular or chronic parenchymatous nephritis exists it is extremely rare, and if it exists we must considerably modify our view of the gravity of the prognosis.

Since I have adopted renal efficiency tests and blood urea estimations I have had fifty-two cases of nephritis in my wards. Two of these were diagnosed as chronic parenchymatous nephritis. Both are still alive three years from the commencement of their illnesses, and a closer examination of their cases makes it almost certain that the condition was one of subacute diffuse nephritis. Similarly with cases seen before the renal tests were introduced—a very striking example of chronic parenchymatous nephritis who was admitted under my care in 1904 is still alive to-day. He was in the Bristol General Hospital from February to October, 1904, with gross oedema requiring repeated tapping, and was discharged in the same condition. He had all the typical signs—anaemia, dyspepsia, small amount of urine (specific gravity 1020), albumin 7 to 9 parts per 1000, low blood pressure, urea excretion fair. The oedema persisted for six months after his discharge. In 1911 the high total of daily urine, low specific gravity, and a trace of albumin suggested secondary sclerotic changes, and in 1919 this was the same, and his phenolsulphonephthalein excretion was 23 per cent. only. The blood nitrogen was very high. The sodium chloride excretion was normal, the two hourly specific gravity never above 1012. Here was a case—the most typical of chronic parenchymatous nephritis I can produce in twenty years of hospital work: yet he has lived eighteen years after his initial attack. I recall one other case, a minor. He was superannuated in 1885 on account of chronic parenchymatous nephritis (large white kidney), but is alive and well to-day at the age of 69 years. The albumin amounts to 2 parts per 1000, the vessels are slightly thickened, the heart is not enlarged, the blood pressure not raised. The point I wish to emphasize is that we must either stercorally modify our conception as to the grave prognosis in this disease, or we must deny altogether that there is such a condition as a chronic tubular nephritis. Personally, I favour the latter course not only on clinical but also on pathological grounds, for, except in the kidney of pregnancy, I never see a case in which the brunt of the disease is borne by the tubuli whilst the glomeruli are but slightly affected. Nephritis is essentially a vascular intoxication, and invariably the glomerulus suffers primarily and the tubular destruction is entirely secondary and consequential. There is no ground for the view that large white kidney is a disease *per se* and that the prognosis is peculiarly unfavourable. The terms "parenchymatous nephritis" and "tubular nephritis," with their evil omen, ought to be abolished from our nomenclature, and the large white kidney regarded as a phase of a glomerular (or diffuse) nephritis; a subacute or chronic phase, probably progressive towards an interstitial nephritis but not necessarily immediately dangerous, and indeed compatible with a prolonged period of comfortable living.

With regard to the question of treatment of the chronic oedematous type of nephritis I have only to note two points.

First, it is not worth while submitting the patient to the prolonged salt-free diet of Karroll or the still more prolonged super-protein diet of Epstein when a diuresis immediate and in every way satisfactory can be established by the administration of urea. There appear to be no ill effects following the administration of urea. I have recently had two boys under my care aged 12 and 14, and one took 18,000 grains in thirty days and the other 7,000 grains in thirteen days with great benefit. The blood urea in the first case at the end of the course was 50 mg. per 100 c.cm. For many days after the drug is withdrawn the diuresis continues and the oedema shows no sign of returning. I have not hesitated to give to these oedematous cases a diet containing 30 to 50 grams of protein a day, and they appear to do better than when on a limited scale. The second point is that the oedematous case may be kept too long in bed. There is no doubt in my mind that a moderate degree of exercise hastens the disappearance of the oedema and generally benefits the patient. It should not be forgotten that chronic nephritis in any form leads to an anaemia of the aplastic type, and that this condition is greatly benefited by the administration of iron and arsenic.

Professor J. SHAW DUNN (Birmingham) said: Until we have more certain information regarding the normal physiology of renal secretion it will be impossible to obtain any complete conception of the relation between the morbid changes in the kidneys and the impairment of renal function in nephritis. Still, something may be gained for the prognosis and treatment of chronic renal disease by a more thorough correlation of modern clinical and pathological methods of investigation. Generally speaking, in nephritis the glomeruli and tubules are always both affected by pathological change, although the type of lesion, its extent, and the proportion between glomerular and tubular lesions vary greatly in different instances. As regards type, the lesions may be grouped provisionally under the headings (1) alterative and (2) destructive.

1. *Alterative*.—Here the glomeruli are free from gross changes and their capillaries are patent; there may be some fatty degeneration of the capillary endothelium, and there is evidence that the capillary walls allow the leakage of albumin from the blood. The tubular changes are more obvious, comprising fatty degeneration, hyaline-droplet degeneration, and oedematous swelling of the epithelium, but there is often little actual catarrh or loss of cells. Where alterative changes are present in the purest form the nephritis is most purely of hydraemic type and shows least evidence of urea retention. The evidence suggests a loss of balance, a pathological modification of excretion, rather than a diminution of excretory power. It is quite possible that the function of the tubular epithelium is so altered as to cause a greater reabsorption of constituents than normal, thus accounting for abnormal retention of water and salts.

2. *Destructive*.—Here the glomeruli are obviously grossly diseased; the capillaries are often blocked by endothelial cells, or there may be closure of groups of capillaries by military thrombi resulting in infarction and fibrosis of the tufts. Accompanying this there may be catarrh of the glomerular epithelium, adhesions between tuft and capsule, and thickening of Bowman's capsule. All of these phenomena tend to the ablation of glomerular function, thus cutting off the function of excretion at its source. It is important that these lesions are often focal in character, and some tufts may remain normal. The tubules here also suffer markedly; the epithelium becomes lowered in type; there is much catarrh, and in later stages there is more and more total destruction and atrophy of tubules. Associated with these grosser changes in the parenchymatous elements there is extensive overgrowth of interstitial fibrous tissue. The effects of the destructive type of change are seen in purest form in so-called chronic interstitial nephritis, and comprise mainly a tendency to retention of urea and to elevation of arterial blood pressure. These effects may be assumed to depend on lack of filtration owing to loss of glomeruli. The tubular function must also be greatly diminished, as the loss of tubules is enormous; possibly this accounts for the tendency to polyuria in such cases owing to inefficient reabsorption of the glomerular filtrate. While it is possible to define these two main groups of renal lesions it is probably comparatively seldom that they occur in approximately pure form. In many instances they are combined, and, further, they occur together in varying proportion, so that it is extremely difficult, if not impossible, to project the nature of renal lesions from a consideration of

the clinical aspects of a case. Reference has been made to the recognition of cases showing clinically a high blood pressure with totally unimpaired renal function. In relation to this it may be remarked that in *post-mortem* work it is much commoner to find evidences of the existence of a high blood pressure associated with arterio-sclerotic atrophy of the kidneys than with any form of chronic nephritis.

Dr. KATHERINE O. ROBERTSON (Glasgow) said: Judging from the literature on renal disease it appears that while much has been done in the study of renal disorders from the pathological, clinical, and more recently from the biochemical points of view, little attempt seems to have been made to correlate these findings, although various authorities have fully recognized this necessity. With this in view I have tried to follow my cases to the final court of appeal and correlate my clinical findings with the condition of the kidneys and blood vessels at *post-mortem* examination. So far I have only succeeded in making a complete study of six cases. These consisted of two cases of primary arterio-sclerosis with secondary involvement of the kidneys, two cases of primary chronic nephritis with secondary arterial degeneration, one case of advanced pernicious anaemia, and one case of acute malignant endocarditis. The two cases of arterio-sclerosis, Nos. 17 and 31, had many features in common. The blood pressures were respectively 190 and 240. Case No. 17, however, did not come under observation until cardiac failure had set in. Both cases complained of long-standing gastric and intestinal disturbances, and more recently of polyuria and breathlessness. Both cases had enlarged hearts. Neither case gave any history of long-standing renal disorder. Case No. 17 had been treated eleven years ago for haemorrhage from the bowel, and at that time was diagnosed as a case of cirrhosis of the liver; the heart was somewhat enlarged, but there was no albumin in the urine. Patient improved under treatment, and his health remained fairly good till three months before his death, when breathlessness and heart failure set in. By the time the patient was admitted to the hospital he was suffering from headache and the chronic slight uraemia so common in these cases. At *post-mortem* examination there was no sign of cirrhosis of the liver. Case No. 31, on the other hand, remained mentally clear almost to the end, though headache was a distressing symptom. An interesting point in this case is that about five weeks before her death a urea concentration test was carried out, and the highest point reached was 2.1 per cent. in the third hour after the usual dose of 15 grams urea by the mouth. The blood urea was estimated in the third hour and found to be 112 mg. per 100 c.cm., giving a urea concentration factor of 18. Eight days later the test was repeated, and this time the highest point reached was 1.5 per cent. in the first hour, the concentration in the third hour being 1.3 per cent.; the blood urea in the third hour was 103 mg. per 100 c.cm., giving a urea concentration factor of 12. This low reading may have been due to the fact that the patient vomited about half an hour after taking the urea, but a blood urea of 103 mg. should have stimulated a reasonably active kidney to concentrate to its fullest capacity. In cases giving good concentrations in the urine I have found that the blood urea estimated in the third hour after the dose of urea was well below 100 mg. per 100 c.cm. *Post-mortem* examination showed even more resemblance between these two cases. Both cases had hypertrophied hearts; the kidneys were granular but not much altered in size. Microscopically the vessels of the mesentery, both large and small, were greatly sclerosed and the lumen of the vessels decidedly narrowed by the multiplication of the internal elastic lamina. The kidneys showed marked interstitial and glomerular fibrosis of vascular distribution. The small vessels of the kidney were tortuous and thick-walled, in many the lumen was almost completely occluded. It seems wrong to class these as cases of kidney disease. The renal manifestation was a late symptom of the general vascular degeneration, which in each case had given rise to gastric and intestinal symptoms long before any functional change was noticed in the kidney. On the other hand we have cases Nos. 15 and 20, which were both primary kidney conditions. Here the history revealed repeated attacks of nephritis. The blood pressures were respectively 190 and 220. Case No. 15, however, was suffering from heart failure when the blood pressure was taken. They showed the headache and slight chronic uraemia of the previous two cases. Both gave a poor urea concentration and the blood urea estimated in the third hour

was high, giving a low urea concentration factor. Case No. 20 showed retinal and sclerotic haemorrhages. Neither case gave a history of long-standing gastric or intestinal disturbances. At *post-mortem* examination both were found to have enlarged hearts, the kidneys were granular but not much contracted. Microscopical examination showed that the larger vessels of the mesentery and kidney were more affected than the smaller ones. The change was chiefly a medial fibrosis, though the renal artery in case No. 20 showed marked . . . of the intima. The kidneys showed . . . and glomerular fibrosis. There was no sign of vascular distribution. Thus we have four cases which in the late stage were clinically indistinguishable. The albumin was not excessive; the blood pressure was high with enlarged heart; the urea concentration test was low. There was headache, restlessness, breathlessness, cardiac failure, and chronic slight anaemia tending to deepen in all four cases. The clinical difference lay solely in the history which, as has been pointed out in the arterio-sclerotic cases, centres round the alimentary tract and in the cases of chronic nephritis round the kidney. The *post-mortem* examination also showed resemblances between the four cases. The heart was hypertrophied and the kidneys were granular but of nearly normal size in all four cases. Microscopical examination showed interstitial and glomerular fibrosis in all four cases. In the arterio-sclerotic cases the fibrosis showed vascular distribution, but this was absent in the other two cases where the fibrosis was equally distributed. Another difference was seen in the distribution of the vascular degeneration which, in the arterio-sclerotic cases, affected large and small vessels alike, but in the chronic nephritis cases affected the larger vessels more than the smaller ones. This brings me to the case of pernicious anaemia, which gave a low urea concentration. It is just possible, however, that this may have been due to poor absorption, as the blood urea estimated in the third hour was very low. In this case the kidneys showed marked catarrh of the secreting tubules with cloudy swelling and some fatty degeneration. It is interesting and suggestive to note that there is one factor common to all these five cases, and that is the poor supply of oxygenated blood received by the kidney. The sixth case, one of acute malignant endocarditis, gave a very good urea concentration the day before she died. Death in this case was sudden. The kidneys showed marked catarrhal and interstitial nephritis with cloudy swelling, and were of large size. The mesenteric and renal arteries showed commencing medial degeneration. These cases all show . . . features clinically, biochemically, and . . . does not admit of further detail.

Dr. O. L. V. DE WESSELOW (London) pointed out that, though in chronic interstitial nephritis the rise in the blood pressure often bore some relationship to the degree of impairment of nitrogenous waste products, this relationship was not one of cause and effect. In certain surgical affections of the kidney, in amyloid disease, and in cystic kidney marked nitrogenous retention was often associated with a normal blood pressure. From the point of view of immediate prognosis, he regarded the estimation of the inorganic phosphorus content of the plasma as valuable. The figure for inorganic phosphorus in the normal was in the neighbourhood of 3 mg. per 100 c.cm. of plasma. In acute nephritis figures of 5 to 7 mg. were common. An inorganic phosphorus content above 10 mg. appeared to indicate an exceedingly grave prognosis. A patient in whom a definite urea retention was associated with a retention of inorganic phosphorus was in a much graver condition than a patient showing a similar rise in the blood urea but a normal phosphorus content. From the clinical point of view, the symptoms of uraemia showed a much closer connexion with phosphate retention than with retention of the nitrogenous waste products. A diminution in the calcium content of the serum was frequently found in nephritis, but this diminution did not appear to bear any relationship to the convulsive phenomena. In the only case in which he had found an extreme reduction in the serum calcium, administration of calcium per os produced no increase in the calcium of the serum. This was to be expected, since in view of the large calcium reserves of the body the deficiency in the serum was more likely to be due to a change in the chemical composition of the blood than to actual lack of calcium.

Dr. H. L. Tidy (London) thought it was our duty to correlate both the clinical symptoms of the disease and the renal efficiency tests with the histology of the kidneys. For many

years physicians, from observation of clinical symptoms, had foretold with considerable accuracy the type of pathological changes which were present in the kidneys. Obviously the clinical symptoms and pathological changes had some relationship. So, too, had the clinical symptoms and the renal efficiency tests. He considered consequently that the renal efficiency tests and the histological changes in the kidneys must be capable of correlation. He did not agree with former speakers that histological types could be clearly divided into two classes, and he believed that this view was partly responsible for the failure hitherto to connect the renal efficiency tests with the histology. There were, he held, at least four types. He was surprised that the small white kidney had not been mentioned during the discussion. It was a definite pathological type which could often be diagnosed from its clinical symptoms.

Dr. E. J. Tove (Bideford) made a few remarks on the subject from the point of view of the general practitioner. He emphasized the simplicity and utility of the urea concentration test. He concluded by stressing its great value in testing the adequacy of the renal function in cases of albuminuria of pregnancy.

Before calling on Professor Hugh Maclean to reply, the President emphasized the value of the urea concentration test as a means of ascertaining the actual condition and the progress of a case of nephritis. It could not replace the observation of symptoms or the study of certain other well-recognized signs, but it had the advantage, not shared by many other signs and symptoms, that the findings could be kept on record in black and white for comparison with corresponding results obtained in the same case later on. It would be a great gain if one could recognize the existence of a lesion, whether stationary or progressive, which had diminished the total functional capacity of the kidneys and yet had left them with sufficient reserve power to respond to all tests to which, at the present time, they might be subjected by the physician. Patients who came under observation on account of acute or subacute nephritis sometimes gave a history of previous attacks many years before; and one would like to know whether each of these earlier attacks had left behind it a lessened reserve of functional capacity, or whether the attacks merely revealed the weak spot in the particular patient and passed off without doing any permanent harm, and without diminishing the enormous reserve power of the kidneys.

NOTES OF A CASE OF ACUTE MYELOGENOUS LEUKAEMIA AND OF A CASE OF APLASTIC ANAEMIA.

BY

ROBERT A. FLEMING, M.D., F.R.C.P. (Edin.),
Physician, Royal Infirmary, Edinburgh:

AND

JAMES DAVIDSON, M.B., Ch.B.,
Assistant, Pathological Department, Edinburgh University.

Case of Acute Myelogenous Leukaemia.

J. S., a male aged 58, was admitted to Dr. Fleming's wards on October 28th, 1920, on the recommendation of Dr. Lang. He complained of feverish attacks, each attack lasting for one to two hours, during which his temperature rose to 104° or 105° F. and fell with profuse sweating. He had two or three of these attacks each twenty-four hours, and each commenced with a rigor. His occupation, originally that of a shale miner, had for three years been limited to loading ammonia sulphate into bags.

His past history was as follows. He had had rheumatism three months before admission, with pains in shoulders, elbows, wrists, and fingers, and the pains flitted from joint to joint. He had no fever at that time, and recovered in four weeks. There was also a history of influenza in 1919, lasting for seventeen weeks. His family history was unimportant.

On examination on October 28th, 1920, there was no splenic enlargement, no enlarged glands were found present, and nothing abnormal was noted in his blood. On November 8th the spleen was found to be definitely enlarged, and he complained of pain due to perisplenitis. His red cells numbered 3,330,000 and his leucocytes 8,000. On November 9th his leucocytes had increased to 18,500 and the differential count showed polymorphs 30 per cent., eosinophils 1 per cent., myelocytes 11 per cent., large mononuclears 13 per cent., and small lymphocytes 44 per cent. The majority of the

larger cells resembled myeloblasts, and were difficult to place accurately in any group. Films stained by Loishman's method showed a dark basophil cytoplasm in certain cells with numerous azurophil granules. Some cells had an intensely basophil-stained cytoplasm. The nuclei were large, varying in shape. Some of the cells showed mitotic division with beautiful examples of monaster and diaster stages.

On November 11th numerous petechial haemorrhages were noted over the chest, and especially round the hair follicles. On November 14th the patient died, twenty-one days after the pyrexial attacks commenced and six days after his spleen was found to be enlarged. The lymph-gland groups enlarged coincidentally with the spleen, particularly in the cervical region.

[Slides of the blood, spleen, bone marrow, and liver were demonstrated.]

Case of Aplastic Anaemia.

J. W., a female aged 26, a cook, was admitted to Dr. Fleming's wards on the recommendation of Dr. John Craig, Edinburgh, on November 11th, 1920. The duration of the illness was from December, 1918, and her chief complaints were weakness and shortness of breath.

She had had no previous illness before 1918, except "headaches." Since 1918 she had a "blister-like" rash on

her face, shoulders, and chest, in 1919 lasting for three weeks. There was also severe pyorrhoea, which gave continuous trouble and required much treatment. Her mother and her only sister were anaemic, and both had a history of gastric ulcer. Her father died of pulmonary tuberculosis at the age of 35.

On examination the patient was stout and very pale but with a lemon-tinted skin. She had the usual haemic murmurs and a slightly dilated heart. There were periods of pyrexia lasting for ten days at a time with no definite periodicity. The diagnosis of aplastic anaemia was made because, during the patient's stay in the wards, extending up to the time of her death on October 19th, 1921 (a period of eleven months), her blood never showed any normoblast or megaloblasts. There was poikilocytosis, varying in degree from time to time, but no punctate basophilia and no polychromatophilia. Anisocytosis was peculiarly marked there being many microcytes and megalocytes.

Direct transfusion proved the only really effective treatment, although the benefit obtained was temporary.

The post-mortem examination showed that an extraordinary degree of haemolysis had occurred.

[Slides of the blood, the bone marrow, etc., were demonstrated.]

A CASE OF INTRAPERICARDIAL ANEURYSM OF THE AORTA.

BY

B. T. PARSONS-SMITH, M.D., M.R.C.P. LOND.,

PHYSICIAN TO OUT-PATIENTS, THE NATIONAL HOSPITAL FOR DISEASES OF THE HEART, LONDON.

The patient, a labourer aged 48, attended hospital on August 10th, 1920, complaining of pain in the chest, on the right side especially, shortness of breath, and cough during the previous four weeks.

Physical Examination.

The findings at the physical examination were as follows:

A well-developed man, somewhat above the average in general physique; expression anxious, clefts sunken, malar eminences flushed; obvious pulsation in carotid, temporal, brachial, and other superficial arteries. Chest wall well covered, normal contour except for visible pulsation to the right of the sternum in the third, fourth, and fifth spaces; area of cardiac dullness extends 4 inches to the left of the mid-sternal line to the apex beat, which is situated in the sixth intercostal space and 3½ inches to the right of the mid-line at the level of the fifth rib and corresponding space. The apex beat is forcible in character, diffuse in extent; there is a heaving impulse to the right of the sternum of maximum intensity in the fifth, but also felt in the third and fourth spaces. On auscultation a short systolic and long diastolic murmurs are audible over the entire precordium, the latter being of maximum intensity at the aortic area, but clearly heard over the dull region to the right of the sternum, and conducted upwards into the vessels at the root of the neck. The arteries are thickened and tortuous, the radial pulses collapsing in character and synchronous; the jugular veins are unduly prominent in the recumbent position, otherwise there is no evidence of venous stasis or obstruction of either superior or inferior vena cava. The pulmonary excursion and air entry are normal over both lungs, no tracheal tug; no indication of pressure on vagus, phrenic, recurrent, or sympathetic nerve trunks. The electrocardiogram suggests left ventricular preponderance, but is otherwise normal as regards wave sequence and conformity in all the leads.

The x-ray examination defines the left margin of the heart sloping towards the apex region in the sixth intercostal space, 4½ inches from the mid-sternal line; the aortic shadow is abnormally wide—namely, 3½ inches; its margins are blurred and irregular; a pulsating swelling, similar in density to the cardiac shadow, and apparently continuous with this latter, is seen to extend 3½ inches to the right of the mid-sternal line, its edge, sharp and clear, stretching inwards at its superior extremity to join the aortic shadow at an acute angle, its lower margin, distinctly above and separated from the diaphragm, blending imperceptibly with the inferior aspect of the cardiac shadow; the lungs appear to expand normally, and the range of diaphragmatic movement is unimpaired.

Simultaneous curves recorded on a rapidly moving drum from small receivers placed over the apex and the pulsating tumour to the right of the sternum indicate that the impulse in each region is an outward thrust, and measurement makes it clear that the movements are not synchronous, the apex beat, by a fraction under a fiftieth of a second, being the prior event.

The urine was normal in every respect. The Wassermann test was positive.

Discussion of Diagnosis.

The condition was thought to be an intrapericardial aneurysm of the aorta; and in arriving at this diagnosis one was largely guided by the following considerations:

1. The punctate heaving quality of the pulsation, which to palpation appeared synchronous with the arterial pulse.

2. The presence of aortic reflux, which, in view of the positive complement fixation test, would suggest syphilitic disease of the aortic stem, and the conduction of the diastolic murmur from its seat of production over the entire region of the tumour and upwards into the cervical vessels.

3. The fact that the aortic root and the first 2 inches of its ascending arch are situated within the confines of the pericardial sac.

4. That the direction of least resistance to the spread of a dilatation aneurysm proceeding from the aortic root would be downwards within the cavity of the pericardium.

5. The fluoroscopic appearances which identified the shadow of the tumours with that thrown by the heart and great vessels, and the distinct line of continuity which connected the marginal extremity of the tumour with the right-hand border of the ascending aorta; also the definite character of the expansile pulsation which seemed to warrant the exclusion of new growth or encapsuled pericardial effusion.

6. The absence of pressure signs, which, moreover, would be hardly likely to complicate the early stages of an aneurysm originating within, and governed in the matter of the direction of its spread by, the pericardial investments.

After-History and Progress.

Considerable relief to the subjective symptoms was noted during the first three months of treatment, for which, no doubt, physical rest was mainly responsible; there was, however, no material improvement; the aneurysm was palpably increasing in size, a note of February 18th, 1921, giving its outer border a distance of 4½ inches from the mid-sternal line, and the patient was at that time complaining of sharp attacks of pain with the least effort, also cough and a feeling of suffocation, the latter aggravated by any attempt to assume the recumbent position. A month later the outer border of the impulse extended 5½ inches from the mid-line, and examination at this time made it clear that pressure was being exerted on the right bronchus, and, further, that the superior vena cava was suffering obstruction. During April the symptoms increased in intensity; the cough, more especially troublesome at nights, the violent pain and the insomnia combining, at this time, to produce an extreme degree of debility and physical exhaustion; the outer border of the impulse was then to be found extending a distance of 5½ inches from the mid-line; moist sounds were heard at both pulmonary bases; the air entry to the right lung was diminished.

During the last fortnight of life expectoration was profuse, and every paroxysm of coughing was accompanied by violent

and intense prostration. On May 13th the sputum became tinged with blood, and several small recent clots were expectorated. The patient died next day.

Autopsy Findings.

The two layers of the pericardium were found to be closely adherent, and numerous firm adhesions united the pericardial surface to the pleura on each side. The pleural cavities were in great part occupied by dense adhesions in the neighbourhood of the pericardium, but on separating these on the right side the cavity was found to contain a large amount of recent blood clot.

The heart was considerably enlarged; the aortic valve was incompetent; the cusps of the aortic valve, more especially the anterior and right posterior, were thickened, retracted, and distorted; there were no obvious vegetations; the wall of the aorta showed the macroscopical appearance of the process. Immediately at the junction of the anterior and right posterior cusps, a large saccular aneurysm measuring $4\frac{1}{2}$ inches by $4\frac{1}{2}$ inches arose; it was completely covered by the adherent layers of the pericardium, and it was about two-thirds full of laminated clot; its upper aspect was adherent to the right pleura and lung, which had suffered much dislocation, and here it was that the aneurysm had ruptured into the adjoining pleural cavity and pulmonary tissue.

THE PRESENT VALUE OF THE WIDAL REACTION IN THE INOCULATED SUBJECT.

BY

A. G. SHERA, M.D., CANTAB., M.R.C.S. ENG.,

CLINICAL PATHOLOGIST TO THE PRINCESS ALICE MEMORIAL, EYE, AND EAR, NOSE AND THROAT HOSPITALS, EASTBOURNE.

An acutely febrile case was recently admitted to the Princess Alice Hospital, Eastbourne, on which I was asked to perform a Widal reaction. The technique used was Dreyer's macroscopical method with the Oxford standard cultures. The result read as follows:

CASE I.

	Serum Dilutions:			
	1 in 25.	1 in 50.	1 in 125.	1 in 250.
Typhoid cultures ...	+	+	+	+
Paratyphoid A ...	Trace	-	-	-
Paratyphoid B ...	-	-	-	-

The reading was "strongly positive for typhoid."

The patient was an ex-soldier, inoculated for enterica during the war, the last time most likely in 1917. The clinical signs were those of continuous fever with some physical signs in the chest, and a provisional diagnosis of pneumonia had been made. The case was subsequently regarded, on the strength of the Widal reaction, as typhoid fever, probably pneumonic in type, it being assumed that the war-time inoculus had died away by this time.

The day after the test the patient was removed to the Borough sanatorium as an infectious febrile case. He died some days later. Clinically the symptoms were not typical of enteric, and a *post-mortem* examination was performed. Miliary tubercle was found to be the cause of death. It was then suggested by Dr. W. G. Willoughby (M.O.H. for Eastbourne), under whose care the case had been, that the positive Widal reaction might have been due to residual effects of war-time inoculation. I reported the case to two leading authorities for their opinions. One of them held that miliary tubercle may accentuate any existing agglutinins. He also pointed out that miliary tubercle and enteric may coexist, and that he had had a case of this kind where Peyer's patches showed no signs of inflammation yet where culturally 50 per cent. of the colonies in the mucous membrane of the lower part of the small intestine agglutinated with paratyphoid B serum in high dilutions, the blood of the same case also giving a highly positive Widal reaction to paratyphoid B, on which alone a diagnosis was made. The second authority offered the opinion that it was quite possible that "residual"

agglutination could account for my results, but that one would expect, if this were so, a lower titre of agglutination than 1 in 250 after four or five years unless the man had given a very high response to his inoculations.

In order to prove what degree of residual agglutinins occur normally I estimated the agglutinin reactions to typhoid, paratyphoid A; and paratyphoid B of five healthy ex-soldiers, with the following very instructive results:

CASE II.

	Serum Dilutions:			
	1 in 25.	1 in 50.	1 in 125.	1 in 250.
Typhoid cultures ...	+	+	+	+
Paratyphoid A ...	-	-	-	-
Paratyphoid B ...	-	-	-	-

This case had had Flexner dysentery in 1916, and agglutinated Flexner's bacillus up to 1 in 250.

CASE III.

	Serum Dilutions:			
	1 in 25.	1 in 50.	1 in 125.	1 in 250.
Typhoid cultures ...	+	+	+	Trace
Paratyphoid A ...	+	Trace	-	-
Paratyphoid B ...	-	-	-	-

CASE IV.

	Serum Dilutions:			
	1 in 25.	1 in 50.	1 in 125.	1 in 250.
Typhoid cultures ...	+	+	+	Trace
Paratyphoid A ...	-	-	-	-
Paratyphoid B ...	Trace	-	-	-

CASE V.

	Serum Dilutions:			
	1 in 25.	1 in 50.	1 in 125.	1 in 250.
Typhoid cultures ...	+	+	-	-
Paratyphoid A ...	-	-	-	-
Paratyphoid B ...	-	-	-	-

CASE VI.

	Serum Dilutions:			
	1 in 25.	1 in 50.	1 in 125.	1 in 250.
Typhoid cultures ...	+	+	-	-
Paratyphoid A ...	-	-	-	-
Paratyphoid B ...	-	-	-	-

We thus have a fairly complete answer to our queries. Fifty per cent. of the cases agglutinate typhoid up to 1 in 250, so that such a high response is no uncommon thing in the inoculated after four or five years. Paratyphoid agglutinins are very slight in all cases, as compared with typhoid residual. The explanation of this no doubt lies in the greater strength of the typhoid vaccine given and possibly also because this was used alone at first during the war.

I cannot agree that the existence of miliary tubercle accentuated any potential agglutination titre, otherwise the paratyphoid titres in Case 1 should have been higher, but of course one cannot generalize too much from these few cases.

The essential point of the matter is that a positive Widal reaction in the inoculated subject, even some four or five

years after inoculation, is of no diagnostic value whatever in typhoid fever and is of very doubtful value in paratyphoid fevers unless of markedly high titre. But this in no way detracts from the superlative value of the reaction in the non-inoculated.

A repetition of the reaction after several days' interval is, as a rule, not sufficiently decisive in everyday work to recommend itself to those of us who must, if possible, supply a rapid and unequivocal answer to our colloagues in the wards, but where this can be done it is sometimes helpful as an aid to diagnosis, but no more. Finally, this note illustrates very clearly the need for close co-operation between the pathologist and the physician in all obscure cases of this nature.

I am indebted to Dr. A. Deane, Surgeon to the Princess Alice Hospital, and also to Dr. W. G. Willoughby, Medical Officer of Health for Eastbourne, for their helpful suggestions and for their permission to report the original case; likewise to Dr. Dennis Emblton and Dr. A. D. Gardner for giving me the benefit of their wide experience in these matters.

LAPAROTOMY FOR INTESTINAL OBSTRUCTION ON BOARD SHIP.

BY

VINCENT MOXEY, M.R.C.S., L.R.C.P.,
SURGEON TO THE ROYAL MAIL STEAM PACKET COMPANY.

LAPAROTOMIES on board ships of the mercantile marine are perhaps sufficiently uncommon to be worthy of record, and the case related below presents certain points of interest:

During the voyage of the R.M.S.P. *Desna* from Liverpool to Buenos Aires, on the day after leaving Lisbon (August 20th), a Portuguese lad, aged 17, went down with abdominal pain and vomiting. He was seen by Dr. Seroa de Carvalho, the Portuguese surgeon, and the condition was provisionally diagnosed as intestinal colic. Next day he was no better, and Dr. Carvalho concluded that the case was one of intestinal obstruction and asked me to see him.

Dr. David de Sarmiento, professor in the faculty of medicine, Lisbon, who was a passenger on board, also very kindly joined us. We found all the classical signs of intestinal obstruction present, and the question was whether the causation was volvulus, intussusception, or strangulation of the internal hernial type. As the patient seemed to be relatively well—that is, not so severely ill at the moment as one would have expected—the possibility that it might be one of those uncommon cases of pseudo-strangulation such as is described by Lejars (*Medicine de Urgence*, Oddo, p. 375) crossed one's mind. Perhaps the wish was rather father to the thought, as operation under the conditions was not particularly attractive. Anyhow, valuable time was wasted with no results. By the evening of August 23rd it was clear that intervention was imperative, but, his state being still fair, it was left until the morning of the 24th.

He was taken to the ship's operating theatre; Dr. Carvalho gave chloroform, and Dr. Sarmiento was good enough to assist me. On opening the abdomen, by an incision four inches long a little to the left of the umbilicus, the enormously distended and congested small intestine protruded in a troublesome fashion. A considerable quantity of sero-sanguinolent peritoneal fluid escaped, and patches of lymph were to be seen on the visceral peritoneum. It was not difficult to bring the seat of the trouble into view—a knuckle of ileum, about two feet from the caecum, was incarcerated in a mesenteric pocket; this was withdrawn. The condition of the compressed portion, about three inches long, was not encouraging, and one now regretted not having operated earlier. Had the loop been a longer one it would surely have been gangrenous, whereas this one was small and comfortably supported all over its surface, and had avoided the deadly venous congestion of the ordinary hernia. It looked just possible to avoid resection, and I decided to chance it, as excision of a piece of intestine, with the central end in the condition it was, would probably have been disastrous anyhow. Further, a temporary anus seemed almost as risky. The protruded intestines were replaced, no flushing of the peritoneal cavity was employed, and the abdominal wall was sewn up in the usual three layers. This latter, owing to the vagaries of Father Neptune, was the most tiresome part of the whole procedure. Still, the weather was very good; we were about the latitude of Cape Verde, and there was only a moderate swell on: Simple

the patient passed flatus, and next day

started eating well and with a good appetite. There is nothing further to relate of any moment, save that an abscess of the abdominal wall had to be evacuated a few days later, by loosening the two lowest stitches. Foul faecal-smelling pus escaped, evidently due to infection of the wound by the peritoneal contents. On September 7th he was landed in Buenos Aires in good condition, the abdominal incision almost healed.

Surgery at sea raises many interesting questions, which it is not possible to discuss here. But the ship's surgeon must be prepared, above all, to open an abdomen if necessary, as

this is obviously the most likely form of urgency to be met with. It therefore behoves him to have ready in his mind the requisite plan of campaign, the best place to operate, likely assistants, the anaesthetic, the simplest ways of dealing with the conditions found, simple dressings, and arrangements for after-treatment.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

"HAEMORRHAGIC" CHICKEN-POX.

The following personal history may interest Dr. Wanklyn (November 18th, p. 977). When within three months of my final examination I saw in the Sick Children's Hospital a case of chicken-pox. The child was isolated in a side room awaiting transfer to the fever hospital, and the physician showed the case to a few students and asked for a diagnosis. I was in the room for about one minute and did not touch the patient. Exactly fourteen days later I began to feel rather seedy and the idea occurred to me that I had got chicken-pox. I stayed in bed and looked anxiously for the rash next day, but nothing was to be seen. On the second day, however, a few characteristic spots were present. Not more than a dozen appeared in all, but haemorrhages took place into several of the larger vesicles. I do not think there was any surrounding ecchymosis. There is still a faint scar from one on my wrist. Slight fever and malaise for a couple of days constituted the whole illness. I was much too annoyed to let a real doctor see me, but I think Dr. Wanklyn may take it that the diagnosis was correct.

W. F. SHANKS, M.B., Ch.B.

University of Glasgow, Physiology Department.

ACUTE MENINGITIS FOLLOWING INFLUENZAL MASTOIDITIS.

As acute meningitis, following aural suppuration, is always looked on, and unhappily rightly so, as a fatal complication we venture to publish the following report. We regret that the exigencies of the case did not allow of a bacterial examination of the cerebro-spinal fluid.

G. E., aged 7, developed influenza during the March epidemic of this year. Pain in the right ear was complained of on the third day, with gradual increase, until discharge was noticed on the sixth day. Except for the aural discharge no other sign or symptom was noted though carefully looked for, and the child rapidly convalesced, when measles developed on the thirteenth day.

The measles took a normal course, and on the nineteenth day the child was apparently well, sitting up and playing with toys. The aural discharge continued, but there were no mastoid symptoms whatever, when suddenly on the twenty-first day the child complained of deep pain behind the ear, and two hours later typical cerebral vomiting commenced. Five hours later we found the child collapsed with clammy skin, roused with difficulty and then very irritable. There was marked photophobia with right external squint. There were no external mastoid symptoms and no tenderness; the discharge was profuse and ropy, the drum red, and the posterior inner nictal wall red and swollen. Marked head retraction was present, Kernig's sign positive, and vomiting frequent.

An immediate operation was advised and carried out under light anaesthesia given by Dr. J. F. Walker. The mastoid was of the pneumatic type and bathed with pus throughout, the intercellular bone being largely necrosed and easily removed; the lateral sinus was inflamed and granulated. On removing the tegmen antri a bulging dull red dura was exposed, and on making an opening into this much very turbid fluid escaped under pressure. The posterior cranial cavity was similarly drained in front of and below the sinus, a small wick drain being left in each fossa. The whole operation occupied nine minutes, as speed was in our opinion most necessary.

Next day the child was given 12½ c.cm. of polyvalent anti-streptococcal serum, a similar dose being injected on the five following days. The dressing was changed daily, also the wick drains. For two days the condition was extremely serious; all the meningeal symptoms remained, but the vomiting was even more persistent. Slight improvement was noticed on the third day, and it continued till the eighth day, when all meningeal symptoms had disappeared and a complete recovery eventuated.

FRANCIS MURCKE, C.B.E., F.R.C.S.,

Assistant Aural Surgeon, The London Hospital.

W. H. SARRA, M.R.C.S., L.R.C.P.,

Lo-don, W.

Leigh-on-Sea.

In a recent visit to Guatemala and other countries of Central America Professor Filleborn, of the Hamburg Tropical Institute, found that 90 per cent. of the Indian laborers in the coffee plantations were suffering from ankylostomiasis.

Reports of Societies.

BLOOD TRANSFUSION IN CIVIL PRACTICE.

At a meeting of the Medical Society of London on November 27th, with Lord DAWSON OF PENN (President) in the chair, a discussion took place on "Blood transfusion in civil practice."

Mr. GREGORY KEYNES, who introduced the subject, exhibited the title-page of the earliest monograph on transfusion, published in Italy in 1669. The practice, he said, was in abeyance in the eighteenth century and was revived in the nineteenth. The literature was now growing very fast, and the great majority of contributions in recent years had been American. Earlier methods were by direct transfusion, which the speaker regarded as being now only of historical interest. There were at present two schools of technique, one of which held that whole blood was the more desirable, while the other insisted upon the use of an anticoagulant. Whole-blood methods were satisfactory in the hands of those accustomed to them, but anticoagulant methods, depending upon the employment of solution of sodium citrate, were most satisfactory for general use, and it was these which had popularized transfusion. A good many fatalities followed transfusion in former years, and the cause was supposed to be the introduction of air bubbles into the circulation, but a certain small amount of air could be introduced without harm, and it was probable that in most of these cases incompatibility of bloods was the responsible factor. Post-transfusion reactions were occasionally severe, owing to gross incompatibility, but there were also a number of slight reactions following the transfusion of compatible bloods, and suggested causes for these were:

- (1) The anticoagulant; (2) incipient clotting; (3) effect of anaesthetics on serum; (4) "minor agglutinins"; (5) protein shock; (6) distilled water for dissolving anticoagulant.

These slight reactions were of no very great importance; he had never seen them interfere with the efficacy of the method, and it was not necessary to be alarmed even with a rise in the pulse rate to as high as 150. In addition, moderate reactions had been noted attending second or later transfusions, the causes of which were induced incompatibility and possibly true anaphylaxis. The disquieting thing about these moderate reactions was that they could not be eliminated even by the most careful grouping of bloods, but they did not seem to happen often enough to make necessary the abandonment of transfusion on account of the danger. It was well never to use the same donor twice, if possible, and to ensure that blood of the same group as that of the recipient's blood was always used. He classified the indications for transfusion as follows (italics indicate that in those cases transfusion is of less importance or of doubtful value):

- (1) *Shock*: Traumatic haemorrhage, ectopic haemorrhage, gastric ulcer, etc.
- (2) *or* *anæmia*: hæmorrhage, hæmorrhage.

Post-operative: Following severe operations. Cases involving much loss of blood are more benefited than those suffering purely from post-operative shock.

Hæmorrhagic Diseases: Hæmophilia, melena neonatorum, jaundice, purpura.

Blood Diseases: Pernicious anaemia, leukaemia.

Toxaemias: Pyogenic, severe burns, carbon monoxide and nitrobenzol and benzol poisoning.

Blood transfusion was a very useful therapeutic measure, though its limitations were quite definite. In this country its use was restricted owing to the absence of any system of professional donors, such as existed in America, and possibly also to an exaggerated idea of the technical difficulty.

Mr. GORDON TAYLOR, who had a preference for the whole-blood method, said that he had seen only one case of post-transfusion reaction. During the last three years he and colleagues associated with him had done nearly one hundred transfusions. In cases of pneumococcal peritonitis very favourable results had been reported from blood transfusions, and in at least one such case within his own experience the result had been almost dramatic. From what he had seen in that case and in one or two others he would be disposed to go on using blood transfusion from the moment of the septicæmic onset. In operations of magnitude he had used blood transfusion several times with very good results. Pre-operative transfusion had been used successfully in malignant disease of the stomach and bowel. In ten cases of bleeding gastric ulcer, in which hæmorrhage continued in spite of medical treatment, partial gastrectomy was done, and the

patients were transfused either before, during, or after operation, with recovery in nine of the cases.

Dr. A. E. GOW said that in cases of pernicious anaemia in which the blood picture of the first attack suggested that the anaemia was due to increased hæmolytic, as apart from the distinctly aplastic type, a single transfusion of 600 to 800 c.c.m. of citrated blood was usually of benefit. The result was far more rapid than with arsenical medication alone. The choice of donor was important if a powerful reaction was to be avoided. In the aplastic type of pernicious anaemia transfusion might stimulate the marrow to activity through the effect was temporary. The transfusion acted as a "strike-breaker" for a time, but the "strikers" eventually gained the day. It was better in these cases to give a small dose of not more than 200 c.c.m. and repeat it in five or seven days, rather than to transfuse a larger quantity.

Dr. ALEX. FLEMING described the technique employed in the transfusion of defibrinated blood, which he and his colleagues at St. Mary's had used recently in place of the citrate method. Sir Almoth Wright had been doing what he called immunal transfusions in septic cases during the past few months, using defibrinated blood, to which was added a very small quantity of a vaccine, giving an increase in the antibacterial content to the staphylococcus or streptococcus, and after the blood was introduced there was an almost immediate increase, which could be tested, in the bactericidal power of the recipient's blood.

Sir THOMAS HENDERSON expressed disappointment at hearing Mr. Keynes say that this was a therapeutic measure with very definite limitations. He still hoped that these limitations were not so definite, if only because he felt that any therapeutic method which did not put money into the pockets of wholesale chemists was one that deserved exploiting to the utmost. With regard to gastric ulcer, he was not sure that the extraordinary improvement which followed transfusion was due only to the effect upon the hæmorrhage. He thought that the healing of the gastric ulcer was more rapid with transfusion than without it. In six cases of gastric or duodenal ulcer within his experience transfusion had been employed; the astonishing difference in the results he attributed to the type of the disease and the age of the patient, but generally speaking he was convinced that the ulcerative process itself was influenced. In ulcerative oedocarditis, notoriously very disappointing in its therapeutics, he was coming more and more to believe that transfusion was a valuable method. He thought it more useful to give many small transfusions frequently than a few larger transfusions at longer intervals. He had seen benefit from transfusion in ulcerative colitis. In some of those difficult cases in which the colon seemed to be intolerant of chemicals and the patient of vaccines possibly small repeated transfusions might be of great value. In pernicious anaemia he had been disappointed, so much so that in his practice he did not transfuse in this condition unless the relatives suggested it and seemed disturbed because it was not done.

Mr. KENNETH WALKER had been struck by the extraordinary result that followed the transfusion even of a very small quantity of blood. Sometimes it had been possible to use only 200 c.c.m. in bad surgical cases, and yet the results had been altogether out of proportion to the amount of blood used. He emphasized the importance of fluids to supplant blood and transfusion in cases where there had been hæmorrhage and severe shock. The blood appeared to "fix" the fluid in the veins and prevent the transudation which occurred when using saline alone. There was no branch of surgery in which blood transfusion had greater scope than in genito-urinary cases. From American literature it appeared that good results had followed in uræmia from a combination of venesection, blood transfusion, and saline injections. He favoured the citrate method on the ground of simplicity.

Mr. EARDLEY HOLLAND said that in obstetrics and gynaecology, while he could not get on without blood transfusion, the cases in which he employed it were fewer than formerly. At the London Hospital its use had been given up in acute puerperal sepsis. Hæmorrhages in obstetrics and gynaecology might be divided into two groups: (1) acutely arising hæmorrhages in otherwise normal cases, of which ectopic hæmorrhages was an example, and (2) repeated hæmorrhages, of which examples were placenta prævia and secondary post-partum hæmorrhages due to sloughing of deep tears of the cervix. In the former, while blood transfusion was useful, the opportunity was not always forthcoming, neither donor nor apparatus being immediately available; but in the latter, the patients being in no state to withstand the slightest additional

check, blood transfusion was extremely valuable, and, in the nature of the case, more practicable also. He had rarely seen a case of ectopic pregnancy in which transfusion was essential or saving life.

Mr. KEYNES, in a brief reply, said that in a good many surgical cases transfusion might be a luxury, but undoubtedly operative risk was reduced, even though it was not possible to say that a patient would have died if there had not been transfusion. In the technique rapidity was not of first importance; he had given citrated blood twenty-seven hours after it had been taken from the donor, and the result was as good as if it had been given immediately, and there was no reaction whatever.

EPIDEMIOLOGY OF SCARLET FEVER.

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine held on November 24th, the President, Dr. R. J. REECE, in the chair, Dr. F. M. TURNER read a paper on the age and sex distribution in scarlet fever. The author submitted a full biometric analysis of the statistics of age distribution amongst both notified cases in London and cases admitted to the Metropolitan Asylums Board's hospitals, together with tables relating to certain provincial cities. Notwithstanding the general similarity of the figures from year to year, it was possible to show that the age distribution differed more than would be expected, were the fluctuations random, in successive years. The mean age of females in notified cases was always higher than that of males and, with one exception, in the admitted cases. The mean ages of cases notified uniformly exceeded that of cases admitted. The statistics showed a general tendency for the mean age to increase with the prevalence, although the arithmetical value of the coefficient of correlation between mean age and number of cases notified was small. The mean age had increased over the period studied (1887-1922). Manchester statistics likewise showed an apparent increase of mean age in periods of prevalence and a general increase of mean age through the series.

In opening the discussion on the paper, Dr. HAMER pointed out the existence of a tendency for the mean age and the prevalence to increase together in the case of small-pox mortality statistics. In his view the phenomenon was dependent upon changes in the amount of susceptible material in the population; this explanation he was sure best accounted for the epidemiological course of measles. Measles was an easy case, influenza a very difficult one, scarlet fever fell between the two. Dr. ISSERLIS, in commenting upon the statistical aspects of the paper, remarked that the application of the theory of sampling to a problem such as this involved theoretical difficulties, so that it was necessary to be particularly cautious in drawing inferences as to the limits of chance fluctuations. Dr. MAJOR GREENWOOD congratulated the author on his valuable contribution to biometry; he suggested that the smallness of the coefficient of correlation between prevalence and mean age might be due to non-linearity of regression, so that the *prima facie* inference that the correlation was a real one might be justifiable. The biological interpretation of this suggested by Dr. Hamer seemed the most feasible one. Dr. BROWNLEE said that it was essential to bear in mind the factor of mass of infection; whenever the mass of infection was great—for instance, in milk epidemics—the mean age of attacked persons was high. Dr. McVAIL inquired whether the excessive incidence upon females might not be accounted for by the greater proportion of females in the general population at susceptible ages. Dr. BUTLER commented on the difference between the age incidence in a disease such as scarlet fever to which the whole population was not susceptible and that of a disease such as small-pox attacking an unvaccinated population. It appeared that in the former case immunity came with age and that an accumulation of susceptible material was not the whole explanation. Dr. TURNER, in replying, remarked that an obvious and possible explanation of the higher mean age of females attacked was that the girls nursed children in the interval before the latter were removed to isolation hospitals.

Dr. JOHN BROWNLEE then read a communication on the relation between rainfall and scarlet fever. He exhibited an extensive series of charts which led him to conclude that the influence of deficient rainfall upon the prevalence of scarlet fever, to which the late Dr. Longstaff had devoted special study, was not a direct one. There was some evidence that if a period of deficient rainfall coincided with the epoch

at which, from a study of the periodicity of the disease, an epidemic was to be expected, the rainfall deficiency increased the magnitude of the epidemic. Deficiency of rainfall was not, however, a sufficient single cause of an epidemic. Sir GEORGE BUCHANAN inquired whether the English rule that scarlet fever was an autumnal epidemic were universal and whether grouping rainfall in smaller than annual units had been tried. Dr. BROWNLEE said that the case in favour of deficiency of rainfall as a precursor was not strengthened but weakened when a fine time unit was adopted.

THERAPEUTICS OF QUINIDINE.

A MEETING of the Liverpool Medical Institution was held on November 16th, with the President, Dr. J. HILL ABRAM, in the chair, when Dr. JOHN HAY read a paper on the after-results of quinidine in disorderly action of the heart. He reported the results of treatment with quinidine in 21 cases; 13 of these had been described in an earlier communication to the society, and of the 13 cases only 3 had retained a normal rhythm. During the last seven and half months quinidine had been administered to 8 additional patients, and in each case the fibrillation had been broken and a normal rhythm restored. Four, however, had relapsed. In all there were 6 complete failures; 8 cases had relapsed after temporary cessation, and 7 patients had maintained a normal rhythm. Not included in the above series were two recent responses to quinidine, but it seemed to him a little early as yet to include them in the successes. Dr. Hay discussed the type of cases suitable for treatment with quinidine, and also the type of case in which the exhibition of that drug was unjustifiable.

Dr. A. DOUGLAS BIGLAND described observations made by Dr. Voigt and himself on patients treated with quinidine. Out of 7 cases of auricular fibrillation 2 had regained normal rhythm and maintained it up to the present, over periods of six and five and a half months respectively. One case died suddenly after having had a normal rhythm for five weeks. Two cases had relapsed and were still under observation, while two other cases were not able to continue the treatment.

Dr. I. HARRIS considered there were three striking facts in connection with quinidine: (1) Provided that the drug was given long enough and in sufficient quantities, in a great majority of cases a normal rhythm could be restored. (2) There was a pronounced tendency to relapse after a normal rhythm had been restored. (3) The sudden restoration of the normal rhythm effected by quinidine favoured embolism. The drug as such was not dangerous. He had given the drug in normal cases without observing ill effects. Dr. Harris considered that there was another factor in the treatment by quinidine which might bring undesirable results. In the great majority of cases of fibrillation the pressure in the veins was greatly increased, which suggested that the total output of the heart was diminished and the strain on the heart muscle correspondingly lessened. To restore the rhythm meant increased output and increased strain on the heart muscle. Dr. Harris was of opinion that, since quinidine was a dangerous drug and did not influence the heart disease itself, it was questionable whether it was worth while endangering the patient's life for the sake of restoring the normal rhythm, considering that in many instances, after a shorter or longer period, fibrillation returned. He thought that further observation was necessary before a definite conclusion could be arrived at regarding the value of quinidine in fibrillation.

Blood Transfusion.

Mr. J. T. MORRISON read a paper on two cases treated by blood transfusion.

The first patient, a girl 5½ years old, subject to nose bleeding, had a very severe epistaxis one week before admission to hospital. On admission her nose was bleeding in spite of having been plugged. Her pulse rate was 176, her temperature 99.6°. She was blanched, and her haemoglobin was below 20 per cent.; the white blood corpuscles numbered 44,650, no abnormal types being present. There were purpuric spots on her back and legs. The cervical glands were enlarged (perhaps from recent impetigo), the spleen was palpable, the liver apparently normal. The treatment given was horse serum, 10 c.cm. subcutaneously, and calcium lactate, 10 grains four-hourly. During the following three days there was no improvement; indeed, there were further haemorrhages. After four days transfusion was decided on, her condition being desperate (pulse rate 164). To supply the supposed missing factor in coagulation without unduly raising the blood pressure only 50 to 60 c.cm. of blood were used. The father of the patient was the donor, his red cells having been previously tested. The technique used—as the

quantity was so small—was the multiple syringe method: 20 c.cm. Record syringes, dried with ether and sterilized in liquid paraffin, were employed. The blood was injected into the external jugular vein of the patient, the vein being exposed under local anaesthesia. Great improvement followed, and the transfusion was repeated the following day; convalescence thereafter was uninterrupted. The patient had had an operation safely since.

The second case was a boy, aged 6, who had had tonsils and adenoids removed, with a good deal of reactionary oozing for the first two days. On the third and fourth days there was no more oozing; on the fifth day, however, there was a sharp haemorrhage from the post-nasal space. Calcium lactate and horse serum were given as in the previous case. The sixth day was uneventful, but on the seventh day bleeding began again and oozing was very persistent. A dangerous degree of anaemia was soon reached. The case was regarded as one of secondary haemorrhage, but transfusion was tried in spite of the fact that the source of the bleeding could not be controlled. Between 50 and 60 c.cm. were given, as already described, from a No. 4 blood donor, and immediate improvement was obtained. There was no further bleeding, but it was thought advisable to repeat the dose on the next day, and no further trouble of any kind ensued.

Mr. Morrison concluded by saying that this experience confirmed some of the indications for transfusion now beginning to be recognized—namely, the haemorrhagic diseases, including melæna neonatorum and haemophilia, CO and above all, desperate cases of primary in the last named, the amount transfused need not be large.

Observations on General Anaesthetics.

Dr. MINNITT read a paper entitled "Some observations on general anaesthetics." He explained what ethanesal was and how it was obtained, and, in reviewing his experience of about 300 cases, he contrasted its advantages and disadvantages as compared with ether, the result being greatly in favour of ethanesal. He pointed out important matters in connexion with an induction, laying stress upon full anaesthesia being obtained before operative interference began. He then described his observations with regard to blood pressure during operations, and showed how there was a normal graphic record in ordinary cases. He compared the differences from this normal graph with the variations in difficult cases, and showed that these observations would be valuable to both the anaesthetist and the surgeon. He instanced McKesson's interpretation of blood pressure findings, and suggested treatment in the case of patients having a poor blood pressure, emphasizing the value of heat, administrations of oxygen, and hypodermic injections of pituitrin. Dr. Minnitt exhibited a specimen of a hot-water bottle to warm the air breathed from the mask by the patient. Slides were also shown depicting the influence of oxygen and pituitrin upon falling blood pressure. Gas and oxygen anaesthesia was discussed, and Boyle's apparatus and a No. 8 Ohio monovalve apparatus were shown.

Dr. G. F. R. SMITH confirmed Dr. Minnitt's favourable opinion of ethanesal, but was doubtful if its advantages over ether rendered its use in hospital practice justifiable in view of the greater expense. Dr. Smith thought that equally good results could be got with nitrous oxide and oxygen, with simpler and cheaper apparatus than those on the market. He gave a word of warning in regard to the danger of that method in major surgery.

ACUTE NEPHRITIS.

A MEETING of the Manchester Pathological Society was held on Wednesday, November 8th, when Professor SIAW DUNN read a paper on some aspects of acute nephritis.

Professor DUNN referred to the impetus which the study of the minute morphological changes in the kidney in acute nephritis had received of recent years—on the one hand through the wealth of material afforded by the appearance of the disease in epidemic form in the armies of the western theatre of war; on the other hand by the acquisition of a fuller knowledge of the minute structure of the normal kidney. The modern conception of the kidney as an organ composed of nephrons or units each composed of a glomerulus and tubule, with a blood supply rather more than less of their own, had an important bearing on the interpretation of diseases of the organ. The correlation of disturbed anatomy and disordered function became more interesting and more fraught with possibilities and with clinical profit.

Histologically, the majority of cases of nephritis dying in the acute stage showed predominantly a diffuse glomerulonephritis. This had been the case not only in the war necropsies but in civilian practice as well. The glomerular

capillaries were blocked by proliferated endothelium and leucocytes; thus the lesion was vascular. At times there occurred in addition catarrh and accumulation of desquamated cells in Bowman's capsules, this type of lesion generally being more destructive to the kidney as a whole.

Professor DUNN analysed the results of his investigations on the kidney, both in cases clinically diagnosed as acute nephritis and also in a further series where no special renal disturbances had been noted during life, but where the naked-eye appearances had led him to make detailed studies. In two cases with oedema, dying of uraemia and coming to necropsy, a diffuse glomerulonephritis was present of such degree as to give the impression that renal function had been largely arrested. The cases which were incidentally discovered at necropsy fell into two histological groups. A small group corresponded closely to Gaskell's focal embolic nephritis, plugs of thrombus being found in the glomerular capillaries. The second type showed a condition similar in kind to that exhibited by the uraemic cases, but less in degree. It was interesting to note that these latter all occurred in cases dying of sepsis of some kind, and it appeared that this was a most important factor in the causation of diffuse glomerulonephritis. On the extent of such a glomerulonephritis—an extent varying from case to case—depended the presence and quality of physical signs of kidney disease. In these cases where bacteriological examinations were carried out the infecting organism was found most commonly to be the haemolytic *Streptococcus pyogenes*.

DEMENTIA PRAECOX.

A MEETING of the Ulster Medical Society was held in the Medical Institute, Belfast, on November 16th, with the President, Mr. R. J. JONES, in the chair, when Dr. W. CALWELL read a paper entitled "Dementia praecox from the ordinary physician's point of view."

Dr. Calwell drew attention to the claim that this type of case was a distinct group in insanity, just as one hundred years ago the same claim was made for general paralysis of the insane, a claim now fully substantiated. Kraepelin's classification of mental diseases, based on age at onset, general course, peculiar symptoms, progress, and termination, was an advance on the older one, based on mental symptoms alone; but, just as in skin diseases, it would, he believed, ultimately give place to a classification based on pathological findings. Kraepelin's guiding points in dementia praecox—the age of adolescence at onset, the progressive but intermittent course, the hopelessness of prognosis, and ultimate termination in complete dementia, with absence of direct fatal termination—had all many exceptions. The onset was generally slow and insidious, but little or no reference had been made to the question of any preliminary illnesses; this was a subject that required investigation, and that could be carried out only by the practitioner in charge of family work. If a case of infantile paralysis or of encephalitis lethargica was seen a year after onset, it would be difficult to reconstruct the initial trouble. Long lists of symptoms could be made; perhaps some sort of order could be evolved by a study of psychology and by the application of Hughlings Jackson's dicta that in degeneration the higher levels went first and were marked by a loss of function of this level and an uncontrolled action of the lower. It must, however, be remembered that the destruction in that case was so slow as to be imperceptible, like the hour hand of a clock; and, while that destruction was taking place, it was accompanied by a certain amount of perversion, such as would be expected from the slow, minute deterioration found in the nerve cells. Besides, there were no clearly defined authorities in the mental hierarchy, one above the other, but a gradual evolution from the projection centres in front of the Rolandic fissure, forward to the intermediate, and then to the frontal and the pre-frontal areas, where the motor type of cell seemed to act as the physical basis of will, conation, and the sense of effort, as well as of high intellectual concepts requiring a motor basis. Similarly, the sense of sight rose in evolution as it spread forward from the occipital lobes, and of hearing as it spread from the Sylvian fissure. Much difficulty existed as regards diagnosis, as the delimitations had not been agreed upon, but the mentally deficient were always a stumbling-block. The extent of the disease was impossible to ascertain, as the name was not yet universally adopted, but 10 to 20 per cent. of admissions to asylums were of this nature, and as such patients lived and became more

markedly affected these institutions became crowded with them. Of the pathological theories advanced, that of Mott's seemed to bear a critical examination best—namely, a genetic weakness in the higher cortical cells, which yielded to any stress, physiological, psychological, or toxic, under the stimulation of the onset of puberty. The coincidence of the degeneration of the nerve cells in the cortex, of atrophy of the seminiferous tubes in the testes, and also of atrophy of the ovary, pointed to a cause acting on both nerve and reproductive organs, and seemed to ask for some close connexion. The testicular atrophy was much in excess of that found in other forms of brain degeneration. Prophylactic treatment should be entertained. Heredity existed in a very large percentage, but the infections of the mother when pregnant, influencing the thyroid, when the nervous system of the foetus was at a stage of critical development, should not be forgotten. The peculiar mental ataxia, or schizophrenia, where the perception, the intelligence, and the memory were but little impaired, but the emotion, the will, conation, interest, were markedly so, suggested an escape of the receptive cells, and a susceptibility of the motor type of cell, as was seen in infantile paralysis and in encephalitis lethargica. Dr. Rivers's suggestion of trying to discover the children who developed dementia praecox was valuable. Hope lay in prevention, and, perhaps, in very early treatment.

Colonel Dawson said that the want of interest and emotion in the patient rendered cases of dementia praecox hopeless for suggestion as a treatment. He had, however, seen cases with all the manifestations of dementia praecox recover. As regards heredity, it had been stated that many of these cases were the offspring of general paralytics. He also pointed out that negativism meant an active reverse of the request, not merely a passive resistance. Professor Lindsay and Dr. Adamson also spoke, and Dr. Calwell replied.

EDINBURGH OBSTETRICAL SOCIETY.

The first meeting of the eighty-first session of the Edinburgh Obstetrical Society was held on November 8th, the President, Dr. J. LAMOND LACKIE, in the chair. The President delivered his inaugural address, and drew attention to the fact that the mortality and morbidity among women in childbirth were no less than seventy years ago, and that childbirth was second only to tuberculosis as a cause of death among women. Such a state of matters could only be improved by close co-operation between the practical obstetrician and the laboratory worker—biochemist and bacteriologist—and by intensive training of students by actual residence in the maternity hospital and constant practice for a fixed period, including instruction in the ante-natal and post-natal departments, with subsequent attendance upon cases in the extern department. Unless the bedroom could be converted into a surgical operating room, every lying-in woman should be removed to hospital or nursing home. Each practitioner should have his private ante-natal department, and should regard it as his duty to exercise the closest supervision of every pregnant patient. He advocated a mixed diet during pregnancy, red meat being taken once or twice weekly, the necessary protein being obtained from eggs, fish, fowl, peas, beans, and nuts, with cereals. By limitation of fluids, especially milk, and of carbohydrates, according to the Prochownik method he believed it possible to obtain a smaller child with consequent diminution of the risk of dystocia. A timely induction of labour was often a far finer thing than the most brilliantly executed Caesarean section, which was too often the outcome of bungled midwifery. "Prophylactic forceps" as practised by certain American obstetricians he considered an unjustifiable proceeding, and advocated patient "standing by" combined with twilight sleep, provided pelvis, foetal head, presentation, and position were normal, as often yielding better results than the most brilliant abdominal or vaginal surgery. He now used forceps much less frequently than formerly and high forceps very seldom. Neither was he convinced of the value of the so-called Potter's version, which he looked upon as the best example of meddling midwifery, the introduction of which into this country as a routine method of delivery he would deeply deplore. The greatest need in the modern maternity hospital was a follow-up department to which the women should return, well or ill, for examination and advice. Much suffering might be prevented by early recognition and treatment of pelvic abnormalities resulting from parturition. Maternity insurance would also be of advantage in that it would tend to assure a period of proper convalescence.

Reviews:

CRIME AND PSYCHO-ANALYSIS.

THE author of *The Psychology of the Criminal*,¹ Dr. HAMBLIN SMITH, has had twenty-three years' experience as a medical officer in the English prisons, both "local" and "convict," and has given great attention during the last three years to the mental condition of offenders sent specially to him for examination and report from the courts at Birmingham, where he is chief medical officer of the prison. He is also lecturer on criminology at the University of Birmingham, and thus is specially equipped for undertaking to illustrate in this book the principle that "the intensive investigation of individual cases is the road to the solution of the problems of criminality."

The author deals with various aspects of his subject, but the most novel feature of the book is his discussion of psycho-analysis in relation to the criminal, and to this I propose to devote the greater part of the space at my disposal.

It may be said at once that a careful study of each individual offender's bodily and mental condition and behaviour, including as far as possible inquiry into his early mental history as evidenced by his conduct, is unquestionably an important desideratum in order to arrive at the best judgement on the questions whether he should be punished, and what, if he be rightly punishable, should be the nature of the penalty awarded. From a practical point of view it may be said further that the more we know of the individual offender the less we are concerned with what are so frequently and indefinitely alluded to as the "problems of criminality"; and all may agree with what the author in his first chapter somewhat obscurely lays down "as a fundamental position, that conduct is the direct result of mental life," etc. This dictum will scarcely at first sight be questioned by any psychologist to-day. Many years ago Dr. Charles Mercier persistently taught that a person's conduct is the main index to his mind, and that the careful study of his conduct is the essential preliminary to forming a judgement on the health or defect of his mental state. But much that is said in this book indicates that Dr. Hamblin Smith really means that study of the "mental life" is the necessary preliminary to a judgement on a person's conduct, and that the term "mental life" implies here the hypothesis of the "unconscious mind." In one place, indeed, he virtually sums up the matter of the problems of criminality in these words: "It follows that the real question is not so much what should be done to an offender in the way of punishment, but what can be done for him in the way of treatment," and proceeds to emphasize his view that the right method of studying "the psychology" of the criminal, or indeed of anyone, is to act on the Freudian hypothesis of the "unconscious mind." This "discovery" he ranks in value with those of Copernicus and Darwin. Each of these, he says, "changed our whole conception of our origin and destiny; but there has arisen another in this our time. Sigmund Freud, by his hypothesis of the unconscious mind, has radically altered all our views of human nature."

Two chapters—nearly half of the book—are devoted to the "offender's unconscious mind," and include an exposition of Freud's psychological doctrine and the method of applying it in practice now widely known as psycho-analysis, or as the new psychology, or, simply, as psychotherapy. Psycho-analysis is pronounced to be a science, and the discovery and elaboration of it to have been made in a scientific manner. The author is certainly to be credited with full success in his expressed endeavour to state fairly and dispassionately his own views on psycho-analysis, and most of the exponents of the Freudian teaching will probably accord him their approval. It is clear from what has been said above and from the trend of the last two chapters of the book that Dr. Hamblin Smith fully accepts the Freudian doctrine as indicating the best form of intensive investigation of individual cases, as the true road to the solution of the problems of criminality, and equally appropriate to the study of mental activities generally. It follows that an adequate notice of this book would require a more or less detailed consideration of the hypotheses the truth of which the author assumes as his postulate, though he

¹ *The Psychology of the Criminal*. By M. Hamblin Smith, M.A., M.D. Medical Officer of H.M. Prison, Birmingham; Lecturer on Criminology in the University of Birmingham; and at Bethlem Royal Hospital, London. London: Methuen and Co., Ltd. (Cr. 8vo, pp. vi + 182. 6s. net.)

admits that "there is much in psycho-analysis which is still highly controversial."

It is impossible within the limits of this notice to attempt an adequate criticism of the doctrines on which the author relies for his contentions. But it may be briefly noted that the hypothesis of the "unconscious mind," with all that it is held to imply by those who regard it as an established "discovery," is but an elaborate and complicated guesswork and wholly lacks scientific verification. One may search in vain in the writings of the originators and disciples of the various schools which hold this doctrine in common, however much they may differ *inter se* on more or less important details of practice, for anything like a clear setting forth even of the exact meaning they attach to the terms "mind" and "consciousness." Without some consensus on the extent and content of the fields of mind and of consciousness the concept of the "unconscious mind" is at least extremely nebulous; and, unless it be assumed that the innumerable processes of cerebration and nervous action which persist while the individual subject is quite unaware of them are to be declared as "mental" phenomena, the very notion of the unconscious mind will "pass into nothingness." Even apart from its usage in the newly formulated hypothesis of the unconscious mind the meaning of the term "unconscious," as often applied to actions and thoughts and desires by many speakers and writers, is generally vague and mostly misleading. The psycho-analytic schools, however, treat the "unconscious" as if it were a recognized and definite compartment of a somewhat indefinite whole called *Mind*, and apparently hold that in this compartment are retained in potential or actual activity all the impressions that have been instinctively experienced or otherwise *learned* during an individual life from its outset. Many of such memories, as all must agree, can be instantly recalled on receipt of the appropriate stimulus; but many others, and especially such as are related to instinctive desires and have unpleasant associations, are held, on the hypothesis in question, to be preserved and active in the unconscious mind, having been purposively or otherwise repressed thither by the conscious mind. In view of the indefinite nature of what may be implied in the term *consciousness*—that "vague and treacherous word," as some psychologist has styled it—it appears that the basic principle of the methods of psycho-analysis is a highly fanciful and unverified assumption of a vast region of the mind, the most important contents of which are consciously—or unconsciously—repressed and purposive activities, frequently or constantly struggling, in the case of large numbers of persons, to escape from this repression which they suffer from the counter-activity of the conscious mind, or of some special factor of it assumed to exist, and to be delegated to carry out the repressive function while the whole mind's personal proprietor is quite unaware of the process.

This is, of course, but a very scanty outline of the hypothetical system on which the practice of psycho-analysis is founded, but it may serve to indicate the point of the allegation that the teaching of the new psycho-analytic does not satisfy any of the requirements of scientific investigation. The home of this school, indeed, seems to be much in the clouds, and its philosophers, like the Socrates of Aristophanes, to be "walking on air" while they "contemplate the sun."

But quite apart from this important question as to whether there is any scientific basis for the Freudian doctrines it must be recognized that the spreading employment of the now popular therapeutic methods arising from those doctrines is liable to produce, and actually does produce, multifarious harm to many sufferers from various kinds of mental or nervous disorder. Doubtless some patients are benefited or may recover under treatment by psycho-analysis; so also do many who are treated by those who analyse (in the pro-Freudian sense) the cases of mental disorder which come before them, whether without knowledge, or with knowledge and general disapproval, of the Freudian doctrines. It is indisputable that minute and careful inquiry into the previous individual histories of all that large group, commonly called "functional" or "nervous" cases, has, for long, been made by thoughtful and experienced physicians, whether mental specialists or not, nor is it doubtful that there is a considerable field worked in common by some of the new psycho-analysts and the large group just indicated who ignore, or reject, the conception of the "unconscious mind" as set forth in the new psychology.

Since the main intention of the author of this book is to advocate the wide employment of the Freudian psycho-analysis in the medical investigation of criminals generally,

the consideration of a few points mentioned by him seems to be of importance and to require short comments.

1. In the last three paragraphs of Chapter IV, "On the offender's unconscious mind," Dr. Hamblin Smith writes:

"And what is the conclusion of the matter? . . . It is summed up in the saying that to understand all is to pardon all; the author does not mean that nothing is to be done to delinquents. He considers them worthy of the most careful treatment. . . . It is not meant that they" (that is, any officials of the law or others appointed in connexion with institutions, "are to make the . . . it must have the ultimate . . . But it must employ experts

It is clearly intended to imply that such experts must be chosen from among "psycho-analysts" only. Therefore further comment is needless on this extraordinary proposal to employ only one section of the medical profession to serve the State in this matter. Who is to direct the State authorities in this important matter of its choice of doctors?

2. On page 74 it is stated that "psycho-analysis is a science consisting in the investigation of the mode of working of the unconscious mind," and on page 79 we read that "nothing has to be more carefully avoided in psycho-analysis than any trace of suggestion by the psycho-analyst." This precaution is one on which there may or not be general agreement even among psycho-analysts, but it is to be gravely doubted whether the advice is likely to be generally followed in this form of practice.

3. The possible, or even probable, risk during the process of psycho-analysis of the transference of the patient's feelings towards other persons (whatever the feelings may be) to the psycho-analyst himself is strongly emphasized by the author.

"It will be seen," he writes, "that psycho-analysis is a method of great difficulty, requiring knowledge of a special technique, much experience, and perhaps certain gifts which are not possessed by all. It is a trying process for the psycho-analyst; until an attempt has been made no one can conceive what a severe strain this method is."

This warning by Dr. Hamblin Smith doubtless comes from one who is unbiased by any consideration other than a desire to advocate the best method of investigation into the mental workings of offenders sent to him by courts of law, and whose evidently earnest belief is that psycho-analysis is the best method. One reflection following on the reading of these words of his is that only a very small proportion of men or women doctors could possibly be expected to combine all the qualities necessary to practise psycho-analysis properly, even were its soundness as based on science, and its successful application in practice, to be generally admitted. Several other comments suggest themselves on some of the actual results of this practice, but space forbids further enlargement on this particular point.

4. There is much significance in what the author says about the frequent resistance made by the subjects of psycho-analysis and the necessity for such persons to be frankly willing for the investigation to be made.

"There is a form," he says, "of unconscious resistance, more . . . patients. Some psycho-analysts think . . . are the best to deal with, and that lack of . . . indecap to the method. If this opinion be . . . correct it will limit the application of psycho-analysis to court work."

The author, however, states that he has had "some success in dealing with subjects who are far from intelligent," but he gives no details.

In his last short chapter, "Conclusions," the author faces the above-mentioned and other difficulties, and sketches a preliminary scheme for introducing the method of psycho-analysis into the English prisons, recommending that at first the effort should be limited. But although he regards it as doubtful whether any offender should be placed by a court even on "probation" without the most thorough examination, he suggests that a beginning might be made only with: (1) young offenders; (2) those who repeatedly commit the same kind of offence, especially when the motive is not apparent; (3) cases in which there is any other marked peculiarity about the offence. But this condition is extremely wide, for it must be remembered that of the large numbers of thieves, burglars, persons who obtain money on false pretences, and so on, nearly all confine themselves to one special line of offence only. The motive for this specialization is in most cases sufficiently apparent, and gives no occasion for raising any psychological problem: the criminal, like other

men, recognizes that practice in his craft, as in others, leads to perfection.

There are parts of this book well worthy of study by prison administrators and reformers, apart from the special matters already noticed. In the second chapter especially, where Dr. Hamblin Smith deals with the subject of the "Offender's conscious mind," there is much that deserves attention, and especially his thoughtful comments on the various test methods devised for arriving at a normal standard of intelligence for the purpose of comparison with the intelligence of persons whose mental power is under investigation.

Both professional and lay readers of the book who may be already acquainted with some of the many works on psycho-analysis which are issued frequently from the press will accord to the author their recognition of the high degree of clarity in expression and logical consistency that mark his writing; qualities not readily detectable in most publications by adherents of this school.

H. BRYAN DONKIN.

FEEDING IN INFANCY AND CHILDHOOD.

THE fourth edition of Dr. ERIC PRITCHARD'S *Physiological Feeding of Infants and Children*² is a much larger book than its predecessor. The new edition will be welcomed, and deserves a high place among British textbooks devoted to this difficult and very controversial subject. Dr. Pritchard has given much study to the theoretical side of the subject, and has had a very extensive experience in the practical side; his opinions therefore have weight and authority. It does not at all detract from that authority that he frankly confesses in his preface that he has changed his views in some important respects; he now advocates feeding from the first day of life, at intervals of three hours, and opposes also the doctrine that as the artificially fed infant grows older its milk mixture should be made stronger.

The title of the book fairly indicates its scope—the proper food for infants and children up to puberty, both in health and sickness, and the guidance of dietetics throughout this period by physiological teaching. The greater part of the book deals with infants, and the physiological standards here are human milk and maternal nursing. After setting out the physiological laws of breast-feeding, Dr. Pritchard lays down the main principles which should govern the artificial feeding of infants. The total daily energy value of the food taken must be known, and must correspond to the output of energy; the ratio of the organic constituents in the milk mixture must roughly approximate to that in human milk; accessory factors in the diet, such as vitamins, salts, and lecithin, must not be omitted; the importance of training the digestive organs of the infant to a fuller capacity must be kept in view. The illustration and application of these main principles run throughout the book, and it is by his insistence and reliance on principles that the author is able to give clearness and cohesion to his exposition of a complicated subject. He will, perhaps, not expect that all his doctrines, theoretical and applied, will be accepted by the critics; but he may be assured that they have the great and not too common merit of being readily understood. It is a great point with Dr. Pritchard that the energy output of the baby should be roughly measured and allowed for in planning his diet; that, for example, a lively, vigorous baby should be given a larger ration than a quiet and passive one; also that in wasted infants heat and energy should be conserved by warm clothing. He also strongly recommends the daily use of a vegetable and bone soup (for which a recipe is given) in order to supply salts, extractives, lecithin, and cholesterolin; in addition to this, he advises the daily use of orange-juice, of some animal fat, and even of yeast preparations. He favours the use of barley water, and even of dextrinized flour in small amount, after the third month; and, after the sixth month, of some farinaceous food, to replace an equivalent amount of sugar. On all these and many other important, and often disputed, points in the dieting of infants and children Dr. Pritchard offers clear and reasoned opinions drawn from his own experience and study. Further experience and fresh discussion may change or confirm these opinions, but meantime, as presented in this book, they are an authoritative contribution to the subject.

²The *Physiological Feeding of Infants and Children*. By ERIC PRITCHARD, M.A., M.D. Oxon., M.R.C.P. Lond. Fourth edition, entirely rewritten and enlarged. London: Henry Kimpton, 1922. (Roy. 8vo, pp. xvi + 536; 90 figures. 21s. net.)

DURATION OF FATAL LUNG TUBERCULOSIS.

THE *Clinical Course and Duration of Fatal Lung Tuberculosis*³ is an unpretentious little book compiled by Dr. C. H. WÜRZEN from statistics collected over a period of nearly fourteen years at the Oresund Hospital, Copenhagen. In order to avoid the fallacies inherent in all methods dependent upon the following-up system, he has confined himself to the consideration of those patients who actually died during their stay in hospital. In this way he had before him data referring to 1,032 men, 780 women, and 87 children, nearly all of whom belonged to a more or less homogeneous class of insured people working in the city. Dating the onset of the trouble from the first manifestation of symptoms, adding together the number of months elapsing in each case before death, and dividing by the total number of patients, he has obtained a figure which represents the mean duration of the disease. For men this works out at 37.1 months, for women at 34.4 months, and for children at 11.9 months. Further, by subdividing each class into age and sex groups, he has shown that though the preponderating incidence of phthisis falls amongst young adults, the greatest fatality occurs in childhood and old age. An initial hæmoptysis appears to be a favourable sign, while complications such as diabetes and syphilis increase the gravity of the prognosis. Limited as the book is in its scope, the data themselves are of considerable interest.

PUBLIC HEALTH CHEMISTRY.

THE *Chemical Examination of Water, Sewage, Foods, and Other Substances*⁴ is the title of a book written by J. E. PURVIS and T. R. HOPKINSON for those who perform laboratory investigations for public health purposes; it deals also with a number of other matters of a kind commonly submitted as subjects of inquiry to analysts. The first chapter describes methods for determination of the dissolved constituents of water and sewage, and gives the results of analytical examination of a number of samples; analytical methods applicable to works effluents are also noticed. In the second chapter milk, cream, dried milk, and condensed milk are dealt with on a similar plan. Succeeding chapters relate to oils, edible fats, beverages, cereals, spices, and other articles of diet. One chapter is devoted to the recognition of poisonous metals in foods, another to toxicological analysis. Air, coal gas, rag flock, and the examination of urine are included among the miscellaneous subjects.

The text consists chiefly of methods which are well known to experienced analysts and which are described, often with greater detail, in other works; a certain number, however, are based on principles differing from those of the older type. There is no remarkable departure from the plan of other books of its kind and no fault is to be found with the quality of the matter—indeed the information given is presented tersely and without ambiguity; but anyone looking for the help that will lift him above the difficulties inherent in analytical practice will be disappointed. There is a growing disposition to give directions in the terms that might appropriately be used to a chemical factory hand, and to omit reference to the highly important principles of theoretical chemistry involved in the instruction. Such directions are suited only for routine work; those who have to deal with the same problems complicated by unusual conditions are obliged to seek refinements in methods of procedure and prefer to receive directions couched in the language which one chemist would use to another. What the authors have done in this direction is only sufficient to make prominent the need for more chemistry in the discussion of technology. The collection in a handy form of much that is required for public health work renders the volume quite suitable for those engaged in that practice. It contains some interesting descriptions of the authors' own results in the analyses of sewage products and other matters.

The fact that the work has reached its second edition in a brief period is proof that it has met with appreciation; it can be recommended to those who already possess treatises on its subject, since some of the methods of procedure offer advantageous alternatives to the older methods of practice.

³*Clinical Course and Duration of Fatal Lung Tuberculosis*. By C. H. WÜRZEN. London: Gyldendal, 1922.

⁴*Chemical Examination of Water, Sewage, Foods, and Other Substances*. By J. E. PURVIS, M.A., and T. R. HOPKINSON, M.A. Second and enlarged edition. Cambridge: The University Press, 1922. (Demy 8vo, pp. 316. 20s. net.)

NOTES ON BOOKS.

THAT a second edition of TIDY'S *Synopsis of Medicine* should be called for within sixteen months of the publication of the first proves that it is popular and has realized the objects intended by the author. The book is not meant to take the place of the larger treatises of medicine, but by its compactness, its accuracy in detail, and its clearness of arrangement will appeal to the student reading for an examination and to the examiner himself. The new edition does not differ substantially from the first; a few minor mistakes have been corrected and the section on encephalitis lethargica has been rewritten. Had a fuller revision been considered desirable we might have hoped for more on the subject of the pathogenesis of gastric ulcer, which is barely touched on. We note also that Vincent's angina has been omitted and are somewhat surprised to find that in the section on asthma no space has been allotted to the discussion of the relation of that disease to hypersensitiveness, whereas in the section on the nervous system perhaps too much space has been given to such conditions as myotonia congenita, paramyoclonus multiplex, and amaurotic family idiocy. Otherwise we have nothing but praise for the book; impartial consideration has been given to all views of any importance, and the information provided is nearly always comprehensive and up to date. A word of praise is due also to the skillful way in which Dr. Letheby Tidy has dealt with the treatment of each particular disease; for this reason alone the book is of great value for reference in a difficulty, and it has a good index.

The modern nurse is expected to absorb so much science in the course of her training that it is sometimes urged against her by her critics that the pursuit of knowledge leaves her no time to cultivate that sympathetic attitude which means so much to the helpless patient. There should be no room for any such criticism in the case of anyone who takes as her textbook Miss BERTHA HARMER'S *Text-book of the Principles and Practice of Nursing*.⁵ In the course of the introduction Miss Harmer sets out in clear and simple language the spirit and ideals of the nursing profession and those qualities which every nurse should strive to cultivate. Something deeper than sympathy, kindness, and unselfishness is called for in the perfect nurse, and can only be attained by a wide professional knowledge, assisted by the priceless gift of understanding which brings not only comfort to the body but ease and rest to the mind of the sufferer. Miss Harmer never allows the reader to regard the patient merely as a subject upon whose body certain rites have to be performed; the patient is always a sensitive human being whose feelings are to be respected. The first half of the book covers the general principles of elementary nursing, the second part being devoted to a more detailed account of the technique of medical and surgical nursing. There is also a section on the care of eye, ear, nose, and throat cases. In each instance the underlying principles are lucidly explained, so that the student can adapt the teaching to meet any conditions, whether in a private house or in hospital. The various methods and procedures are very fully described, and no pains have been spared to make every detail perfectly clear. The illustrations have been well chosen, and the publishers are to be congratulated on the excellence of their execution. This book is a mine of information for the probationer who is preparing for her examinations; it should prove of equal value to the fully qualified nurse, and should be of great assistance to those responsible for the teaching of the coming generation of nurses.

The report of the Conference on Mental Deficiency, held at the Caxton Hall, Westminster, on July 26th and 27th (of which an account appeared in the JOURNAL of August 5th, 1922, p. 222), has been published by the Central Association for Mental Welfare, and copies may be obtained from the honorary secretary of the association, Miss Evelyn Fox, 24, Buckingham Palace Road, S.W.1. The report contains papers on "Crime and mental deficiency," by Sir Bryan Donkin, on "Criminal defectives," by Dr. W. Norwood East, and on "Economic difficulties which prohibit the development of special schools," by Dr. H. B. Brackenbury, with speeches by Sir Leslie Scott, Mr. H. A. L. Fisher, and others, and a full account of the interesting discussion which took place.

⁵ *A Synopsis of Medicine*. By Henry Letheby Tidy, M.A., M.D., B.Ch., Oxon., F.R.C.P. Lond. Second edition, revised. Bristol: John Wright and Sons, Ltd.; London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd.; Toronto: The Macmillan Company of Canada, Ltd. 1922. (Cr. 8vo, pp. xv + 956. 21s. net.)

⁶ *Text-book of the Principles and Practice of Nursing*. By Bertha Harmer, B.Sc., Columbia Univ., R.N. New York: The Macmillan Company, 1922. (Demy 8vo, pp. xiv + 695; 153 figures. 14s. net.)

SIGHT-TESTING BY OPTICIANS.

REPORT BY THE COUNCIL OF BRITISH
OPHTHALMOLOGISTS.

THE following report on sight-testing by opticians has been issued by the Council of British Ophthalmologists, and will appear in the *British Journal of Ophthalmology*. We are indebted to the Honorary Secretary for an early copy.

In 1906, and again in 1919, opticians have made application to the Legislature that their craft may be legally recognized for the purpose of sight-testing, and it is consequent upon these efforts that the Council of British Ophthalmologists has thought it desirable to consider the matter in the interests of the general public.

Training of Opticians.

The Council would warmly welcome any scheme which would lead to greater efficiency in the making and fitting of spectacles. It fully recognizes that there is a very definite need for a greater supply of properly trained opticians, and ophthalmic surgeons often have cause to deplore the inefficiency displayed in carrying out their prescriptions for glasses.

Sight-testing by Opticians.

In a recent petition (1919) the British Optical Association claimed that opticians should be recognized as capable, not only of carrying out the optician's art of making and fitting glasses in conformity with prescriptions, but also of measuring and determining what glasses are required to compensate for defects of vision in any member of the public who may apply to them. Paragraph 10 of the petition stated:

"In a very large majority of refraction cases which can be treated by glasses, members of the public do, in fact, visit an optician rather than an ophthalmic surgeon or medical man, and the association humbly submit that it is eminently in the public interest that the optician should be a skilled man and under suitable supervision. An optician, especially when holding a diploma from the Association, would recognize a case of disease or otherwise, could not be properly treated by glasses, and would direct the patient to an ophthalmic surgeon or medical man. An ignorant optician would be likely to supply the patient with glasses which might do great harm."

Training Necessary for Sight-testing.

The Council, however, considers that no course of training short of that required for full medical qualification can produce the skill and judgement necessary to secure the requirements stated in the above paragraph. Every medical man dealing with ophthalmic cases must be equipped with the knowledge necessary for ordinary qualification in medicine, and, in addition, with special knowledge of the most delicate and complex sense organ in the body.

It is the opinion of the Council that any State recognition of sight-testing by persons possessing only an optical qualification would not be in the interests of the community.

The Scientific Principles of Sight-testing.

The art of prescribing glasses can be divided into two periods—the purely empirical period preceding 1850, when only subjective methods of testing were available, and the period following 1850, when accurate objective measurements began to be used. (See Appendix.) Those scientific methods have been developed by medical research, and to a great extent they are not available to the optician. The statement that where defective vision is due to other than optical conditions it should be treated by a duly qualified medical practitioner (see petition of the British Optical Association, par. 10, quoted above) is in itself sufficient argument against the optician's claim, since it is well known that changes in the refraction of the eye are often produced in the early stages of serious eye disease. In many such cases an optician may be successful in raising the acuteness of vision to a normal standard, but he would almost inevitably fail to recognize the disease which is the cause of the refractive error. In fact, disease very serious to the eye, or threatening even life, may occur in an eye with perfect acuity of central vision.

Use of Drugs.

An adequate examination of the eyes and a correct determination of the error of refraction cannot be made in young children, especially in cases of squint, while the accommodation (that is, focusing power) is active. The absence of accommodative effort can only be ensured by the use of certain drugs, which also dilate the pupil. These drugs

must not be used in an indiscriminate manner. In certain conditions of the eye their employment is attended by grave risk to sight. In some individuals they produce serious constitutional disturbances. As dilators of the pupil their use is frequently essential in order to determine the presence or absence of changes in the retina or optic nerve. Such changes may be the first indication of general disease, by the prompt treatment of which the life of the patient may be saved or prolonged.

Eye Defects and General Disease.

The treatment of headaches, associated with errors of refraction, demands not only the use of glasses, but also constitutional treatment, which can only be determined by a medical man. In some cases of defects of the muscular balance of the eyes the use of prisms is necessary. The correct estimation of these and a complete investigation of the case are most difficult problems, since some of these muscular defects are among the earliest signs of serious diseases of the nervous system.

Changes in the refraction of the eyes are often produced in the early stages of eye disease. For example, myopia ("short sight") often appears in the early stages of cataract, or of chronic glaucoma, a disease which untreated inevitably leads to blindness. Hypermetropia ("long sight") may be met with in the early stages of a malignant tumour. In such cases glasses may bring visual acuity up to a normal standard, but an optician will fail to recognize the disease, which will thus be left to run its course.

Optical defects and disease constantly overlap; the former cannot be differentiated with certainty from the latter, nor the latter definitely excluded, by any, but a medical practitioner who has had special training and experience.

Optician's Standpoint.

The "sight-testing optician" endeavours either to supply spectacles with which the customer considers he can see to his liking, or to provide such lenses as will convert optically imperfect eyes into accurately focusing instruments. All are agreed that the former procedure is indefensible: the latter needs further consideration.

The eye is an integral part of the human body. Developmentally it is, in its most essential elements, an offshoot of the brain. There is practically no organ of the body which does not react upon it to its advantage or its detriment. Without exposing it to the gravest misfortune it cannot be dealt with as an inert, isolated optical instrument, yet it is in this way only that the optician can view it, and in this way only can he adapt mechanical apparatus to such of its optical defects as his limited means may enable him to recognize. Without the use of drugs to dilate the pupil or paralyse the focusing muscle, in many cases he cannot measure accurately the error of refraction or be in a position to identify the cases which demand medical advice and treatment. If he were allowed to use such drugs he would become an even greater danger to the community by reason of serious disease which he in his ignorance might produce.

Ophthalmic Surgeon's Standpoint.

The ophthalmic surgeon approaches his refraction work from an entirely different standpoint. To him the eye is an optical instrument, but it is also an integral part of the human body in complex interrelation with the other parts. Its anatomical proportions and its physiological activities are before his mind. Its pathological disturbances, both local and those dependent on general disease, are known to him. He has at his disposal the use of all drugs necessary for his purposes, and of the indications for and against their employment he is fully aware.

In the investigation of diseases of the eye, the measurement of the acuteness of vision, both with and without lenses, is one of the first steps in the examination of the patient. In refraction work the surgeon takes into consideration the physiological activities of the normal eye. The hypermetropic eye he regards as developmentally imperfect. Astigmatism may be due either to developmental malformation or to disease. Presbyopia (loss of focusing power associated with advancing age) is a physiological condition, but undue rapidity in its progress may herald glaucoma, and apparent recovery of focusing power may indicate the earliest stage of cataract. Myopia is in many instances pathological, and the myopic eye is exposed to grave disorders. With a comprehensive knowledge of facts such as these, the ophthalmic surgeon decides in a pure refraction case what lenses should be prescribed. With what lens the patient sees best is only

one point he takes into consideration when prescribing. His aim is not only to improve vision, but also to secure the health and comfort of the patient. No case is dismissed until full ophthalmoscopic and other examination has excluded all objective signs of disorder.

If disease be present, its causation, whether local or general, has to be ascertained, and this demands a knowledge of the diseases of the other organs of the body which produce changes in the eye. The ophthalmic surgeon must have an adequate knowledge of diseases of the brain and central nervous system, of the blood vessels and vascular system, of the kidneys, of the nose and its accessory sinuses, of the various ductless glands, etc. In fact, there is no branch of medicine which is not in close relationship with this special domain, nor is there any specialty in which a general medical knowledge is of greater importance.

The Public Interest.

It cannot be in the interests of the community to allow such grave responsibilities to pass into the hands of men with no medical training, and to hall-mark by official recognition a practice involving such dangers.

Many people in the past have gone to opticians to obtain glasses for failing vision under the impression that they are fully qualified to prescribe. Official recognition of sight-testing opticians would encourage the practice and would increase the feeling of security which our arguments show to be unwarranted. There can be little doubt that this impression has been fostered by such "qualifications" as F.S.M.C., F.B.O.A. (Fellowship of the Spectacle-makers' Company, Fellowship of the British Optical Association), etc. It is the duty of the State to guard against legislation which may in any way entail detriment to the community.

APPENDIX.—HISTORICAL.

An inquiry into the history of the science and art of refraction will show that this branch of ophthalmic work has been initiated and developed by medical men, and that even at the present day the optician works, and must of necessity work, largely on the more purely empirical lines of the early part of the nineteenth century.

The discovery of spectacles as an aid to vision dates from the thirteenth century. There is no absolute certainty as to their first inventor, but the probabilities point to Roger Bacon (1214-1294), who, in his "*Opus Majus*," wrote of the enlarging power of a plano-convex glass and of its value "*senibus et habentibus oculos debiles*." Either directly from Bacon, or from some other monk, the discovery became known in Italy, and at the end of the thirteenth century spectacles were being made by Alessandro de Spina, a Dominican friar of Pisa. He did not claim to be the actual inventor, but had seen glasses made by someone else who was unwilling to reveal the secret. It may have been from Salvino d'Armato, of Florence, that Spina obtained the secret, since Armato's tombstone bears the inscription: "*Here lies Salvino d'Armato degl' Armati of Florence, inventor of spectacles. God forgive him. Anno D. 1317.*"

If Roger Bacon invented spectacles it was probably some time before the year 1257, when the "*Opus Majus*" was written for Pope Clement IV. By the middle of the fourteenth century convex glasses had become fairly common. Concave glasses seem to have come into use first in the sixteenth century, and early in the seventeenth century Kepler wrote the first important scientific work on the use of spherical lenses.

The next important discovery did not take place till the beginning of the nineteenth century, when Thomas Young, the distinguished physician and physicist, in his "*Memoir on the mechanism of the eye*" (*Phil. Trans. Roy. Soc.*, 1801), gave the first description and measurement of astigmatism and a table of optical constants in close agreement with modern determination. He had previously (1793) written a paper on the mechanism of accommodation which secured his election to the Fellowship of the Royal Society. His observations were subsequently confirmed by Airy in 1823, but remained practically unknown to opticians.

Until the year 1853 the prescribing of spectacles was entirely empirical. It was known that men, as they reached middle life, had difficulty in seeing to read, and that their difficulty was relieved by wearing suitable convex glasses. It was occasionally found that younger people also were helped in reading by the use of convex glasses, and they were said to have "old sight," a phrase still to be heard in use amongst opticians. Another group of people was said to have "weak sight," and it was found that they were enabled to see more clearly in the distance by the use of concave glasses. The sale of spectacles was often in the hands of country pedlars, and people chose from the stock what seemed to suit them best.

With the discovery by Helmholtz of the ophthalmoscope and the ophthalmometer in 1853, the scientific investigation of the refractive media of the eye became possible and the work of Donders, the great Dutch surgeon, speedily laid the foundations on which all modern refraction work is built. He showed the way in which a hypermetropic eye and a myopic eye depart from the normal, and the liability to disease existing in a myopic eye. He showed the relationship between the long-sighted eye and squint, and the essential difference between long sight and old sight. He discovered the frequency of astigmatism and laid down the rules for

STANDARDIZATION OF PITUITARY EXTRACT.

THE first of the reports of the Medical Research Council on "biological standards" deals with the methods available for the standardization of pituitary extract, and gives an account of experiments carried out by Dr. J. H. Burn and Dr. H. H. Dale with a view to establishing a more accurate method of estimating the activity of this substance. Extracts of the pituitary gland are widely used in medical and surgical practice, yet up to the present very little attempt has been made by different manufacturers to provide extracts of similar potency. Some system of standardization is all the more necessary because this remedy is often used in emergencies—as, for example, in the difficulties and accidents of childbirth—and on such occasions it is all-important that the correct dose should be administered. Pituitary extract, a remedy of great value when accurately used, may, when inaccurately employed, produce dangerous and even fatal consequences. Obviously the physician should know the strength of the preparation he intends to administer, yet the experiments described in this report show that commercial preparations may vary so greatly that the most potent may have eighty times the strength of the least potent. Thus a doctor, having become thoroughly familiar with the activity of one preparation, may, when employing another which is apparently equivalent, inadvertently administer eighty times the intended dose. This absence of uniformity in the strength of different preparations is not necessarily the fault of the manufacturers, since no official guidance has in this country been given to them as to the strength of the extract most suitable for therapeutic purposes, and there has been no standard of activity available for common use by which fresh extracts can be judged. The authors of this report describe a method by which a preparation of uniform activity can be made and used for purposes of reference, and recommend the adoption of a definite standard of potency in the *British Pharmacopoeia*. The absence of official standards of value and authenticity for drugs of this kind and for the numerous biological preparations, such as serums and the like, used in general practice, has already been publicly denounced as "discreditable to our national position in the world of science and a source of grave danger to the community." Burn and Dale point out in the report that the active principles of the posterior lobe of the pituitary body are unknown, so that the only method of estimating their presence is the physiological. A watery extract is very unstable. The active principles are easily destroyed in the process of preparing the extract, so that the first essential is some standard with which all preparations can be compared. The therapeutic properties of pituitary extract depend on at least two principles, one acting on the blood pressure and one on the uterus, and any method of standardizing must measure one or other of these activities accurately. Difficulties arise when the blood pressure is selected as the standard, owing to the fact that no great delicacy of discrimination can be secured in estimating the pressor activity of the gland, the total effect being dependent in all probability on the action of more than one pituitary principle. Moreover, recent work has shown that tolerance is rapidly estab-

lished for the action of the most important pressor principle, a fact which further complicates attempts to estimate the value of the extract on the basis of its effect on blood pressure. On the other hand, tests made on the isolated uterus of the guinea-pig detect differences of activity within much narrower limits, and actually determine the particular form of activity which has given to the extract its widest use in therapeutics. The authors conclude that this test is by far the most suitable for quantitative comparisons with a standard, but that it should be supplemented occasionally by a test on the blood pressure to ascertain that the pressor activity is not disproportionately defective.

Full particulars of the method recommended are given in the report, but the essential details are as follows. The apparatus consists of a cylindrical glass testing vessel holding about 200 c.cm., set in a stout copper thermostat bath filled with water kept at 37° C., the testing vessel being so arranged that it can be emptied and refilled from a reservoir of warm saline. The uterus to be examined is fixed in the testing vessel, and the upper end attached to a lever which writes on a rotating drum. The fluid used in the testing vessel is a modification of the Locke-Ringer solution, differing in that it contains more sodium bicarbonate and a minute proportion of magnesium chloride, which has the useful effect of weakening the tendency to irregular spontaneous rhythm and preserving the excitability of the muscle to pituitary extract. Virgin guinea-pigs weighing between 200 and 300 grams are chosen for the experiments; when the uterus is "on heat" it is unsuitable, and the authors recommend that the young females should be segregated as soon as they are ready to leave the mother, and that the absence of oestral activity should be verified by external inspection before the animal is killed. The whole horn of the uterus should be used, suspended between a cervical tag at one end and the ovary at the other. The pituitary extract for the test is diluted 100 to 200 times with Ringer's solution, so that the dose to be added to the bath shall not be too small for reasonable accuracy of measurement, or so large that its addition unwarmed will sensibly affect the temperature of the solution in the testing vessel.

It would be a great advantage if a stable chemical substance could be prepared of known chemical composition which acted on the uterus in the same way as the pituitary extract, and which might be used as a standard with which the pituitary extract could be compared. Many experiments were carried out with histamine in the hope that it would fulfil these requirements, but the authors were led to the conclusion that the uteri from different guinea-pigs vary independently in their sensitiveness to histamine and to pituitary extract respectively, and these variations are such that histamine as a standard for pituitary extract is unsatisfactory. A similar disappointment attended attempts to use potassium chloride as a standard, for here again it was found that sensitiveness to potassium chloride did not run concurrently with sensitiveness to pituitary. No satisfactory artificial standard having been found, an extract made from the perfectly fresh pituitary gland was chosen as a standard. This extract must be prepared from glands received direct from the slaughterhouse as soon as possible after the ox has been killed. The posterior lobe is shelled out and divided up with small dissecting scissors and weighed, extracted with water in the proportion of 1 gram of gland to 40 c.cm. of water, raised rapidly to the temperature of boiling water and filtered. The filtrate represents 2.5 per cent. extract of the fresh gland substance.

In carrying out the test a fiftyfold dilution of the standard fresh extract is added to the testing vessel and the effect on the uterus recorded on the drum. The aim

* Reports on Biological Standards. I: Pituitary Extracts. Special Report Series No. 69. By J. H. Burn, M.A., M.B., and H. H. Dale, C.B.E., M.D., F.R.S. (As 6d. net.)

in every case is to establish for the particular preparation the dose, which is about 60 to 70 per cent. of that needed to produce contraction of the muscle to the maximum. When the standard dose is thus fixed the determination of the exactly equivalent dose of the preparation to be tested is made from another series of experiments.

There are many stages in the preparation of the standard extract where any departure from the method recommended will result in serious loss of activity, but the authors have shown that an extract of perfectly fresh infundibular material, prepared by a method kept exactly constant in all its details, furnishes a sufficiently constant standard of reference for the biological testing of pituitary extracts. It is, however, not possible to prepare the large quantities of pituitary extracts required to meet the present-day demands with all the precautions observed in the preparation of the standard extract, and local conditions and the different processes adopted by commercial firms are the causes of the widely differing potency of various extracts to which reference has already been made. Dale and Burn have compared three British and two American makes of the extracts on the English market with the standard extract previously described, and have found very marked variation both in the effect on the isolated uterus and in the pressor effect on blood pressure, although in each case the extracts were described by the manufacturers as "physiologically standardized." This variation is due to two different factors. In the first place, the proportion of gland substance in a given volume is not constant for different preparations. Several manufacturers have now abandoned the custom of stating the supposed strength of their extracts, and medical practitioners, finding two different preparations of the pituitary gland, both dispensed in sealed ampoules containing 1 c.cm., are naturally apt to assume that they are equivalent, or intended to be so. The *British Pharmacopoeia* has not yet recognized the existence of this remedy, but the *United States Pharmacopoeia* has officially settled the theoretical strength at 10 per cent. of the fresh infundibular substance. The report recommends the general adoption by British manufacturers of this theoretical standard, so that the practitioner may be justified in his assumption that the dose contained in the same volume is at least supposed to be the same, whatever preparation he uses.

In the second place the actual yield of activity obtained from the same weight of gland substance is widely different in the case of different preparations, owing to variations in the method of manufacture. Preparations as potent as the standard fresh extract cannot be produced on a commercial basis, but the report suggests that 60 per cent. of the activity of the standard extract is a level which should be attained without difficulty by any manufacturer who has the necessary equipment and staff for the careful extraction of fresh material which has been dried at low temperatures when perfectly fresh and used without unduly long storage. The standard should be freshly prepared as often as required, but it is not suggested that a new standard solution is necessary for the assay of every batch of commercial extract. A comparison of each batch with its predecessor would suffice for limited periods, reference being made to the independent standard at regular intervals.

Until some such uniformity has been achieved it will be impossible to arrive at any correct value for the dose of pituitary extract to be used in treatment. A committee appointed by the Obstetrical Section of the Royal Society of Medicine, with the co-operation of the Medical Research Council, is conducting a thorough investigation into the question of the doses appropriate to various conditions.

SUICIDE AND FELO DE SE.

OBSERVATIONS made from time to time by coroners show that there is still considerable misunderstanding as to the precise meaning of the words "suicide" and "*felo de se*," and of the effect of adding to a verdict the words "while temporarily insane" or "while of unsound mind." The general practice at inquests is to use the word "suicide" where the jury or coroner is of opinion that the deceased, through unsoundness of mind, was incapable of appreciating the distinction between right and wrong, and accordingly of committing a crime; the term "*felo de se*" being restricted to the very small proportion of cases in which the deceased was considered to have been of sound mind. This custom appears to have grown up among coroners without any legal sanction or guidance.

The whole question of terminology and legal effects in these cases was very thoroughly investigated by Mr. Henslowe Wellington, whose able paper on the subject will be found in Volume I of the *Transactions of the Medico-Legal Society*. In law, there is no distinction between suicide and *felo de se*. The word "suicide" does not seem to have been used in works on law previous to 1736, when it appears in Hales's *Pleas of the Crown*, edited by S. Emlyn sixty years after Hales's death. A long series of judicial decisions and opinions show conclusively that suicide means self-murder.

Sir James Fitzjames Stephen says in his *Digest of Criminal Law* (fifth edition, 1894) that "a person who kills himself in a manner which in the case of another person would amount to murder is guilty of murder, and every person who aids and abets any person in so killing himself is an accessory before the fact, or a principal in the second degree in such murder." It is for this reason that when two persons agree to commit suicide together and only one dies, the survivor can be indicted for murder. Suicide is accordingly the same as *felo de se*, and the use of one or the other term might well be discontinued. The verdict "suicide while of unsound mind" is a contradiction in terms, and from the legal point of view meaningless. Chief Baron Pollock stated in 1847, "in point of law, as soon as it is ascertained that a person has lost his sense of right or wrong (it matters not what else of the human faculties or capacities remain) he ceases to be a responsible agent, and in my judgement can no more commit suicide than he can commit murder." The Home Office Departmental Committee on Coroners in its report published in 1909 recommended that the verdict of *felo de se* should be abolished. It advised that in cases of suicide the verdict should simply be that the deceased died by his own hand (stating how), but the jury should be at liberty to add to their verdict that there was no evidence to show the state of his mind, or that at the time of taking his life he was of unsound mind.

It seems clear that the verdict "suicide" coupled with the words "while temporarily insane" came to be used by coroners' juries for the purpose of avoiding the degradations which were inflicted upon the corpse of the *felo de se*, and the penalties which his relatives suffered. Until 1823 it was the practice to bury those found *felo de se* in a public cross-road, with a stake driven through the body. This barbarous ceremony was last performed in that year on the body of one Griffiths, who was buried at the junction of Eton Street, Grosvenor Place, and King's Road. The driving of a stake through it was, however, on this occasion dispensed with.

By an Act passed in 1823 the interment in a churchyard or other burial ground of persons who had committed *felo de se* was authorized, but performance of the rights of Christian burial was still prohibited. Under an Act of 1882 any form of orderly religious service may

now be used at the interment of a person who has committed *felo de se*, except that of the Church of England by a minister of the Church of England, since this is forbidden by the rubric. The practice of forfeiting the goods and chattels of a suicide to the Crown originated in Anglo-Saxon times, and was not abolished by law until 1870, though it had fallen into desuetude long before that date. Pepys gives an interesting account of the precautions relatives were led to take in consequence of this cruel practice. Antony Joyce, his cousin's husband, threw himself into a pond at Islington, and, though rescued, was dangerously ill. Pepys went to see the wife, and found her; to quote his words, "in fear that the goods and estate would be seized on, though he lived all this while, because of his endeavouring to drown himself. My cozen did endeavour to remove what she could of plate out of the house, and desired me to take away my flagons, which I was glad of, and did take them away with me in great fear all the way of being seized; though there was no reason for it, he not being dead, but yet so fearful was I." Antony died, and an inquest was opened. After several adjournments, during which Pepys saw the King and endeavoured to get his help, the jury eventually found that the deceased died of a "feavor."

The last point which remains to be considered is the effect of suicide on claims under insurance policies. If a person who has insured his life kills himself, and is not found insane and irresponsible for his actions, the policy is vitiated. Some companies include in their policies a condition vitiating the policy if the insured takes his own life. If there is no such condition the rule of common law is that whether the amount of the policy can be recovered depends on the question whether or not the person was at the time responsible for his own acts. Some companies protect themselves by a clause which excludes the risk of suicide for a certain period of years or months. But most companies pay in the case of death from suicide except where there is reason to believe that the deceased had insured his life with fraudulent intention.

THE MAUDSLEY HOSPITAL.

The building of the Maudsley Hospital established by the London County Council at the suggestion of the late Dr. Henry Maudsley, who made the magnificent gift of £30,000 towards its cost, had just been finished at the outbreak of war. It was lent in the first instance to the military authorities, and later to the Ministry of Pensions for the treatment of neurological cases. Its reorganization for its original purposes is now approaching completion. The hospital is intended for the treatment—entirely on a voluntary basis—of nervous disorders, both organic and functional, and of early and recoverable types of the psychoses. It is designed also for the investigation of cases presenting unusual scientific interest or difficulties of diagnosis, for research into the causation of nervous and mental disorders, and for education. It will, we believe, be the first institution in this country on the lines of the neurological and psychiatric clinics of other countries. The medical staff so far appointed includes Dr. E. Mapother, medical superintendent; Dr. A. A. W. Petrie, deputy medical superintendent; and Dr. W. S. Dawson, senior medical officer. Additional medical officers will be added as the work of the hospital increases, and there will be vacancies for qualified medical men and women as voluntary clinical assistants. Those desirous of acting in the latter capacity are invited to communicate with the medical superintendent. The staff will very shortly be supplemented by the appointment of a consultant surgeon, a gynaecologist, a dentist, and specialists in diseases of the eye, ear, nose, and throat. The association with the hospital of the pathological department under the direction of Sir Frederick Mott

assures the application of the most modern laboratory methods of diagnosis and treatment. The hospital will afford facilities for all remedial measures, including physical methods, as well as various forms of psychotherapy. The out-patient department is to be opened on December 4th, in advance of the wards, and cases will be seen there on four days a week from 2 p.m. (men, Mondays and Thursdays; women and children, Tuesdays and Fridays). A charge will be made for attendance as at the general hospitals. Cases with all types of nervous and mental disorder will be eligible as out-patients, but especially those whose symptoms and desire for treatment would render possible their later admission to the wards, if necessary.

SIGHT-TESTING OPTICIANS.

DURING recent months much activity has been observable amongst the sight-testing opticians. There is a strong move on the part of some of them to secure a State register, ostensibly for the protection of the public against the dangers of the more ignorant of their fraternity. The more established of the sight-testing opticians have for some years banded themselves together, through the Spectacle-makers' Company and the British Optical Association; for the conferment of such cryptic appendages as F.S.M.C. London and F.B.O.A. These elder self-examiners view with apprehension not unmixed with indignation the action of another and newer association of opticians which grants "diplomas" after an examination the standard of which they hold in some scorn. This stimulus from within arouses the elder opticians to try to secure their position before they are swamped by the smaller fry. There is also perhaps a stimulus from without. The establishment of a midwives' register some years ago, the more recent formation of a register of nurses, the extension of the dental register, possibly also the registration of teachers, have all stimulated the desire for the protection and status which such a registration gives. The movement has not been overlooked by those best able to judge. We print on page 1084 the report of the Council of British Ophthalmologists on this matter. It is a detailed and reasoned statement; it is simply written and can be understood by everyone. It leaves no room for misapprehension of its purport. The ophthalmic surgeons of distinction and experience who form that Council are of opinion "that any State recognition of sight-testing by persons possessing only an optical qualification would not be in the interests of the community." But it may be argued that this Council by reason of its personnel is prejudiced; being themselves ophthalmic surgeons they may fear that a register of sight-testing opticians would endanger their own calling. Such a suggestion can scarcely be maintained of members of a profession whose interest in the public weal is unquestionable. But there is another basis for judgement. Last week we gave the concluding instalment of a summary of the Report of the Committee on the Causes and Prevention of Blindness. That committee, we understand, dealt with this subject at the request of some of the protagonists of the sight-testing opticians. The committee had a mixed personnel; seven were laymen experienced in public affairs and health matters, four were Government officials, and only three were practising ophthalmic surgeons. This committee, with its preponderance of laymen, without hesitation reported that the proposal for registration of sight-testing opticians is a danger. "The public would regard the register as an official guarantee that those whose names were included in it were competent not only to provide but to prescribe glasses, and generally to deal with defects of vision from whatever cause arising." The organized bodies of opticians who state "that many people who test sight and prescribe spectacles are untrained and incompetent" tell the truth; but the truth is wider than they admit. Their statement is true not only of the chemists, drapers, toy vendors, and petty hawksters who sell glasses to those who will buy: it applies also to their own practice; they themselves are incompetent in the absence of medical training, and sometimes they are the more dangerous by

reason of the "qualifications" with which they seek to reassure the public. Admittedly there is a problem: the provision of a sufficient number of practitioners competent to do eye work. But the cure is not to be found by an increase of sight-testing opticians, but by an increase of medical practitioners trained in the work of refraction. This provision is being brought into being rapidly. The institution of treatment for elementary school children has given it a great impetus. Public authorities can stimulate the provision and make it widely available by arranging that those practitioners who do ophthalmic work for them shall be part-time officers and not whole-time officers, so that in their unofficial time their skill and experience may be at the service of the community generally. Sight is the master sense of man; it plays an ever-increasing part as civilization becomes more complex. No member of the body is more closely knit with the welfare of the body generally, and none is more delicate, than the eye. "Safety first" applies with peculiar force to vision, and that can only be secured by those who would practise eye work undergoing the strenuous discipline in observation and treatment which a full medical curriculum and hospital course provides. There is a subcommittee of the British Medical Association which has this matter under consideration; through it any necessary action for the enlightenment of both public and legislators could be initiated.

THE ART OF VACCINATION.

A POSSIBLE disadvantage incidental to extensive resort to vaccination during small-pox prevalence may consist in the heavy pressure on the time of a busy public vaccinator or private practitioner. If people would only take the trouble to get vaccinated or revaccinated in quiet times there would be no chance of omission of any of the precautions which may with advantage be observed in the operation—the cleaning of the surface of the skin, the use of sterilized instruments, including a blower instead of the operator's lips, and the protection of the vaccinated surface against extraneous infection in vaccinating and in inspecting the result—all as specified in the "Instructions to Vaccinators under Contract" of the Ministry of Health. The private practitioner has the additional responsibility of providing himself with suitable lymph, which duty in the case of the public vaccinator is performed by the Ministry of Health. As regards the art of vaccination, we have asked a public vaccinator of high standing and great experience to give our readers the benefit of his views. They are to the following effect: Primary vaccination has been so standardized by the use of the Government's vaccine and the simple methods of asepsis employed, and accidents are so rare, that occasion does not exist for much further improvement. If a vesicle be accidentally broken or a crust prematurely detached an opportunity for introduction of infection may occur, but that possibility attaches to every scratch of a pin. In revaccination the real difficulty lies much less in the technique of the operation than in the fact that people beyond infancy are not under the watchful eye of the mother, and the site of vaccination is open to all kinds of mechanical interferences which lead to the breaking of the vesicles and possible staphylococcal or streptococcal infection of the vaccinal site. The irregular vesiculations of revaccination are more vulnerable than the full, hard vesicles of primary vaccination, and ought therefore to be protected with special care. Probably not many "bad arms" are due to infection from the skin directly, but to violence of some kind or other; when once the vesicle is open and lymph exudes, germs may get in. The character of the dressing is of consequence in determining whether a vesicle shall break or not. A pad of boracic wool over the site, fixed by two strips of rubber plaster or zinc oxide plaster, works well, but sometimes there is a slight adherence to the vesicle or crust when the dressing is removed on the eighth day, or the pad may be damp with lymph. On removing the pad it is a very useful precaution to paint with tincture of iodine, though it may cause smarting for half a minute after application. The iodine hastens the drying of the scab and reduces risk of infection.

"Bad arms," however, are often not septic at all, but due to intense reaction tending to choke temporarily the axillary glands, resulting in some degree of lymphatic stasis. In such cases the vesicles are not broken, but become crusts quite regularly. If there is axillary pain, a hot sponge in the armpit gives relief; and if occasionally the skin of the arm is tight and shiny, a hot lead and opium lotion will usually clear up matters in twenty-four hours. If some accident to the crusts should lead to their separation, any small raw surface left may, if dry at the base, be painted with iodine, but if inclined to "weep," a simple antiseptic ointment, or, still better, a moist, warm fomentation may be applied. For preparation of the skin before vaccinating, methylated spirit is suitable and convenient, but iodine washed off with alkaline spirit soap might be worth a trial.

THE STAGES OF HUMAN LIFE.

THE progress of human life from the cradle to the grave is so naturally interesting to all humanity as to have engaged the thoughts and the pens of writers in every age. Few students can have steeped themselves more thoroughly in the literature of the subject than Dr. J. Lionel Taylor; he has fullness of knowledge and a fitness in selection and quotation. The subject has many aspects, and the best known classification of the ages of man is that which Shakespeare put into the mouth of the melancholy Jaques. It is too hackneyed to quote, and we may turn to a new classification which Dr. Taylor has made from a biological point of view. He has written a series of essays marked by knowledge and wisdom and full of judicious advice, and has collected them in a volume published some time ago. For one or two of the stages into which he divides human life he has had to devise new names, which, however, are self-explanatory; they are ante-nateny, nateny, infancy, weanlinghood, childhood, pubescence, adolescence, youth and maidenhood, maturity, and old age—not seven ages but ten. To whatever period of life a reader has attained he will find much that will be of value in aiding him to govern himself and to regulate wisely his relations with others. In the parts concerned with the life periods through which he has already passed he will probably feel some regret that he had not the benefit of Dr. Taylor's suggestions and guidance—say in the training of his own children and in his attitude to them after they had passed the age for direct parental control, so that they should develop from dependency into companionship. He deals with every stage of life, whether past or current or still to come, in an interesting manner, and the family doctor, who is often the confidential consultant outside the directly medical sphere, will find the volume one to keep on his bookshelf, to be taken down at any time for a quiet hour's browsing. The following exordium addressed to the adolescent, concerning spiritual travellers, may be quoted as a sample of the author's quality, and of how he utilizes his wide reading to help him in his own message: "Or perhaps your sympathies are with another kind of traveller, the enthusiast, the prophet, the seer, and you like the lonely untrodden path not of 'the has been' but of 'the will be.' If so take Lessing with you as your guide and accept one of his warnings. Do not be one of those enthusiasts who egotistically wishes the world accelerated through him; you will be made use of, have no fear of that if you do your part, but remember that that which takes thousands of years to mature will not specially hurry its ways because some human being wants it to come in the moment and only the moment of his existence. You must take disinterested joy in all your journey, and remember to learn, as Herbert Spencer bids us, that in a world so vast as ours, single efforts seem comparatively so very small when we look at them after a few years of striving, or even at the end of our lives, but that little must be felt worth while to us."

THE ROYAL DENTAL HOSPITAL.

THE annual dinner of past and present students of the Royal Dental Hospital of London was held at the Trocadero Restaurant on November 25th, with Mr. P. L. Webster in the chair. After the loyal toasts had been honoured, the chairman presented the scholarships, prizes, and certificates to the successful students. In proposing the toast of the "Past and Present Students of the Royal Dental Hospital and Dental School," Mr. Webster said that during the afternoon he had had an opportunity of visiting the hospital and inspecting the new departments made necessary by the introduction of new branches in dental science and changes of ideas and methods, and he was almost overwhelmed. While agreeing that students should have the highest standard of teaching, he warned them of the danger of specializing too much and losing sight of general principles and also the sense of proportion. He urged past students to make a point of attending the "At Home" held in the afternoon of the day of the annual dinner and to see something of the progress which had taken place during the year, and thus keep in touch with new methods and ideas. One of the great advantages of the annual dinner was that it afforded past students an opportunity of renewing old friendships. The toast was acknowledged by Mr. F. Breese for the old students and by Miss F. H. Bachrach for the present students. The dean of the school, who also replied to the toast, reported the progress made by the school, and certain changes which had taken place. He said that during the year sixty students had obtained diplomas, and that the University of London had decided to continue the school as a school of the University for a further period of three years. The University had also instituted a degree of Bachelor of Dental Surgery. The athletic side of the school had been very successful, and he appealed for subscriptions for the purchase of a recreation ground for the students. The toast of "The Visitors," proposed by Mr. J. G. Turner, was acknowledged by Sir Humphry Rolleston, President of the Royal College of Physicians of London, and Sir Anthony Bowlby, President of the Royal College of Surgeons of England. Sir Frank Colyer proposed the health of the chairman, which Mr. Webster acknowledged. The music and recitations during the evening were provided by students of the hospital.

THE GENERAL MEDICAL COUNCIL.

SIR DONALD MACALISTER opened the winter session of the General Medical Council with an address as lucid as ever, but shorter than usual because the Council has less than its customary amount of work to do. The reason is that it has said its say for the present about medical education and the curriculum, and the matter is now transferred to the licensing bodies, some of which have already taken steps which show readiness to accept the Council's recommendations. The President expressed his confidence that all will come into line, recognizing that the Council's schemes should each be considered by them as a connected and co-ordinated whole, though opinions may differ as to minor details. To one such detail the President made specific reference—to that of what he called "the pre-registration test" in chemistry and physics. He made it plain that the Council intended the test to be in addition to any examination in these subjects at matriculation. A student intending to enter medicine is to complete his school course of general education to the same level as his fellows intending the faculties of arts or pure science, and then to acquire in addition, in his post-school but pre-registration stage, such further knowledge of chemistry and physics as will enable him, immediately after registration, to take up the study of these sciences in their application to medicine. This is a change—we venture to say a reform—of greater importance than may at first sight appear, for it ought to ensure that the schoolboy, whether on the classical or modern side, shall not specialize on quasi-professional subjects, and that he shall, after he has finished his school days and matriculated, go on with the study of these sciences, which underlie the special professional subjects to which the rest of his life is to be devoted. If the purpose is to be justified

it must have the loyal co-operation of the teachers of these subjects to medical students. The President's observations to those schemes of the Council lent point to his graceful reference to the admirable work done in their preparation by Dr. J. C. McVail before his second term of office expired this year. The revised curricula, Sir Donald MacAlister said, include much that is due to the initiative and perseverance of Dr. McVail, who in this and other ways has left the profession his debtor. The debt has been recognized by the British Medical Association and by the Royal Society of Medicine, as well as by his own university, but it may not be out of place to recall that Dr. McVail was a great public servant the State should delight to honour. The full text of the President's address is published in the SUPPLEMENT this week. It will be seen that the Council welcomed two new members—Sir Humphry Rolleston, representative of the Royal College of Physicians of London in succession to Sir Norman Moore, who has resigned office after twenty-one years' service, and Dr. R. B. Wild, who succeeds as representative of the University of Manchester Professor Roy Dean, recently appointed to the Chair of Pathology, Cambridge. Sir W. Leslie Mackenzie, the new Crown nominee for Scotland, was absent; owing, unfortunately, to illness.

THORACOSCOPY IN SURGERY OF THE CHEST.

THE occasional lecture, which Dr. H. C. Jacobaeus, professor of medicine at the University of Stockholm, gave to the Royal Society of Medicine on November 22nd, when the president, Sir William Hale-White, was in the chair, followed the same lines as that which he gave at Manchester on November 17th, already reported at some length in our columns (JOURNAL, November 25th, p. 1043). During his visit to London Professor Jacobaeus gave two practical demonstrations of his method of dealing with pleural adhesions—one at Guy's Hospital and the other at the Brompton Chest Hospital. In his lecture at the Royal Society of Medicine he dwelt on the practical importance of the thoracoscope, especially in the pneumothorax treatment of pulmonary tuberculosis, and illustrated his remarks by a large number of lantern slides of skiagrams, which showed the excellent results of his method for the cauterization of pleural adhesions under thoracoscopic control. Mr. Geoffrey Marshall, who described a case in which that morning, at Guy's Hospital, Professor Jacobaeus had cauterized pleural adhesions, said that it was particularly noticeable how comfortable the patient was throughout the course of the operation, which was performed under a local anaesthetic. Dr. Vere Pearson congratulated Dr. Jacobaeus on his results, and asked for information regarding the improvement in the clinical condition of the patients after pleural adhesions had been cauterized, as compared with other patients who had not undergone such treatment. Professor Jacobaeus, in reply, recalled his statement that in about 75 per cent. of the cases reported the method was technically successful in removing adhesions which had prevented the complete collapse of the lung; the clinical results were not so favourable, but about 63 per cent. of the patients had been freed from symptoms.

INTERNATIONAL ADVISORY COMMITTEE ON ANTHRAX.

THE Government of the Commonwealth of Australia has appointed Sir Thomas Oliver, M.D., of Newcastle-upon-Tyne, to be the Australian representative on the Advisory Committee on Anthrax of the International Labour Organization of the League of Nations. The other members are: Dr. Gilbert (Belgium), M. Boulin (France), Dr. Frey (Germany), Lieut.-Colonel Hutchinson (India), Professor Loriga (Italy), Dr. Hoshiai (Japan), Mr. R. W. Dixon (South Africa), Professor Roca (Spain), Mr. Ribbing (Sweden). The Government of the United States will be represented in an unofficial and consultative capacity by Dr. M. Dorset of the United States Department of Agriculture. The Committee will meet in London on Tuesday next, December 5th, under the chairmanship of Sir William Middlebrook, the nominee of the British Government. The Committee is instructed to inquire

into the disinfection of wool and hairs infected with anthrax spores, and also into the practice and effective methods of preventing infection among flocks. It is to report on these subjects to the governing body of the International Labour Office in time for the consideration of the International Labour Conference in 1923. It is also to inquire into the possibilities of dealing with infection by anthrax from hides, skins, and other materials. The Committee is prepared to receive representations on these matters, which should in the first place be addressed in writing to Sir William Middlebrook, care of the International Labour Office, 26, Buckingham Gate, London, S.W.1.

INSTRUCTIVE MISTAKES.

It is admitted on all hands that it is a good thing to learn from our mistakes, and the meeting of the Surgical Section of the Royal Society of Medicine which will take place on Wednesday next, December 6th, at 5.30 p.m., will be given up to hearing from the President of the Section, members of its Council, and several other well known surgeons, the story of a mistake in diagnosis or treatment. Each instance is to be related quite briefly, each must have befallen the surgeon himself, and the lesson to be learnt from it is to be pointed out. The details of these cases will not afterwards be published. It ought to be a most interesting meeting and we foresee a large attendance. Surgeons wishing to take part in the meeting by relating instructive mistakes of their own are requested to communicate with the Junior Secretary, Mr. Philip Turnor, addressing him at the Royal Society of Medicine, 1, Wimpole Street, London, W.1. A good many years ago Mr. Ernest Hart, then Editor of this Journal, established a column which he called "The Confessional," for the receipt of reports of mistakes. This column started fairly well, but it very soon became apparent that most of the contributors to it wished to relate the mistakes of other people, and after a short trial it had, on this account, to be given up. We wish the President of the Section, Mr. James Berry, success in the rather difficult task he has set himself of presiding at a "mistakes meeting."

SIR CLIFFORD ALLBUTT has recently accepted the position of President of the West London Hospital Post-Graduate College. In accepting the invitation and wishing success to the College, Professor Clifford Allbutt, whose interest in post-graduate education is well known and whose recent lectures at the College on "Kinds of pneumonia" and "Angina pectoris" attracted large and appreciative audiences, expresses his conviction that the future of medicine in Great Britain depends upon the continued development of general practice and its opportunities.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

Conditions in the Near East.—In the course of the debate in the House of Lords on November 23rd, on the address in reply to the King's speech, the Archbishop of Canterbury referred to conditions in the Near East. He was in closest touch with the Patriarch of the Orthodox community. There were at this moment a million and a half persons the great proportion of whom were not members of the poorer classes a little while ago, but were to-day literally without the means of subsistence or shelter or a home of any kind. The matter called for the thought of European statesmanship and the intervention of European funds if appalling dangers were to be stayed—dangers of pestilence which might spread to a degree that it was impossible to calculate. He was receiving where the flecs covered with sheds and stations were without food or adequate covering. The conditions at the ports were almost beyond belief. He read a telegram giving an account of 50,000 persons who had been travelling on foot for ten days, the majority without food. The rain and cold increased the suffering and were causing many deaths. An utter lack of sanitation threatened cholera and typhoid. Scarlet fever had broken out. The services of doctors, nurses, and medicine were imperatively needed. The greatest sufferer the babies owing to lack of milk.

The surviving members of the medical group elected for dinner in the House next Monday, unless, the group will again be constituted.

NOTES ON SMALL-POX.

BY

W. MCCONNELL WANKLYN, B.A. CANTAB.,
M.R.C.S., L.R.C.P., D.P.H.

GENERAL OUTLOOK.

To keep himself posted in a general way about the current position of small-pox is an essential for every medical practitioner. A table giving the deaths from small-pox in England and Wales (London deaths recorded separately), and the admissions to the hospitals of the Metropolitan Asylums Board, from 1881 to 1921, together with the total cases certified for the years 1911–21, was printed in the JOURNAL of November 11th at page 943. The following figures give the number of cases recorded this year down to November 28th: Cases certified in England and Wales, 890 (approximately); total deaths, not yet ascertained; London deaths, 20; admissions to Metropolitan Asylums Board hospitals, 62.

All the 1922 London cases have occurred since the end of July; that is to say, for the first six months of the year London was clear of small-pox. How it was introduced is unknown. The first known case fell ill on July 1st and was overlooked until August 3rd, when he was discovered owing to the occurrence of a group of secondary cases; it is probable that infection came from the Continent, and possibly by means of a London resident returning infected from a visit there.

It will be noted that the death rate is over 30 per cent. London proper and parts of the home counties are inseparable so far as small-pox is concerned, for it occurs in them without respect of boundaries; the figures for the wider area are therefore of importance; they show 75 cases and 24 deaths for 1922. The rest of England, mainly the North, has had nearly 1,000 cases which have been proceeding steadily throughout the year. These have been of a light type, only one death having been reported in 700 cases. This latter type is often spoken of as "aberrant" or "atypical," phraseology not justified by the facts. Severe and mild epidemics of small-pox are equally classical, being recorded by Sydenham, van Swieten, Jenner, and many others; the mild epidemics have comprised cases which certainly must be reckoned in millions; the type is of equal interest in diagnosis, inasmuch as it displays the distribution which is characteristic of the disease.

Guiding Points in Small-pox Diagnosis, with Illustrative Cases.

If I were discussing the subject with junior assistants whom I wished to arm with sound equipment, I should beg each one of them first of all to do three simple things, which, in fact, I should make obligatory: (1) bring his own state of vaccination to date; (2) understand the few simple facts about the repeated invasion of small-pox into the country; (3) know exactly where he can get further information about small-pox. As a rule these last two points are ascertainable from the respective medical officer of health.

I should then counsel him most emphatically to place this question in his mental armoury for use during the rest of his life: "Can this case before me possibly be small-pox?" That is, he should use that test question, amongst others, in respect of every single case the diagnosis of which has not been positively made. I should tell him that while he might put this question one thousand times and have "No" for an answer, the one thousand and first case might be small-pox. That probably he would never see a case of small-pox in his life, but that the present position is such—it being now not to the point whether it be reasonable or not—but in fact is such that a single "missed" case may result in hundreds of deaths, and in hundreds of thousands of pounds sterling being spent; that in consequence of the mass of the community having divested themselves of their individual anti-small-pox protection—namely, their immunity obtainable from vaccination—an almost inconceivable strain is thrown upon our profession which is more than any human flesh and blood should be asked to undertake; that is the obligation for every one of us instantly to recognize every single case of small-pox which may be presented to him, a watch requiring an almost inconceivable degree of perfection, so that we are to be right one hundred times in one hundred. That is the task which is set us under pain of letting in a devastating and diabolical invader, an effort which we could hardly undertake to continue were it not that the laity, at last

were similar. He regarded it as characteristic of all small-pox epidemics, but there, as after events proved, he was mistaken; the Edinburgh epidemic of 1903-4 showed no such hesitation in its onset. The lesson, however, is that throughout the winter which has now begun the public authorities concerned—namely, the Guardians and the Borough Councils—should in no degree relax the efforts in which they have so actively engaged to protect the populations for which they are responsible.

It is good to learn that meanwhile the Education Committee of the Loudon County Council is exercising special vigilance over schools in the affected area. In Poplar every absentee in a group of fourteen schools is being followed up by the divisional medical officer and the borough medical officer; the scheme is working smoothly; the head teachers of the schools in question have been given any necessary advice as to vaccination of pupils, and arrangements have been made for the public vaccinator visiting thirteen of them. Under the present law there can be no compulsion to vaccination, but it is right that the offer should everywhere be freely made.

CENTRAL MIDWIVES BOARD.

A special meeting of the Central Midwives Board for England and Wales was held on November 16th, with Sir Francis Champneys in the chair. Eight cases were down for hearing and the Board removed three of the midwives from the Roll. At the ordinary monthly meeting held next day the Standing Committee considered a letter from the Macalpine Maternity Home, Manchester, forwarding a copy of the following resolution:

"The Committee of the above Home desires to urge upon the Central Midwives Board its conviction of the need for a longer and more adequate training for midwives. It asks the Board to give immediate attention to this matter and urges them, before any change is made, to make careful investigations into the methods and scope of training in other countries and into the needs of all classes of institutions employing midwives."

It was agreed to inform the Macalpine Maternity Home that the Board has already under consideration the question of lengthening the period of training. To a letter from the Central Midwives Board for Scotland it was agreed to reply:

"That in the opinion of the Board it may be a matter of extreme difficulty for a Local Supervising Authority to inspect satisfactorily in respect of cases, taken in the area of another Local Supervising Authority, as the Local Supervising Authority of the area in which the cases are taken is likely to have the better knowledge of them. The Board thinks, however, that the matter might be satisfactorily adjusted if the Local Supervising Authority concerned were to come to a working arrangement with the Local Supervising Authority of the area in which the cases are taken, for instance, the counties of London and Middlesex and in other adjacent areas."

The report on the work of the Board for the year ending March 31st, 1922, was considered and it was decided that after amendments and signature by the Chairman and Secretary it be forwarded to the Ministry of Health.

Scotland.

GLASGOW STUDENTS' HANDBOOK.

THE issue for 1922-23 of the *Students' Handbook*,¹ published at Glasgow University under the auspices of the Students' Representative Council, has appeared. The intention of this volume is mainly to enlighten the students of Glasgow on many matters which, on their entrance upon academic life, it is to their interest to know, and a great deal of information is given in it regarding the innumerable students' societies and clubs. The volume is prefaced by a little story told inimitably by Mr. R. B. Cunningham-Graham, the moral of which is that "a university training gives a man the arms with which to face life, but he has to learn to use them himself." The Student Welfare Scheme of the University is commended in an introduction by the Principal, Sir Donald MacAlister, and articles on the different faculties, and on such subjects as the O.T.C. and the higher Civil Service examinations, are contributed by authorities. In the section devoted to the Faculty of Medicine Professor E. P. Cathcart reminds his readers that the profession of medicine is going to be a crowded career, and that, although undoubtedly it is a magnificent career, the practice of medicine is difficult and its disappointments

many; it calls for enthusiasm of a robust type. Medicine, he continues, is not an art to be acquired in the few years of the student curriculum. These are merely years of elementary apprenticeship. The real knowledge, the knowledge which will be of inestimable value, is mainly obtained during the first few years following graduation, provided they are rightly used. It is rare, he says, to find the student who has really grasped and fully appreciated the fact that the curriculum, as at present designed, is not drawn up at random for the gratification of a body of pundits out of touch with reality; the presence of each subject in the course, its position in the course, and the amount of time to be devoted to it, have all received the most earnest consideration. The volume is distinguished by a cover design by Mr. Louis Raemaekers and contains many excellent photographs. It is edited by Mr. H. H. Livingstone, and he and his undergraduate committee are to be congratulated on the result of their efforts.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

The annual business meeting of the Aberdeen Medico-Chirurgical Society was held in the Society's hall on Thursday, November 23rd. The following office-bearers were elected:

President, Dr. Alexander Ogston; Vice-President, Sir H. M. W. Gray; Secretary, Dr. G. M. Duncan; Treasurer, Dr. George Rose; Assistant Secretary, Dr. H. Edgar Smith; Recording Secretary, Dr. H. Ross Souper; Editor of *Transactions*, Mr. G. H. Colt. Members of Council: Dr. J. Scott Riddell, Dr. George Williamson, Dr. Henry Peterkin, Dr. Robert Richards.

GLASGOW SEWAGE DISPOSAL.

At the weekly meeting of the Glasgow Medical Lunch Club, held on November 23rd, the guest of honour was Mr. F. W. Harris, F.I.C., analyst to the city of Glasgow. After lunch he gave an interesting address on the modern methods of sewage disposal. He pointed out that Glasgow had to deal with a dry-weather flow of 90,000,000 gallons, and he described the methods of disposal formerly in use and the improvements therein introduced in recent years. He showed how the most recent methods were really natural methods artificially intensified. The system of activating sludge by the introduction of certain insects into the media was first employed in Glasgow in 1921, and by August of this year five filters showed successful colonization. The effect of these insects saved the corporation thousands of pounds, and their efficiency resulted in a very appreciable reduction in capital expenditure on plant. The process was still in its infancy, but it gave promise of notable success. He also made reference to the high manurial value possessed by the sludge following the use of modern methods, and to its use commercially as a fertilizer. The annual return therefore in the future from this source was likely to prove a very valuable asset to the local authorities.

EDINBURGH SURGICAL APPLIANCE SOCIETY.

Sir Montagu Cotterill presided at the annual meeting of the Surgical Appliance Society in Edinburgh on November 24th. The annual report, submitted by Miss S. Malcolm, honorary superintendent, stated that during the year 237 appliances had been supplied, as against 291 in the previous year. As compared with last year only half the amount of work had been done for ex-service men, but the number of splints supplied to civilians was doubled. The amount received for splints was £153, an increase of about £25, which was accounted for by the appliances being on an average larger and more costly than previously; when the cost of materials was deducted there was only a balance of £78 towards the working expenses, which amounted to £162. Although the whole of the work was done by voluntary workers, the society was unable without outside support to cover working expenses. Sir Montagu Cotterill said that complaints had been made by some instrument makers that it was not fair and right that a society of this kind should compete with them. To take a fair view of the matter, he believed that the voluntary workers of the society who chose to spend their time and energy in making splints and other appliances for poor and necessitous people, at a price which suited their pockets, were doing a charitable work at which no one could cavil. If the society were to supply a class of patient able to pay a reasonable fee to an instrument maker then he thought it would go beyond what was right; but so long as members of the society were doing charitable work they were entirely within their rights, and that should be the basis on which they stood. The

¹ *Glasgow University Students' Handbook*, No. XI, 1922-23. Edited by H. H. Livingstone. Glasgow: The Students' Representative Council of the University of Glasgow. 1922. (Cr. 8vo, pp. 152; illustrated.)

society should make it clear to surgeons who sent it orders that it was not prepared to give them these splints at the usual price, or anything approaching it, unless they could assure the society that those patients were in such a financial position that charitable help was appropriate. Mr. Pirio Watson said that the only way he saw out of the difficulty was for the society to be accommodated in a hospital, and to become, as it were, a voluntary staff attached to a hospital, such as the Sick Children's Hospital. The chairman said that it would be worth while seeing whether the Sick Children's Hospital would entertain such a proposal. He quite agreed that it would be a good way of carrying on the society.

Ireland.

ULSTER MEDICAL SERVICES.

Dr. JOHN CAMPBELL, M.P., at the meeting of the Ulster Medical Society on November 16th, called attention to the position of the medical services under the Government of Northern Ireland; he desired the support of the Ulster Medical Society to help the medical members of Parliament to remedy the position. (1) The salary of the chief medical officer was £1,000, rising to £1,150; the parliamentary counsel to the Ministry of Finance received £1,200, rising to £1,500. The two medical inspectors received, on a basis, £500—a salary fixed twenty years ago, and they now had to make inspections of all medical services; their duties had much increased, but not their salaries; clerks formerly in receipt of £500 a year now received £1,000. The prospects of promotion for the medical officers were also substantially reduced. (2) The Ministry of Labour had now charge of the administration of the National Insurance Act; formerly there were three medical men employed, now there were none. (3) The office of Registrar General was always held by a medical man, and this was very suitable, considering the technical work; it was now under the Ministry of Finance, and the duties were discharged by a layman. (4) The very inadequate, unequal, and unfair salaries which were still being paid to medical officers in some of the unions in Northern Ireland should be reconsidered. The various unions should be placed on a more uniform and equitable basis. He moved that a committee should be appointed to draft resolutions on the points under discussion and to submit a proposal for the appointment of a permanent medico-political committee. This resolution was seconded by Dr. Morrison, M.P., and carried unanimously.

COOMBE MATERNITY HOSPITAL, DUBLIN.

The report presented to the annual meeting of the Coombo Maternity Hospital, Dublin, showed that the ordinary income of the year was £5,707, but by the receipts from the hospitals fee and the National Relief Fund, and bequests, the total was raised to £9,954. The total expenditure amounted to £5,393, but this included the purchase of premises adjoining the hospital for £234. Owing to the special efforts made the deficiency, which last year was £4,907, was reduced to £1352.

Dr. Louis Cassidy, master of the hospital, in moving the adoption of the report, said that in four years the hospital would celebrate its hundredth year, and any hospital that had been before the public for so long a time needed no further recommendation. He impressed on the meeting the importance of further apparatus for dealing in a scientific way with disease. He appealed especially for funds to provide an x-ray installation in the hospital. Five hundred women died every year in Ireland from cancer of the womb; of these, a large proportion could be saved if the hospital had the necessary scientific apparatus and an x-ray department. The apparatus would cost £600. A research laboratory also was needed, and that would cost £400 a year. A number of people who used to support the hospital had left the country for one reason or another, and another class of people had arisen who did not seem fully to recognize the responsibility they were under to support it.

The chairman said that the Coombe Hospital deserved the most earnest support of all classes and denominations. The institution was pre-eminently a city hospital, and it had been provided in the Charter that the chairman and vice-chairman should be the Lord Mayor and High Sheriff respectively. The report showed that the number of cases treated during the year was practically 7,000. That fact alone should make the citizens rally to the support of the hospital. He

suggested that they should make every effort to establish a
t and an infant welfare department.
Hospital had such departments, and
ig to mothers and infants. Workers
should also be asked to pay twopence a week of their wages
towards the support of hospitals, to which the employers
should also give a contribution. He also appealed to
the merchant princes to lend their aid to the govern-
ing body to provide the scientific equipment needed. Sir
John Moore, who seconded the resolution, agreed with the
chairman as to the necessity for an organization to provide
for mothers before pregnancy and for infants newly born.
Infant mortality was higher in Dublin than it should be;
this was due to ignorance, though not wilful, on the part of
mothers as to the care of infants. The main support of
hospitals should come from the people voluntarily, but he
agreed that appliances should be provided by the State.
The x-ray installation in the Meath Hospital cost £600, but
that was not a fair charge on the funds of any hospital. Sir
John Moore concluded by paying a tribute to the excellent
staff in the Coombe Hospital, and to the good work done
by them.

Correspondence.

PREVENTION OF PUERPERAL INFECTION.

Sir,—Nearly every year a valuable paper by an expert appears in the JOURNAL lamenting the frequency of puerperal infection. May I as a general practitioner draw attention to three points which in practice are very often neglected?

The first is the thorough washing out of the rectum by an enema or enemata in the early stage of labour. That it often encourages a hesitating os to dilate freely, that it gives more room in a forceps operation, and that it cleanses a part into which the "field of operation" occasionally extends is well known to everyone. Why is it then not a matter of routine in all confinements? Why is it not made obligatory on all midwives and nurses in the preparation of a case?

The second point is the proper use of soap. Ordinary soap is not a disinfectant, nor even a detergent *per se*. It merely disturbs the cohesion between dirt and the skin. To illustrate. I have seen a practitioner dip a piece of soap in water and rub it vigorously over the nates and vulva. Thereupon he made his examination, having used the only available hot water to wash his hands. Again, some years ago a writer in a medical journal remarked that he was so impressed with the value of soap as a cleansing agent that he was always careful in making a vaginal examination, having washed his hands, to take up a quantity of soap suds on his finger before introducing it. Soap without running water or many changes of water is often a delusion and sometimes a snare.

The third point is the avoiding of contamination of the hands in general practice. For pus some sort of protective swab is always available, and for the examination of a body cavity a rubber finger stall is essential.—I am, etc.,

Westcliff-on-Sea, Nov. 20th.

J. C. SMELLIE.

SIR,—Dr. Maclean has rendered a very important service by his presidential address to the Cardiff Medical Society (BRITISH MEDICAL JOURNAL, November 18th, p. 976) pointing out the terrible mortality rate of puerperal fever. No doubt more might be done in the way of prophylaxis—for instance, the putting of the infant to the breast at the earliest possible moment, which not only stimulates the production of milk and so benefits the baby, but also produces powerful contractions of the uterus with consequent expulsion of clots, shreds of membrane, and so on. But, in spite of all prophylaxis cases will occur. Many patients have microbes in their circulation which find in the uterus after parturition a place of low resistance. With our present resources there is no need whatever for such a mortality. In the Rotunda Hospital, while Dr. Tweedy was master and Dr. Rowlette pathologist, the death rate from puerperal fever was reduced to a very small percentage. In my own practice during the past twelve years not a single case I have been consulted about has died! Many of these cases were in cottages far distant down the country, and some were in similar dwellings in the city. It is generally thought that the manufacture of an autogenous antigen (vaccine) for such cases is a slow process. It is nothing of the kind. I have often received nterine swabs at 12 o'clock in the morning, and had the doses

of antigen a hundred miles down the country by 3 o'clock the next afternoon. It is of the utmost importance that the material for culture should be taken from the uterus before any douching of any kind has been used.

I feel very strongly about this matter, and assert again, as I have often done before, that no doctor can be considered to have done his duty to his patient in this condition who has not employed this method of treatment, for no other method has given any material results.—I am, etc.,

W. M. GROFFIN,
University College, Dublin.

November 24th.

THE LIGHT SENSE WITH REFERENCE TO NAVIGATION.

SIR,—A month ago (October 28th, p. 783) an excellent paper was published on the above subject in this JOURNAL; the author, Dr. Freeland Fergus, is a well-known yachtsman, and for that reason his views demand close study. The most noteworthy points that he emphasizes are those:

- (1) The inadequacy of our ordinary tests, which determine only macular vision; and
- (2) The importance of good field vision, which depends very largely upon the seaman's light sense.

Our present tests for seamen on watch are too severe with respect to macular vision, and will not detect a contraction of the field of view nor any failure of light sense. And yet without good peripheral vision one will not see what to look at. Peripheral vision, though very ill defined, is extraordinarily sensitive to a difference between light and shade, and it is quite independent of any refractive defect. I have found that on a very dark night both I and a myopic (—8 D.) friend without his glasses could see equally well distant objects; indeed, it will be found that motorists and bicyclists will see far better on a dark night without their glasses than with them. This is no doubt due to the fact that a considerable part of the incident light (17 to 20 per cent.) is reflected and absorbed by the glasses, and in a very dim light the "marginal utility of the commodity," to use an economist's term, is very high.

I note with pleasure that the author states his strong preference for Landolt's broken-ring test types, which I have strongly urged that the Council should recommend as the standard test for macular visual acuity; it is international, and is well adapted for illiterates.

Neurologists should be very grateful to Dr. Fergus for urging them to test the light sense of their patients. A defect of the light difference test is probably the earliest symptom of a lesion in the optic nerve; it will reveal a retrobulbar neuritis, which most physicians neglect, as it is not associated with the obvious signs of a choked disc, and yet pathologically it has the same significance. A retrobulbar neuritis is merely a choked disc which owing to anatomical peculiarities occurs further back, usually at the optic foramen.—I am, etc.,

ARCH. STANLEY PERCIVAL.

Newcastle-upon-Tyne,
Nov. 27th.

THE TREATMENT OF ACUTE SALPINGITIS.

SIR,—The operation which Mr. Aleck W. Bourne advocates (November 18th, p. 998) is useless for the purpose which he has in view—namely, the prevention of sterility—because the adhesions in the drainage area will almost certainly prevent the ovum from getting into the tube. It is mischievous, because, if the other tube be healthy, pelvic drainage is very likely to cause adhesions which will destroy its function. It is also likely to be a cause of vexation to both surgeon and patient, because the secreting lining of the split tube may cause a sinus in the track of the drain. If we desire to give a patient suffering from suppurative salpingitis the best chance of future pregnancy, we must avoid drainage. The bulk of the tube must be removed; a new mouth must be made for the portion left; and the abdomen must be filled with saline solution and closed without drainage. This procedure attains the three objects mentioned by Mr. Bourne. His own method does not.

As regards the analogy between an inflamed appendix and an inflamed tube, the facts are: In a well-defined case the inflamed organ, whether appendix or tube, forms a bag of infective material. Either may burst and quickly cause death. Either may form a localized abscess, abdominal or pelvic. Either may temporarily recover and become subject to recurrent acute inflammatory attacks. Either may permanently recover and give no further trouble. There is such an obvious similarity between the two organs when inflamed that it is proper to remove them when the attack is severe

and dangerous. The surgeon no longer poultices the acutely inflamed appendix. The gynaecologist continues to poultice the equally acutely inflamed tube by means of hot douches and perhaps vaginal tampons. The inconsistency of the gynaecologist is sometimes seen when he opens the abdomen to remove what he has diagnosed as an acutely inflamed appendix and finds the cause of the trouble to be, not the appendix, but an inflamed tube. He then removes the tube. It seems strange that he should remove the tube when he comes upon it by accident, and should so strongly object to operate upon it when he knows it to be the seat of the trouble.

My critics are confused. Possibly their state of mind results from the fact that the appendix seems to have no important function, while the tube is necessary for reproduction. They forget that a tube which is the seat of an acute or chronic pyosalpinx, or even of a hydrosalpinx, has lost its function and has become as useless as an appendix. They also forget that operation on such a tube affords the only hope of restoring its function. Some of my critics may possibly be influenced by the fact that it has become customary to remove the appendix when the evidence against it is very slight, and indeed to excise it frequently or suspiciously. They fear that the poor tube may get the same scanty measure of justice. This is no argument against the contention that a badly inflamed tube should be operated on as soon as possible. That the surgeon is an appendix-snatcher is no reason why the gynaecologist should become a tube snatcher.

When I was honoured by an invitation to open the discussion on this subject in Glasgow I knew that I had no need to go out of my way to be provocative. I had only to follow the trend of much of the most recent literature and of my own thoughts to excite opposition. "My head is bloody but unbowed."—I am, etc.,

JOHN CAMPBELL.

Belfast, Nov. 21st.

THE ALEXANDER-ADAMS OPERATION.

SIR,—In common with a large number of readers I have read with interest the summary of Dr. Bethel Solomon's presidential address at the Obstetrical Section of the Royal Academy of Medicine in Ireland on tuberculosis of the female pelvic organs (BRITISH MEDICAL JOURNAL, November 25th), with the subsequent discussion (taken part in by physicians and surgeons as well as by gynaecologists of renown), which cannot but be of mutual benefit, especially on a subject like this which overlaps all departments.

I have no criticism to make on the general subject of the discussion, which will well repay perusal, but I would take exception to a statement made by Sir William Smyly and endorsed by Dr. Solomon, that he hoped the paper had given a death-blow to the Alexander-Adams operation. I have not of course had the advantage of reading Dr. Solomon's paper in full, but I would protest strongly against such a sweeping condemnation of an operation which has a useful rôle, albeit a limited one, in gynaecology.

The Alexander-Adams operation has fallen into disrepute mainly from the fact that it has been done so often in unsuitable cases—surely no reason for discarding it when performed with judgement and ordinary prudence. I shall not here enter into the indications and contraindications for the operation, but would only say that a careful pelvic examination, if necessary under an anaesthetic, can in practically all cases eliminate the conditions which would render the operation unsuitable or undesirable.

Dr. Solomon states that he has opened the abdomen in several women suffering from tubal disease on whom the Alexander-Adams operation had been performed. That merely shows that the operation had been performed in an unsuitable case, or that tubal mischief had developed later. No one deprecates the indiscriminate resort to the Alexander-Adams operation more than I do, but I would equally deprecate the indiscriminate condemnation of an operation which has proved itself of value in certain cases even in these days when the peritoneal cavity is not always opened with discrimination.

I have occasionally had to open the abdomen after an Alexander-Adams operation where an ovarian cyst or an ectopic pregnancy had subsequently developed, but manifestly the Alexander-Adams operation was not to be blamed for that.

I have invariably found that the Alexander-Adams operation stands the strain of subsequent pregnancy better than

any of the intra-abdominal operations on the round ligaments, and I have seen no instance of failure, even after three subsequent pregnancies. As an indication of the limited number of cases suitable for the Alexander-Adams operation, I would say that in a large yearly operative turn-over in hospital and private, perhaps about twelve cases will be found where the operation can be really recommended. Peradventuro even twelve successful cases per annum in the experience of one operator may lead Sir William Smyly and Dr. Bothel Solomons to withhold their threatened death-blow from the Alexander-Adams operation.—I am, etc.,

JAMES HAIG FERGUSON, M.D.,
F.R.C.S. Edin.

Edinburgh, Nov. 26th.

TREATMENT OF FEVER.

SIR,—I have read with interest the letter in your issue of November 18th (p. 1000) containing arguments in favour of treating various acute diseases with a compound powder containing aspirin gr. x, phenacetin gr. v, and pulv. ipecac. co. gr. v.

My experience with this combination of drugs in acute specific diseases and in all conditions of acute toxæmia has been very similar to that described by Surgeon Commander Parnell and others. In my opinion the importance of this line of treatment cannot be overestimated.

As I understand it, recovery from acute toxæmia (any acute disease) is due to that increase of resisting power which we call "acquired immunity," and that the essence of such acquired immunity is an habituation to the particular toxin of the disease from which the patient recovers—just as a man becomes used to nicotine or a horse to diphtheria toxin.

There are three ways in which an individual may become habituated to a toxin: (1) by a huge and continuous dose, as in disease—a dangerous method; (2) by weakening the toxin and so providing stopping stones for reaction, as in vaccination and serum treatment; and (3) by giving small doses of the toxin, as in tobacco and opium smoking and in those cases in which individuals remain immune to a disease (for example, yellow fever) as long as they dwell in a country where it is prevalent but acquire it after return from a country where it is not prevalent.

This new treatment applies the third method. By means of it toxins are continually withdrawn in the sweat, so that the individual experiences a series of small doses. The applications of the treatment are more numerous, and it is more easily applied than the serum treatment. At any rate it opens out a new line of inquiry and ultimately may prove as useful as the serum treatment itself. In conjunction with serum treatment (for example, in diphtheria) it is admirable.

Doubtless there are injurious ways of lowering the temperature, and it is an axiom in medicine that the temperature in acute diseases should not be too much lowered by artificial means; but only those who have employed this treatment when themselves suffering from acute disease are able to appreciate the extraordinary and immediate relief and benefit which follows. What can be the explanation other than that which I have indicated?—I am, etc.,

W. BASTIAN,
Surgeon Commander R.N.

H.M.S. Victory, Portsmouth, Nov. 29th.

SIR,—The prescription given in the letter on the treatment of fever in your issue of November 18th (p. 1000) was extensively used in the British Stationary Hospital, Baghdad.

It was used as an almost universal prescription in most of the fever cases admitted. Admissions numbered anything up to 35 per diem during the sandy period of the year, and it invariably relieved the symptoms. To the first powder given on admission calomel gr. iv was added.

During one busy day a sergeant (R.A.F.) was admitted with typical symptoms of sandy fever. I noted, however, that the pain in the back was more severe than usual; the temperature on the third day was normal, the chart being a typical one of sandy fever. The above prescription was used. The following day he complained of heat rash. This struck me as peculiar, as his temperature was normal; on examining him I found him to be suffering from small-pox. His symptoms were only mild, and he was never very ill; he had never been vaccinated. This may have been due to the elimination of toxins through the skin in the early period of the disease. As he was sent to the isolation hospital the case was lost sight of; unfortunately just one month later, when convalescence was just established, he died suddenly, from what cause I do not know.

We got to believe in this prescription to such an extent that we invariably gave it to all heatstroke cases. During

the hot weather of 1921 the percentage of deaths from heatstroke was much lower than it had been previously; whether this had anything to do with the administration of this prescription is, of course, an open question, but it certainly tends to give one faith in using it.—I am, etc.,

T. GELSTON ATKINS,
Captain R.A.M.C.

London, W.C., Nov. 23rd.

SIR,—I noted with considerable interest the joint letter of Surgeon Commander Parnell, Dr. Green, and Sir Archdall Reid. For several years I have employed an almost identical prescription with such general satisfaction that I sometimes accuse myself of using it almost as a placebo. The intention is very remote from this, and although its original use was in some degree empirical it had a liberal element of pharmacological justification. The prescription is very simple: Aspirin, pulv. ipecac. co.—āā gr. x. During the paroxysms of malaria its effect is extremely comforting and beneficial, as I demonstrated in a recent paper (*Medical Officer*, October 21st, 1922). In the prodromal stages of ordinary catarrhal colds and influenza it produces not only a sense of well-being but I am sure often stops further developments. In the notorious P.U.O. of active warfare days, which no doubt had a definite though unknown pathology, one found its use very satisfactory. In such cases as parotitis appearing as a metastatic effect following laparotomies I have seen marked relief. In short, in most febrile states, including the exanthemata, its effect is marked and valuable.

Whether its use is specific or purely palliative, as one is almost compelled to suppose, it is nevertheless a most useful simple combination. Pulv. ipecac. co. in doses of gr. x practically never induces emesis in adults.—I am, etc.,

London, S.E., Nov. 18th.

—DONALD BUCHANAN.

THE SMALL-POX OUTBREAK AT POPLAR WORKHOUSE.

SIR,—Dr. C. S. Thomson, in his letter in the *BRITISH MEDICAL JOURNAL* for November 25th, says that:—

The "unmodified first case, in actual practice, would not be likely to oblige by walking right into the arms of a medical man. More than likely the sufferer would have visited forty or fifty public houses, churches, or cinemas," etc.

I suggest that Dr. Thomson is quite wrong. The unmodified case of small-pox, in my experience, is much too ill to visit places of entertainment, and if he does not go to the doctor he goes home to bed and sends for the doctor to come to him.

Dr. Thomson tells us that his prescription for preventing small-pox is "vaccination at infancy, revaccination at 12 to 14, and a third session at 21," with additional vaccinations as and when necessary. I quite admit that if such a prescription could be applied to the whole population, without exception, small-pox would be quite effectually controlled; but Dr. Thomson must know quite well that such a prescription never has been, is never likely to be, and indeed never could be applied in this or any other country. Moreover, granted that it could be applied, I venture to suggest that the premium to be paid (in the form of so much vaccination) is out of all proportion to the risk to be insured against. Why saturate forty-five millions of people, old and young, with vaccination when there is good reason to believe, from the experience of the past twenty years, that small-pox can be effectually controlled without it? As well advocate the repeated inoculation of the entire population of this country against enteric fever. Perhaps Dr. Thomson would do so, but few common-sense business men would think of listening to him.

As regards Dr. Stansfield's letter, he says that even if we got rid of the danger arising from modified small-pox in vaccinated subjects there would still remain a possibility of missed cases in naturally mild small-pox in unvaccinated persons. My answer to this is that naturally mild small-pox tends to "breed true," and gives rise to a mild strain of small-pox with a negligible mortality (small-pox of this type is really not worth the fuss that is often made about it). Small-pox modified by vaccination, on the other hand, does not breed true, and, so far from giving rise to modified small-pox, it may and often does spread a very virulent form of the disease. Hence vaccinated (but incompletely protected) persons may be a far greater danger to their neighbours than the unvaccinated, under present-day conditions, are ever likely to be.

It is interesting to learn that all of the 22 fatal cases in the present outbreak had been vaccinated, presumably in infancy.

It does not look as if the neglect of infantile vaccination in the East End had had much to do with the present outbreak, certainly not with its fatality. On the other hand, if, as I suspect, the man who originated this disastrous outbreak had been vaccinated, and if the nature of his attack was not diagnosed because it had been "masked" by vaccination, then it would not be unreasonable to contend that not neglect of infantile vaccination, but the presence of it was responsible. This may seem a hard saying, but it may be true and worthy to be believed nevertheless.—I am, etc.,

Leicester, Nov. 27th.

C. KILLICK MILLARD.

Obituary.

CHRISTOPHER VISE, M.D.,

Physician to the General Hospital, Tunbridge Wells.

Dr. CHRISTOPHER VISE of Tunbridge Wells died on November 14th, aged 66. He was the son of Mr. Edward Vise, surgeon, of Holbeach, and received his medical education at University College, London, and the University of Durham, took the diploma of M.R.C.S.Eng. in 1880, and graduated M.B.Durh. in 1882 and M.D. in 1884. After serving as ophthalmic assistant at University College Hospital, house-physician to the Hospital for Consumption, Brompton, and assistant demonstrator of anatomy at the University of Durham, he became house-surgeon and secretary of the General Hospital, Tunbridge Wells, from 1882 to 1887, and in 1893 was appointed an honorary physician, which post he retained until his death. He was gazetted surgeon lieutenant to the old Kent Volunteer Battalion in 1893, and received the Territorial Decoration on completion of twenty years' service. During the first two years of the war he served with the rank of Major R.A.M.C. as medical officer to the 4th Battalion Queen's Own Royal West Kent Regiment and the 5th Battalion of the Buffs. During the last two years of the war he was in charge of military hospitals at Doncaster and Workson, and concluded his period of war service on the headquarters staff of the northern command at York. On demobilization he returned to Tunbridge Wells and resumed his duties as senior physician at the General Hospital. He was a member of the Tunbridge Wells Division of the British Medical Association, and for many years honorary physician to the Convalescent Hospital for Children at Hawkenbury; latterly he was local referee to the War Pensions Committee. He took a great interest in freemasonry, and served in 1890 as Worshipful Master of the Holmesdale Lodge, with which he had been connected for forty years. He leaves a widow, a daughter, and three sons. His sons all passed through Tunbridge School with distinction, and two of them gained scholarships to Oxford.

Sir STCLAIR THOMSON sends us the following notes: Christopher Vise was my very oldest friend in the profession, for we both commenced our studies together in the now extinct stage of "apprentices." He and I were "pupils" in the Infirmary in Peterborough under the well-known Dr. Tom Walker, who was one of the most distinguished surgeons in the Midlands of his time; his name will go down in the history of laryngology as being the first in this country to remove a growth from a vocal cord, through the mouth, by the help of the laryngoscope. Vise represented the sixth generation of medical men in one family who had all practised in the south of Lincolnshire. He presented to the Medical Society of London during the year that I was President (1917) the patent of election of that body given to his great-grandfather. It is printed in Latin, dated "*Die Martis, 4to Augusti, 1789*," and is addressed to *Viro Celeberrimo Gulielmo Vyse, Chirurgo Praeses et Societas Medica Londinensis S.P.D.*" In his sterling character, genial manners, guileless nature, and unselfish service to friends and patients, Christopher Vise was a worthy descendant of this long line of medical men. His simple-hearted devotion to all his duties—private, professional, or civic—his unruffled temper, and his delightful urbanity, made everyone his friend. He lived to please and to be pleased, and all who knew him rejoice to think that he never made an enemy.

The death took place on November 17th at Hampstead of Dr. JAMES ANDREWS, in his 93rd year. He was born at Pershore, and served, as was then the custom, an apprenticeship in his native town. In 1848 he entered as a student at Guy's Hospital. At this time Aston Key was at the height

of his career, and Addison and Bright were active members of the staff. Dr. Andrews was dresser to Brunsby Cooper, and after taking the diplomas of M.R.C.S. and L.S.A. in 1851, and the M.D. Andrews in 1854, commenced practice in the Camden Road. In 1872 he removed to Hampstead and continued in active practice there until his retirement in his 80th year. He knew and had interesting reminiscences of most of the great consultants of the last century, and his greatest admiration was for Sir Thomas Watson. To the last he retained all his faculties, and took a keen interest in modern developments both in medicine and public affairs. His son, Dr. E. Collingwood Andrews, is in practice at Hampstead.

We regret to announce the death, in his 67th year, of Dr. DAVID MAYER, an esteemed country medical practitioner of Bucksburn, near Aberdeen. Dr. Mayer graduated at Aberdeen University M.B., C.M. in 1878. Besides having an extensive practice in Bucksburn he had several parochial appointments, and was superintendent of the Summerfield Hospital. He was a justice of the peace for the county of Aberdeen and was also member of the educational authority.

Universities and Colleges.

UNIVERSITY OF LONDON.

The following candidates have been approved at the examination indicated:

DIPLOMA IN PSYCHOLOGICAL MEDICINE (with special knowledge of Psychiatry).—H. E. L. Canner, G. F. Cobb, R. D. Gillespie, D. I. O. Macaulay, D. Matthew, H. M. North, W. R. Page.

A course of five lectures on "The nature of ultramicroscopic viruses" will be given by Mr. F. W. Twort, superintendent of the Brown Institution, in the theatre of the Royal College of Surgeons, Lincoln's Inn Fields, W.C., on December 11th, 12th, 15th, 18th, and 19th, at 4 p.m. Admission will be free without ticket.

UNIVERSITY OF GLASGOW.

The following appointments to bursaries are announced:

The Arthur (Medical) Bursary, value £20 for three years, to Mary G. Gorgie, who took the highest place among the Queen Margaret College students of the University.
The Noble Bursary, value £34 for three years, to David Hynd, M.A.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

An extraordinary Committee of the Royal College of Physicians of London was held on Friday, November 24th, when the President, Sir Humphry Rolleston, was in the chair.

Licences to practise physic were granted to Cyril Rickwood Lane and Ella Kennedy Will.

Permission was granted to the Museum Galleries to photograph certain oil paintings in the possession of the College, and to the Dean of the Middlesex Hospital Medical School to have a copy made of the portrait of Sir Thomas Watson. It was agreed to lend to Mr. Percy Bigland (who painted it) the portrait of Sir Samuel Wilks, now in the College, for the purpose of exhibiting it at the Corporation Gallery Hall.

The resignation of Dr. R. A. Young of the office of Examiner on his appointment to the Committee of Management was accepted as from July, 1923.

The President announced that Dr. Kenneth N. G. Bailey has been appointed Streatfeild Research Scholar.

Dr. H. G. Turney was appointed Representative of the College on the Council of the Queen's Jubilee Fund for Nurses, vice Sir Dyce Duckworth, resigned.

Sir Humphry Rolleston was elected Representative of the College on the General Medical Council, vice Sir Norman Moore, resigned.

The Services.

DENTAL OFFICERS, R.N.

At the recent examination of candidates for entry into the Royal Navy as dental officers, held at the Royal Dental Hospital of London, in November, the following qualified for appointment:

J. M. Park, L.D.S. (Glasgow); W. T. L. Douglas, L.D.S. (London); J. L. Edwards, L.D.S. (Liverpool); S. E. Brown, L.D.S. (Dublin).
The names are arranged in order of merit.

The fourth annual 19th Casualty Clearing Station dinner will be held at the Imperial Restaurant, 62, Regent Street, London, on Friday, December 15th. All who were active members of, or associated with, 19th C.C.S. are invited to attend. Tickets, 15s., exclusive of wine, may be obtained from the Rev. E. C. Doddrell, 6, Alexandra House, Regent's Park Road, Finchley, N.3.

Medical News.

A REUNION dinner of graduates and undergraduates of the Durham University College of Medicine will be held at the County Hotel, Newcastle-upon-Tyne, on Thursday, December 14th, at 7.30 p.m. The chair will be taken by Professor H. Bruntton Angus, and the guest of the evening will be Mr. Cecil A. Cochran, M.A., D.C.L. Applications for tickets (undergraduates 6s., graduates and others 12s. 6d.) should be sent to Mr. G. C. Parkin, College of Medicine, Newcastle-upon-Tyne, on or before December 6th.

SIR ARTHUR NEWSHOLME, K.C.B., M.D., will give two Chadwick lectures on relative values in public health at the Royal Society of Medicine on Thursdays, December 7th and 14th, at 5.15 p.m. on each day. Sir James Crichton-Browne will preside at the first lecture, which will deal with vital statistics, professional and popular education, and the influence of general sanitation, specific sanitation, and combined action. The second lecture, at which Mr. W. Addington Willis, a Chadwick trustee, will be in the chair, will deal with the degrees of preventability of disease and with financial questions.

THE annual dinner of the Epsomian Club will take place at the Trocadero Restaurant on Thursday, December 14th, at 7.30 p.m. The price of the dinner will be 12s. (exclusive of wine) and will be collected at the table. Any members intending to dine are requested to notify the honorary secretary, Mr. S. Maynard Smith, 49, Wimpole Street, W.1, as soon as possible, and to give the names of friends they wish to sit near so that table plans may be prepared.

PROFESSOR S. LYLE CUMMINGS, C.B., will read a paper on "Acquired resistance to tuberculosis: a factor in clinical type and prognosis," at the meeting of the Bristol Medical-Chirurgical Society on Wednesday, December 13th, at 8 p.m. The meeting will be held in the medical library of the university. Dr. J. A. Nixon, C.M.G., president, will be in the chair.

THE King has appointed Dr. Percy James Kelly (Surgeon General) to be a member of the Executive Council of the Colony of British Guiana.

AT a meeting of the Association of Economic Biologists to be opened in the Botanical Department of the University of Manchester on Friday, December 15th, Dr. W. Lawrence Balls will introduce a discussion on genetics in relation to applied biology. After dinner (in the university refectory) informal discussions will take place on the place of applied biology in universities, and on the relation of biology to medicine. On Saturday a visit will be paid to the British Cotton Industry Research Association at Didsbury.

THE Industrial Fatigue Research Board has issued a report containing two documents, one, on the influence of temperature and other conditions on the frequency of industrial accidents, by Miss Ethel E. Osborne and Dr. H. M. Vernon, and the other, on the relation of fatigue and accuracy to speed and duration of work, by Mr. B. Muscio. We intend to publish a review of the report in an early issue.

THE annual dinner of the Chelsea Clinical Society was held on November 22nd at the Café Royal, with Dr. Campbell McClure, president of the society, in the chair. Sir Sydney Russell-Wells, in proposing the toast of "The Chelsea Clinical Society," pointed out the advantages of the smaller informal medical societies as contrasted with those which were larger and necessarily more formal. In the smaller societies it was better, he said, to discuss things freely without set papers, to discuss failures as well as successes, and to encourage the spirit of research rather than to have as their ambition volumes of printed transactions lying unread in some dusty library. Dr. Campbell McClure, in his reply, said that their society included men from all the many and varied branches of the medical profession. He emphasized the benefit that some years' experience of general practice gave to the specialist, and the value to the surgeon of having been a house-physician. It was a great advantage to the general practitioner to make a point of being present at operations on his own patients. The health of the guests was proposed with many compliments by Mr. Ivor Back. Sir Humphry Rolleston, President of the Royal College of Physicians, recalled, in reply, the many links between Chelsea and the Royal College of Physicians; Sir William Hale-White, President of the Royal Society of Medicine, also replied. The health of the chairman and officers of the society was proposed by Dr. Halls Dally, who stated that the society was never in a more prosperous condition than it was at present; Dr. Campbell McClure and Dr. Eckenstein (treasurer) replied. During the course of the evening some excellent songs were sung by Captain Radcliffe and by Mr. Norman Long.

THE Home Secretary gives notice under date November 24th that in view of the fact that the Dentists Act, 1921 (which prohibits the practice of dentistry by persons who are not registered dentists), comes into force on November 30th he has withdrawn as from the same date the special authority under the Dangerous Drugs Act, 1920, which was given to certain unregistered dentists to purchase local dental anaesthetics containing cocaine. On November 30th those unregistered dentists—if any—to whom the special authority applied, and whose names have not been put on the *Dental Register*, ceased to have any authority to be in possession of cocaine solutions, and should dispose forthwith of any stocks remaining in their possession to an authorized person.

THE third annual dinner and dance arranged by the Panel Committee for the County of London will take place on December 7th, at 7.30 p.m., at the Connaught Rooms, Great Queen Street, Kingsway, W.C.2. Tickets (gentlemen 21s., ladies 15s., exclusive of wine) may be obtained from Dr. Robert J. Farman, Staple House, 51, Chancery Lane, W.C.2. All practitioners will be welcomed. Carriages at 2 a.m.

THE annual dinner of the Medical Society of University College Hospital will take place on Tuesday, December 12th, at Gatti's Restaurant, Strand, at 7.30 p.m. Mr. T. H. Somervell, F.R.C.S., who was a member of the Mount Everest expedition, and has returned to England lately, will be the guest on this occasion. Tickets, 10s. 6d. each, may be obtained from the honorary secretary, J. A. Hadley, University College Hospital.

THE annual address before the Newcastle and Northern Counties Medical Society will be delivered on Thursday, December 7th, at 4.30 p.m., in the Physical Theatre, Armstrong College, by Sir Humphry Rolleston; the title of the address is "Some reflections on high arterial blood pressure." The annual dinner is to be held on the evening of the same day, when the guest will be Sir Humphry Rolleston.

AT a meeting of the Maternity and Child Welfare Group (Metropolitan and Home Counties) of the Society of Medical Officers of Health on Tuesday, December 12th, at 5.15 p.m., Mr. Eardley Holland will read a paper, well illustrated with lantern slides, on the dangers of breech presentation to foetal and infant life. The meeting is open to members of the medical profession.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR OF THE BRITISH MEDICAL JOURNAL, *Aitology*, Westrand, London; telephone, 2630, Gerrard.

2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.

Telephone, 4361, Central.

QUERIES AND ANSWERS.

INCOME TAX.

"D. B. J. F." asks whether he can deduct as professional expenses a proportion of the rates, ground rent, and repairs of his leasehold house.

* We assume that our correspondent has a consulting room and, probably, other professional accommodation at his residence. He is entitled to include in his professional expenses a reasonable proportion of the rates and repairs and of the net assessment to income tax, Schedule A, of the property. This latter deduction takes the place of a proportion of the ground rent.

"H. J. H." bought a secondhand 10-h.p. Singer in 1920 for £350, and sold it in 1922 for £80; in that year he purchased a new 10½-h.p. Fiat for £735, claiming as an expense £735 - £80 = £655.

* The amount allowable is £350 - £80 = £270 only; the balance of the expenditure—namely, £385—was incurred in improving, not merely in maintaining the equipment.

"W. G.'s" ear transactions have been as follows:

1920.	Overland car bought for	£505
1922.	" sold for	£150
1922.	Rover " bought for	£350

The price of an Overland car similar to the one sold is understood to have been £268 when the Rover car was bought.

"In our opinion "W. G." is entitled to claim the amount expended, provided that he does not increase the amount of capital sunk in his equipment. On that basis his allowance would be £505-£150=£355. We assume that the question is not complicated by his having received an allowance for the Overland car as an expense of 1920.

FIRST AID IN COAL MINES.

"COLLIERY SURGEON" asks if there is anything published that could be of use, as far as the first aid attention to wounds is concerned, to the comparatively untrained attendant of a colliery ambulance room, who works under the colliery surgeon's weekly supervision.

A STRANGE "WILD-FOWL."

DR. JAMES R. WHITWELL (Melton) writes: It is probable that this is one of the Ixodoid Acarine which not infrequently attach themselves to my mammal, and are usually obtained from herbage of some kind. The description given, however, is insufficient for identification. They are to be found even in the high civilization of the Midlands!

DR. J. D. RONSON (Dunfriess) writes: I would suggest that Dr. F. G. Layton's strange "wild-fowl" was one of the Arachnids or ticks which infest sheep and sometimes dogs. Shepherds are often affected by them after sheep-shearing, and if the parasite gets itself well dug in it is no easy matter to remove it. Some time ago a child was brought me with one attached to the back of the neck, and it was so gorged with blood that it looked like a naevus until its movements gave it away.

SURGEON REAR-ADMIRAL W. EAMES, R.N., retd. (Bournemouth), writes: The strange "wild-fowl" would appear, from Dr. Frank G. Layton's account of the tenacious hold it had on the patient's skin, to be the ordinary sheep tick, which so frequently attaches itself to dogs moving in sheep-grazing areas, and the removal of which, owing to its extremely firm hold on the skin, causes, in some instances, much pain.

WARNING THE GARAGE.

DR. GEO. SMITH SOWDEN (Elghin) writes to recommend Brown Bros. "Buckingham" radiator lamps. "I used one," he continues, "in a very cold part of the country all last winter, with excellent results. The lamp is constructed on the principle of the miner's safety lamp, and, when not used on the ear, can be used as a garage light. Paraffin is the fuel to employ, and if the frost be very keen a rug thrown over lamp and radiator is quite sufficient." The cost of the lamp is 32s. 6d.

"ANOTHER ROVER" suggests the use of Davy, colliery lamps—one, two, or three, according to the weather—under the bonnet, provided the garage is not draughty.

MESSRS. GAMAGE (Holborn, E.C.1) have on sale the Ever Warm radiator lamp, made on the principle of the miner's lamp, price 17s. 6d. It is recommended for warming garages.

LETTERS, NOTES, ETC.

BAD ARMS AFTER VACCINATION.

We publish in this issue under the title "The Art of Vaccination" (p. 1099) a statement which a very experienced public vaccinator has been good enough to write, giving the precautions which in his opinion should be taken to prevent the occurrence of "bad arms," and we may be able to recur to the subject in a future issue. Meanwhile we may say that Dr. Edgar J. Tyrrell (London, E.C.3) has written to recommend the local application of a 10 per cent. solution of glyco-thymoline if the arm is swollen and irritable.

THE VIOLATORS OF VACCINATION LAW.

DR. C. D. SOMERS, Public Vaccinator (Aldeburgh-on Sea), writes: Night I point out to Dr. H. P. Reynolds (November 18th, p. 1004) that all a J.P. has to do is to witness the signature of the applicant and has not to satisfy himself whether the applicant is a conscientious objector or not. If the applicant insists that he is, the J.P. cannot refuse to witness his signature. I used to think it was the fault of the J.P., but I no longer think so.

REMOVAL OF A PAPER FASTENER FROM THE BRONCHUS.

MR. E. MUSGRAVE WOODMAN, F.R.C.S. (Birmingham), writes: I congratulate Mr. Herbert Tilley not less on the successful issue of his case than on the polished English of his article. Only those accustomed to work in the dismal and dark recesses of these tubes can fully appreciate the difficulties that may be met with. Not the least of these is the impossibility of having at hand the right instrument for each particular case—in regard both to length and to forceps ends. I sympathize with the words of Chevalier Jackson: "When I have fully diagnosed a case

I go into my workshop and make an instrument of appropriate length and design for the work it has to do." One thing I am sure of: Mr. Tilley need make no apology for the use of general anaesthesia. We in this country are blessed by the help of anaesthetists trained to an extent not often found either in Europe or America. I think that general anaesthesia will always be the method of choice in this country.

THE DETERMINATION OF SEX.

DR. J. WEST (Rama, Dacca, Bengal) writes: Dr. R. W. Marsden, in your issue of September 30th, 1922 (p. 616), brings forward a new theory regarding the determining factors in the production of sex in man. During the past six years from time to time letters have appeared discussing this subject. This has caused me some surprise, and at times some confusion. I was on the point of writing to inquire whether the theory expressed sufficiently definitely by E. G. Conklin of Princeton University (*Heredity and Environment in the Development of Man*, Oxford University Press, 1915) was not generally accepted as regards man, since these frequent revivals of the "problem" appeared to ignore it. It so happened, however, that before I had carried out my intention the mail brought in the 1922 edition of this book, in which I read on page 166: "These discoveries appear to settle once for all this vexing question and to establish the fact that in man, as well as in many other animals, sex is determined..." Instead of completing the quotation I prefer to refer your correspondent to the original work.

PLURIGLANDULAR TABLETS.

"B." writes, in reply to "Stratford": I have tablets (P. D. and Co.) for about three. I take one in the morning and another in the evening. They are markedly restorative when one feels effects. They do not tend to preserve the eyesight, however, nor help a cardiac murmur. I propose to try hexaglandular tablets for a while. When bicycling and climbing in Switzerland this summer I found that children of 16 were greatly helped by such a "tetra" tablet when tired, though the effect soon wore off.

SCOPOLAMINE-MORPHINE DURING LABOUR: CORRECTION.

DR. N. HIRSCHMAN calls attention to an error of dosage printed in his paper on the "standardized-dosage" method of using scopolamine-morphine during labour (*BRITISH MEDICAL JOURNAL*, October 14th, 1922). Under "Results" (p. 670, col. 2) the first two lines of Series I should read as follows: "The cases in this series had no initial dose of 2/3 grain omopon and 1/150 grain scopolamine, with an hourly injection of 1/450 grain scopolamine."

A PHARMACIST'S OATH.

DR. ROLAND GUEBARD (St.-Cézaire) has recently sent to *La Chronique Médicale* a copy of the oath taken by pharmacists in France in the seventeenth century. It may be freely translated as follows:

I swear before God, the author and creator of all things, to respect and serve as well as in me is, not only the doctors of medicine who have given me instruction in pharmacy, but also my pharmacist teachers under whom I have learnt.

Not to speak evil of my former doctors, pharmacist teachers, or any other persons, whoever they may be.

To do all that I possibly can for the glory, honour, ornament, and dignity of the profession.

Not to teach its secrets and curiosities to idiots or unsuitable persons.

Not to do anything rashly without the advice of doctors.

To conduct myself properly with women when it is necessary to apply a remedy, and never to give any kind of poison to any person.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 29, 32, 33, and 34 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 30 and 31.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 203.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

		£ s. d.
One line under	...	0 9 0
Half single column	...	0 1 6
Half page	...	7 10 0
Whole page	...	3 15 0
	...	10 0 0
	...	20 0 0

An overage line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 423, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *poste restante* letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

412. Diagnostic Signs in Scarlet Fever.

G. MOURIQUAND, L. LÉORAT, and PAVLOVITCH (*Journ. de Méd. de Lyon*, October 5th, 1922, p. 587) refer to the difficulty of diagnosis in some cases of scarlet fever. A scarlatiniform rash may appear in the course of other exanthemata, in septicæmia, drug intoxications, and anaphylaxis (serum rashes or alimentary urticaria). Some cases of scarlet fever show an atypical or no eruption, or the disease may be associated with another exanthem—for example, diphtheria. Desquamation may follow a scarlatiniform erythema, further confusing the original diagnosis. The authors describe eight new clinical signs. "The sign of the bend of the elbow" (signe du pli du coude) described by Pastia consists of single or more often several bright red lines (changing later to port wine colour) appearing in the flexures of the limbs, in the axillæ, neck, and groins at the commencement of the eruption, and lasting for some time after its disappearance, in the form of a rather intense linear ecchymosis. The explanation given for this sign is that the skin in these regions is more delicate, and therefore more readily injured, than elsewhere. To elicit the sign the forearm should be extended and the skin of the flexure of the elbow gently drawn up and down to render it smooth. The authors state that this sign is very valuable as it is positive in from 90 to 99 per cent. of cases of ordinary scarlet fever, but in the "puerperal" form the authors have found it only in 20 per cent. It is scarcely ever found in erythema or the other exanthemata, but they have seen it occasionally in rubella and in recurrent scarlatiniform erythema. The persistence of the sign after total disappearance of the scarlatiniform rash may enable a retrospective diagnosis to be made. The authors do not regard any of the other signs described by them as reliable, neither do they place any value on chemical tests of the urine, nor on differential leucocyte counts and complement deviation. They rely on "the phenomenon of extinction"—the serum of a convalescent patient whose scarlet fever occurred more than three weeks previously, or that of a normal person who has not had the disease, has the peculiar property of extinguishing the scarlatiniform rash in the region in which it has been injected hypodermically. The authors describe the technique: 20 c.cm. of blood are drawn off in two tubes, one of which is subjected to the Wassermann test; the other is placed in an ice-chest until the serum separates; this is then decanted into sterilized 1 c.cm. ampoules. Some writers recommend that it be inactivated at 56° C. for one hour, others add phenol to the serum, but the authors and other observers consider that the reaction is more distinct if unheated serum be used. Care must be taken to inject the serum beneath the Malpighian layer, otherwise a hila forms and the test must be repeated. It should be done in the first three days of the eruption with aseptic precautions. In positive cases, in from six to ten hours after the injection of the serum, the rash becomes pale and definitely disappears from an area varying from that of a five-shilling piece to that of the palm of the hand; the rash usually disappears first at the centre, but may do so from the periphery. Desquamation in some cases does not occur in the area from which the rash disappeared. The authors describe in detail a number of their observations; they consider that the "sign of extinction" is more reliable than any other.

413. Convalescent Serum in the Prophylaxis of Measles.

O. JERVELL (*Norsk Mag. f. Lægevidenskaben*, August, 1922, p. 601) has achieved marked success with the prophylactic injection of the serum of convalescents in a hospital holding 31 children under the age of 2 years. On January 9th one of the children in a ward accommodating eight developed a typical measles rash, and next day a new case occurred in another ward. On previous occasions the outbreak of measles in this hospital was the signal for immediate isolation of the first case, but this did not prevent all the other children in the same ward from contracting measles. On this occasion all the children exposed to infection were given injections of convalescent serum. The donor was a woman who had suffered from measles eight days earlier. On January 11th 3 c.cm. of her serum were given by intramuscular injection to each of the eight children exposed to infection. The two who had already contracted measles were not given serum and were not isolated, and no special precaution was taken to prevent spread of infection to the injected children, two of whom were only a few weeks old. The remaining six were

about 18 months old. Not one of the children given prophylactic injections contracted measles. Two other children about the age of 18 months were given intramuscular injections of 10 c.cm. of citrated blood from a man who had contracted measles in childhood, and they also did not develop measles. Quoting Degkwitz and Rietschel, the author points out that the prophylactic system under discussion is of particularly great importance in children's hospitals where the inmates are especially liable to suffer from the ill effects of measles. The serum of convalescents remains potent for at least nine months, and inability to provide a sufficient quantity of serum is the chief bar to the wholesale introduction of this system of prophylaxis.

414. Diphtheria of the Vulva.

TRIPPUTI (*La Pediatria*, September 15th, 1922, p. 852) publishes two cases of this uncommon condition. (1) A child, aged 3, who suffered for about a fortnight from redness and swelling of the vulva, with membranous plaques on the labia. The child was very pale, wasted, and ill. There was a trace of albumin in the urine; no sore throat. A brother a month previously had suffered from a bad throat of uncertain nature, but was quite well. Swabs from the vulva showed Klebs-Loeffler bacilli. Antitoxin was given, but the child died subsequently of heart failure. (2) A child, aged 20 months, with similar history, except that there was no record of sore throat in any other member of the family. Similar local conditions were present, and in spite of treatment this child also died of heart failure. In the absence of other symptoms suggesting diphtheria, the diagnosis of diphtheria of the vulva is difficult, and can only be definitely settled by bacteriological examination.

415. The Prognosis of Congenital Heart Disease.

J. S. OUDEMANS-HOEKSMA (*Nederl. Tijdschr. v. Geneesk.*, October 7th, 1922, p. 1628) states that the prognosis of congenital heart disease depends more on the patient's general condition, especially the degree of cyanosis and shortness of breath, than on the character of the cardiac lesion. Patients with a patent ductus arteriosus and with a patent foramen ovale or septum defect have a chance of a fairly long survival if they follow a reasonable mode of life. On the other hand, the prognosis of pulmonary stenosis is very bad, and, when uncomplicated, makes life impossible; only by its association with a patent ductus arteriosus or septum defect is it possible for the blood to pass into other channels, and thus enable the child to survive. The author made an inquiry into the subsequent history of 154 cases of congenital heart disease which had been treated at the Emma Children's Hospital at Amsterdam between 1909 and 1920, with the following results: In June, 1922, 62 were still alive, 87 were dead, and the fate of 4 was unknown. Of the 87 fatal cases 21 had died before the age of 3 months, 35 between 3 months and 1 year, 8 during the second year, and the rest between 3 and 21 years of age. Whooping-cough and pneumonia were frequent causes of death, but probably as many died from the cardiac condition as from intercurrent diseases. In the survivors marked cyanosis was seldom found; clubbed fingers were seen in only one instance, and the general condition was satisfactory in most cases. Examination of the blood pressure showed that it was neither too high nor too low. Only a few of the children were undersized, and some were even above the average height. On the other hand, the mental development left much to be desired. The prognosis, therefore, of congenital heart disease should not be too gloomy, nor should the child be subjected to a number of prohibitions, at least before the age of athletic sports is reached.

416. Responsibility and Modern Psychology.

W. BROWN (*Psyche*, October, 1922, p. 133) regrets the tendency for a deeper knowledge of psychological laws to become a popular fad instead of a serious study, thereby encouraging an extremism foreign to the spirit of true science. Any suggestion that modern doctrines of psychology tend to weaken the sense of moral responsibility both in the criminal and in the judge is fallacious, since psychology is not concerned with the problem of responsibility but merely attempts to trace antecedent factors of wrong-doing in the criminal's heredity, previous mental constitution, and conditions of environment. Most wrong-doing represents the failure of social instincts to control merely self-regarding instincts when such control is called for in the interests of the community, and is caused either by excessive strength

of impulse or exceptional weakness of control, or by a disturbance of intellectual life, preventing the individual from knowing what he is doing, all of which factors may contribute to the resulting act. While the legal definition of responsibility only recognizes the intellectual factor, it must be borne in mind that effective knowledge of an act must include knowledge of the circumstances in which it is performed. In addition to the many forms of mental illness to which such a criterion applies—for example, alcoholic mania, post-epileptic automatism, etc.—there is a class of individuals who suffer from overwhelming compulsion to criminal acts, as in kleptomania, the compulsion being so strong that normal powers of control are inadequate to hold it in check. Psychological analyses in such cases often point to the events and fantasies of early childhood and strong repression of infantile tendencies as being responsible, and the problem of moral responsibility resolves itself into a redistribution of responsibility among the right persons rather than towards its abolition. The psycho-analytical school, according to this author, errs in restricting its investigation to instinctive bases of mental life, and fails to do justice to the nature of volition or other higher forms of mental activity, and it can have no right to deny personal responsibility, because it has not yet even begun to deal with the concept of responsibility. While not contesting the reality of moral responsibility, modern psychology regards criminals who suffer from certain forms of mental disease as being less fully responsible for their acts than normal people, but it in no way lends countenance to the view that all criminals suffer from mental illness or that such illness is an invariably sufficient excuse for crime. Since many forms of psychoneurosis are partly due to defective will, this may be strengthened and re-educated by mental analysis and suggestion.

417. Pepsin and Hydrochloric Acid Medication.

R. EGE (*Ugeskrift for Læger*, September 21st, 1922, p. 1227) has carried out quantitative analyses of the pepsin content of the stomach, and has used a modification of Fild's cystin method for this purpose. He calculates that the quantity of pepsin secreted daily is not less than the equivalent of 10 grams of Armour's pep-sin. As the quantity of pepsin usually given is much less than 1 grain a day, it is difficult to conceive how such small dosage can be of any value. Even in cases of much reduced pepsin secretion the author has found from 3 to 5 grams, and the smallest quantity he has found was about 0.5 gram. The usual dosage of HCl is also ludicrously inadequate, and the amount usually given in Denmark is approximately one-twentieth of the amount normally secreted by the stomach. It is useless to give pepsin to a patient with a low HCl secretion, for the pepsin is inert unless the acidity of the gastric juice is brought up to a certain level. To achieve this object without giving large quantities of HCl by the mouth it is necessary to introduce the HCl through a stomach tube, the discomforts of which are great. The author therefore recommends substituting citric acid for HCl, as the former's capacity for neutralizing bases is approximately 300 times greater than that of HCl. Another advantage of citric acid is that it can be given in a pill, and the quantity of citric acid given would have to be 7 grams to bring the acidity of neutral gastric juice up to its normal HCl acidity.

SURGERY.

Nephrolithiasis.

A. C. JACKSON and W. C. GEWIN (*Amer. Journ. of Surg.*, September, 1922, p. 212) find that renal calculi occur more frequently in males than in females, and in the third and fourth decades. Calculi are probably bacteriæ in origin. The disease is bilateral in about 10 per cent. of cases. Colic rarely occurs unless a stone passes into the ureter. The pain is more often a dull soreness in the back on the affected side and referred down the ureter to the penis and scrotum. Haematuria is usually mild in type and rarely alarming; pyelitis with pus in the urine may be present later. Diagnosis depends on x rays and cystoscopy. There is no medical treatment for renal calculi, so the question of operation must be considered. About 75 per cent. of stones will pass spontaneously, and a large majority within six months after onset, so immediate operation is to be condemned; if the stone is too large to pass, nothing is gained by delay. If stones are found in both kidneys and are large and multiple and the symptoms not acute, operation is not advisable, as these patients usually live as long and as comfortably without operation. The function of the kidneys should be tested before operation to ascertain how radical this may be. The lumbar incision is to be preferred for exposure of the kidney. There are three methods for removal of the stones: pelvolithotomy, nephrolithotomy,

and nephrectomy. Pelvolithotomy causes less destruction of renal tissue and less hæmorrhage. In cases of pyelonephrosis with stone nephrectomy becomes imperative, after being sure of the presence of a second kidney with good function. Conservation should be the keynote in nephrolithiasis, but one must always be radical enough to get results.

419. Radium in Oto-Rhino-Laryngology.

MARTINEZ (*Arch. de med. cir. y espec.*, October 14th, 1922, p. 95) records his experience of radium treatment in otorhino-laryngology since April, 1918. All the cases of rodent ulcer, which were particularly frequent on the nose, were cured. In the mouth success was only obtained in a case of small epithelioma of the palate. In all the other cases the application of radium was not sufficiently intense to affect the lesion. In the pharynx the results were not very satisfactory, owing to a sufficient amount of radium not having been employed. In one case in which a large quantity was used a complete cure was effected. In another case, in which the growth of the tumour was very rapid, application of radium considerably retarded its growth. In the larynx papillomata were nil cured by radium. In epithelioma of the larynx radium was useless, except in one case where it was associated with thyrotomy. In the nasal fossa a fibroma and in the external auditory meatus a naevus were cured by radium. Martinez concludes that up to now radium is the only substance which can modify a new growth, and that not only must a large quantity of it be employed, but that it should be applied at an early stage.

420. Anilin Copying Ink as a Toxic Foreign Body.

E. GLASS (*Dent. med. Woch.*, October 13th, 1922, p. 1383) records two cases showing how dangerous it is to leave the stump of an anilin pen nib embedded in the tissues. This accident is by no means rare, and Erdheim has recently published as many as 21 cases. The author's first patient was a clerk who bruised his right forearm, which became swollen and painful. About two days later the swelling was increased and some violet fluid evacuated. The wound closed without the formation of a fistula, and when the author saw the patient for the first time about four weeks later there was a swelling of the size of half a walnut on the extensor aspect of the right forearm. The tender and oedematous swelling was incised, and about 10 c.c.m. of a bright violet, jelly-like fluid were withdrawn. Analysis of the fluid proved it to be stained by methyl violet. Curiously enough, the patient was unaware of having been pricked by a pen nib, and it was not till six days later that, on reopening of the swelling, a fragment of pen nib was found embedded in necrotic tissues. These were excised, and recovery followed. Common to this and the second case was the general toxæmia produced by the dye; in the second case the patient looked very ill, although he had pulled the broken fragment of pen nib out of his right thumb directly after its entry. These and Erdheim's cases show that the copying pen nib may be a very dangerous thing if it gets into the tissues. When particles of it lodge in the eye, severe conjunctivitis, terminating in necrosis of the conjunctivæ, is liable to occur.

421. Vesical Calculi following Prostatectomy.

CARAVEN and LOURDEL (*Journ. d'urologie médicale et chirurgicale*, August, 1922, p. 111) observe that the presence of calculi is one of the least known, or in any case least studied, complications of prostatectomy. One of the authors has observed 2 cases among 213 prostatectomies in his own practice; details of these cases are given. In both, severe dysuria and chronic cystitis occurred some months after the primary operations; no treatment gave relief until a cystostomy was again performed and phosphatic calculi removed from the base of the bladder or from the cavity left after prostatectomy. The authors' third case "has had prostatectomy performed by a distinguished surgeon," who packed the prostatic cavity with tampons of gauze. The patient subsequently consulted one of the authors. He was suffering from dysuria, and a fistula communicating with the bladder had formed. The symptoms suggested the presence of a neoplasm, and cystostomy was performed: three gauze tampons, which had been placed in the cavity from which the prostate had been enucleated and had been overlooked, were removed. Cure resulted in two been overlooked, but four or five months afterwards or three weeks, but cystoscopy showed three calculi of cystitis recurred, and cystostomy was again performed, phosphatic appearance. Cystostomy was again performed, the calculi were removed, and the scar tissue resulting from the previous operations was sutured. A rapid cure followed. The authors observe that it is very difficult to determine the frequency of the occurrence of this complication. Caution has been seen in 2 cases out of 63; Gonzales in 3 cases in 75 prostatectomies. One of the authors has seen it in 2 cases among 213 of his own

patients, and has been able to collect 68 other published cases. They discuss the mode of origin of these calculi at considerable length, and classify the cases as follows: (1) those cases where the operation is or appears to be clearly responsible; (2) those where the operation is not responsible; (3) those where its part is open to discussion. They conclude the paper by giving particulars of 11 other cases which they have collected, of which the majority have not been published hitherto.

422. Improvements in Pre-operative and Post-operative Care.

The essential point made by F. B. TAYLOR, W. I. TERRY, and W. C. ALVAREZ (*Journ. Amer. Med. Assoc.*, November 4th, 1922, p. 1578) is that in a large hospital, with young and inexperienced house officers, the standing orders should call for as little needless interference as possible. If any patient develops symptoms which require the use of purges or enemata they can always be prescribed, but they should not be made compulsory for the patient who is making a smooth and rapid convalescence. Furthermore, the standing orders must not be such that the life of a man coming in with an acute intestinal obstruction, a perforating appendix, or a gangrenous Meckel's diverticulum must depend on the intervention of some intelligent house-surgeon. The salient points in the treatment endorsed by the authors are: (1) the omission of the pre-operative purge had no definite influence on the amount of vomiting, but it had a decided effect on the amount of pain in the abdominal cases, reducing its incidence from 75 to 42 per cent.; (2) the delay in giving the post-operative purge had a decided effect on the amount of vomiting, reducing its incidence from 45 to 30 per cent. in the abdominal group and from 20 to 4 per cent. in the extra-abdominal group; (3) in both groups there was more complaint of pain when the post-operative purges and enemata were withheld.

423. Cervical Rib.

S. W. BOORSTEIN (*Journ. of Bone and Joint Surgery*, October, 1922, p. 687), in a review of the subject, considers that many cases of shoulder disability are due to cervical ribs. The size of the rib bears no relation to the intensity of the symptoms, some of the large ribs causing little or no trouble. An aponeurotic band extending downwards to the first rib may cause similar symptoms. The symptoms are commoner on the right side, and they usually first cause trouble between 20 and 30 years of age. The symptoms are local, with pain and tumour; nervous symptoms are generally neuralgic pains with numbness and tingling; usually the inner cord is involved and sometimes analgesia is present. Vascular symptoms may vary from slight coldness to actual gangrene; a difference in the radial pulse has been noted; of the muscular symptoms, atrophy of the small muscles of the hand are usually seen with loss of power or grip. A cervical rib must be thought of in a case of sensory symptoms along the lowest cord of the brachial plexus, with paralysis of the intrinsic hand muscles, vasomotor changes, and perhaps tumour in the supraclavicular fossa. X-ray examination is a great help in diagnosis. The treatment consists in removal if there are no definite contraindications. The more the nerves have been damaged, the less likely is the result to be a complete cure. If operation is delayed thrombosis in the vessels may occur. The best method of removal is an incision from the posterior border of the sternomastoid passing upwards and outwards to the border of the trapezius. The brachial plexus is exposed and retracted forward, the rib is then defined, its muscular and ligamentous attachments divided, and finally the rib is removed. Care must be taken of the vertebral artery, and if it is damaged it should be ligated near its origin. Venous haemorrhage may be controlled by packing. The nerve and blood-vessel symptoms usually abate gradually after resection of the rib, but may persist for a year or longer.

424. Haematuria following Sodium Bromide for Pyelography.

K. BÖHRINGER (*Zentralbl. f. Chir.*, October 21st, 1922, p. 1558) remarks that almost all recent reports on sodium bromide in pyelography state that it is completely harmless. Gandy and Stobbaerts recorded two exceptional cases of colic, rise of temperature, and vomiting, and Jules François, who employed a 30 per cent. solution, described a severe case of irritation of the bladder and pain in the kidney after its use. In Germany a solution of 20 to 25 per cent. is usually employed. Böhringer now records 3 cases in which haematuria developed after pyelography or cysto-radiography, in which a 30 per cent. solution of sodium bromide had been used. Two of the cases were women, aged 21 and 49 respectively, who presented symptoms of movable kidney and intermittent hydronephrosis. Severe colic and haematuria developed shortly after the introduction of the solution.

The haematuria lasted in one case about a month, and in the other a fortnight. The third case occurred in a man aged 25, suffering from chronic nephritis, in whom cysto-radiography was performed for dysuria. The bladder was filled with 150 c.cm. of a 30 per cent. solution of sodium bromide. Severe haematuria developed the same day, and lasted, for another six days, when death took place. The autopsy showed cystic degeneration of both kidneys; severe haemorrhagic cystitis, and multiple skin haemorrhages. A fatal issue in this case was inevitable, as was shown by degeneration of the kidney and the high degree of residual nitrogen in the blood, but the sodium bromide had undoubtedly a very irritating effect upon the vesical mucosa. In none of the three cases could an error in technique be regarded as responsible for the haematuria. The solution was some days old, but according to the literature stock solutions have been used by others without ill effects. In future, however, the authors intend to employ only freshly made solutions not exceeding 20 per cent. in strength.

OBSTETRICS AND GYNAECOLOGY.

425. Surgical Treatment of Pelvic Tuberculosis.

R. PETERSON (*Amer. Journ. of Obstet. and Gynecol.*, September, 1922, p. 234) records the after-history of 100 cases of pelvic tuberculosis in which the diagnosis was confirmed by microscopic examination of tissue removed at operation. The primary mortality was 7 per cent. Of the 7 patients concerned 4 showed before operation distinct rises of temperature and pulse rate due to pulmonary tuberculosis; in such circumstances it is better to postpone or avoid operation. Among the remaining 93 patients, of whom all but 2 were traced, there were 16 deaths only in a period of eighteen years, and 9 succumbed to some form of tuberculosis, 7 of them being patients having morbid pulmonary signs at the time of operation. Since in the 100 cases the peritoneum was involved in 60, the omentum in 20, and the uterus in 30, ascites being found in 23, it seems justifiable to conclude that prognosis after operation, especially in afebrile cases, is distinctly favourable. Unless it be too extensive, tuberculosis of the peritoneum will be cured if the other pelvic tuberculous lesions be removed. In the present series 5 faecal and 2 vesico-vaginal fistulae were noted after operation. Fistulae much more readily follow separation of adhesions due to tuberculous than those due to gonorrhoeal peritonitis, and drainage when possible should be avoided in the former group of cases. From examination of 44 cases in which hysterectomy together with bilateral salpingo-oophorectomy was done, it was found that in 23 per cent. the uterus, tubes, and ovaries were involved, in 50 per cent. the uterus, and in 86 per cent. the tubes. On the whole radical rather than conservative resections of the pelvic organs seem to be preferable, although much depends on the extent and severity of the primary focus of the disease; in the group of 44 cases radically treated, 66 per cent. showed affection of the parietal peritoneum, 20 per cent. ascites, and 32 per cent. pulmonary disease, yet the percentage of cure was higher than in the series as a whole.

426. Zinc Poisoning after Vaginal Douching.

R. ENGELMANN (*Dent. med. Woch.*, 1922, 15), records the case of a patient aged 45 who douches herself thrice daily with 1 drachm of zinc chloride solution (50 per cent.) to 1 litre of water. After the second injection made during the menstrual period she was suddenly seized with acute abdominal pain, nausea, and vomiting; the abdomen was swollen and tender, the pulse was small, and the urine showed the presence of albumin and casts. Convalescence occupied six weeks. The conclusion is drawn that patients douching themselves on account of gonorrhoea or other maladies should be warned to suspend during menstruation the injections of zinc chloride, silver nitrate, or mercury oxycyanide.

427. Tabes and Pregnancy.

G. RICHTER (*Zentralbl. f. Gynäk.*, October 7th, 1922, p. 1618) adds records of two cases to the eleven which he has been able to find hitherto described of pregnancy coexisting with tabes. The first patient, a 3-para aged 28, who had borne two children showing signs of congenital syphilis, had presented for three years the classical signs of tabes; pregnancy continued after the initiation in the third month of treatment by salvarsan given in carefully graduated small doses. In the second patient the birth at term of the second, like that of a former child, was painless; this woman, aged 34, showed, in addition to ataxia, sluggish pupillary reaction and absence of patellar and Achilles reflexes, old trophic lesions at the finger-tips, marked impairment of sensation, and a negative Wassermann reaction in the blood (repeated lumbar

De Dion Bouton

Comfort in All Weathers

is afforded by this beautiful Coupé-Cabriolet. It provides the protection of a fully closed car, yet the four windows can be lowered as required, and in fine weather the hood can be easily folded back.

The new 12-24 h.p. model is economical to run (30-35 miles per gallon), whilst its clean design, ease of control and excellent springing, make it the IDEAL CAR FOR MEDICAL MEN.

Reputation gained by many thousands of cars of similar design over a long period of years is your only safe guide when purchasing.

12-24 h.p. 3-5 Seated Coupé-Cabriolet, £660

Chassis with 5 tyres £415

Complete cars from £525

De Dion Bouton Limited, 10, Gt. Marlborough Street, London, W. 1.

Telephone: REGENT 3148 (2 lines).

Telegrams: "ANDESITE, WESDO, LONDON."

INFLUENZA

AND ITS SUCCESSFUL TREATMENT BY

Litmopyrine (BISHOP)

SOLUBLE LITHIUM ACETYL-SALICYLATE

Prompt and Definite in Action. Does not Upset the Stomach.

Antipyretic.—Litmopyrine effects most rapid temperature reductions. The fall begins about fifteen minutes after administration, reaches the minimum within the first hour and lasts for three to four hours, at expiration of which period the dose may be repeated if necessary.

No Harmful By-effects.—Litmopyrine being freely soluble, passes at once through the stomach unchanged, and therefore unlike the insoluble Acetyl-salicylic acid, which splits off its salicylic acid in the stomach. Litmopyrine never causes gastric irritation, nausea or loss of appetite. Litmopyrine has no harmful effect on the heart or kidneys, and does not cause ringing in the ears.

BISHOP'S LITMOPYRINE is free from all the faults, and defects of Acetyl-salicylic acid, and is a much more efficient, reliable and successful

ful antipyretic, analgesic and anti-rheumatic. Its introduction has overcome the last obstacles to the satisfactory administration of the salicylates, and the salt is now widely prescribed for Muscular and Articular Rheumatism, Polyarthritides, Neuritis, Sciatica, Gout, Lumbago, Influenza and all Feverish Conditions, Colds, Catarrhs, Bronchitis, Headaches and Neuralgia.

Analgesic.—Litmopyrine speedily allays the muscular and joint pains of influenza, as well as of Rheumatic and Gouty Disorders and promptly relieves Headaches.

Complete Solubility of Litmopyrine in water and alcohol permits of its administration in syrups, infusions, tinctures and all other alcoholic or aqueous solutions, where Litmopyrine is exhibited in a form to ensure its immediate absorption and full activity.

Litmopyrine is supplied in Powder form in 5-grain Tablets, and as a Granular Effervescent.

Samples and Descriptive Literature sent post free to Medical Men by the Sole Manufacturers of Litmopyrine,

ALFRED BISHOP, Ltd., 48, Spelman Street, LONDON, E.1.

DODGE BROTHERS COUPÉ

PRICE
£395

ESSENTIALLY a car, this, for the physician. In appearance and prestige it is in consonance with the professional man's status. Its dignity is inherent, its inward strength and quiet efficiency worthy of its handsome exterior. A man drives in this car in complete comfort, and in the comforting knowledge that his cost of upkeep is lower far than the average.

International Motors Ltd.

Brook Green, Hammersmith, W.6.

An Ideal Doctor's Car

THE 8 h.p. ROVER Coupé illustrated, will meet the demand for a reliable, comfortable and economical car, particularly suited for Doctor's use. Finished any Rover colour to choice, complete with Self-Starter and all De Luxe fittings, including best fibre floor mat, speedometer, 8-day clock, leather upholstery, large pockets, and curtain to rear window. It is a car that will command consideration through its beauty of line and finish, economy in cost and upkeep.

Send for Catalogue Illustrating all Models.

Observations

ON

THE EFFECT OF CESSATION OF THE IRRITANT ON THE DEVELOPMENT OF EXPERIMENTAL TAR CANCER.*

BY

ARCHIBALD LEITCH, M.D.,

DIRECTOR OF THE CANCER HOSPITAL RESEARCH INSTITUTE, LONDON.

[With Special Plate.]

IN the development of tar tumours, as well in man as in laboratory animals, a long time elapses before there are any visible signs of tumour formation. In the case of mice that have had frequently repeated applications of coal tar it is not till near the end of three months that we see the beginnings of the neoplastic reaction. During this period the area affected has lost its hairs, temporarily or permanently, and the skin has become harsh and scaly: microscopic examination of that particular part of skin in those mice which have died shows irregularity and hyperplasia of the epithelium, destruction of the hair follicles, disorganization of the papillary processes with their superficial elastic felting, and evidences of chronic inflammatory reaction in the corium. But these features are inconstant, and, as I pointed out in January last when communicating to the Pathological Society the results of a year's observations on experimental tar cancers, there are no specific characteristics which we could label as pre-cancerous. As the time goes on, definite hyperplastic plaques make their appearance in the epithelium and small warty growths are formed. The latter generally start as upgrowths from the surface and are found in their early stages microscopically to consist of a branching stalk of connective tissue covered by proliferated epithelium which on the surfaces is excessively keratinized. The connective tissue stalks are well vascularized, but as the wart grows they become more encroached upon by infoldings of the epithelium, and there is downward proliferation of the epithelium below the bases of the tumours: such ingrowth buds, as a rule, exhibit central keratinization. The papilloma grows, too, by further implication of the neighbouring surface epithelium. The cells of the ingrowth may occasionally lack the usual differentiation. How far this ingrowth must proceed before we can call the tumour malignant is, of course, a matter of opinion. There are no hard and fast lines between simple and malignant tumours at any time, and in these particular tumours where the progress from the one to the other is almost certain no one can draw a sure distinction. When, however, the panniculus carnosus is penetrated few will hesitate to pronounce the tumour malignant. In the living mouse deep infiltration can be appreciated by the fingers after a time, and, if we can exclude inflammatory processes, we may be sure that the deep tissues are penetrated. The tumours may increase to a considerable size on the surface, covered by hard horny material, or they may break down. Metastases occur in the lymph glands, the lungs, or other organs. Occasionally the stage of benign wart formation is omitted, and the first sign of neoplasia is an ingrowth with a superficial ulcer; and in such instances it is difficult to date the commencement.

In some of our former experiments we stopped the applications of tar as soon as basal induration was evident, and we found that nevertheless the tumours went on growing with undiminished rate: the removal of the irritant did not arrest the process when once the malignant stage was reached. The failure therefore to detect a causal agent in a cancerous growth cannot be held to be a proof against the previous existence of such.

Now, what would happen if the irritant were suspended before the tumour had reached a malignant stage? Clinical observations in human cases point to various possibilities; some warts disappear, some remain simple for many years and would presumably continue so indefinitely, and some progress to malignancy: instances of all three are known in the soot warts of chimney-sweeps, in the warts of tar and pitch workers, and in the warts of paraffin workers.

It would seem merely to be a question as to how far the development of the wart had gone when the irritation ceased. Yamagiwa and Ichikawa,¹ who were the first to produce tar tumours experimentally, found that when they stopped the applications of tar in rabbits some of the papillomata went on increasing whilst others diminished and disappeared. In my own experiments with rabbits I noticed in several cases that papillomata disappeared though the tar applications were not suspended; and the same thing happens in mice; though apparently less frequently. It cannot therefore be said that the diminution or disappearance of warts is wholly due to the cessation of the irritant. In order to answer the question posed we took two batches of mice which had undergone repeated tar applications for periods of four and five months respectively; the treatment was stopped, and they were examined every few days. Some of these mice already showed evidence of tumour formation, and in all cases we had fairly accurate information regarding the date of their first appearance; in other mice there was no sign whatever of papillomata or even hyperplastic plaques. After the cessation of the tar applications the hair grew again, except where a wart was actually present, and the skin, previously rough, became smooth in some cases and in others remained rough, but the succeeding events could not be correlated with the degree of the return to the apparently normal condition.

Result when Tumours were Present.

When the tar was discontinued there were 15 mice, of which 14 had small warts varying in size from a pinhead to a hempseed at most, the warts having been in existence for different periods from a few days up to a month, and another mouse which had a small subcutaneous tumour with superficial ulceration. Judging from our histological observations on numerous similar growths in animals which died, we would have no hesitation in pronouncing all of them simple, with the possible exception of the one mentioned. The subsequent history of these 15 mice showed that in 5 cases the papillomata disappeared, spontaneously or otherwise, in 3 cases the warts remained simple, 1 had a doubtful ending, and 6 became malignant.

Temporary Tumours.

1. A wart was present, small and flat, less than one-eighth of an inch in diameter, which had arisen within 13 days. It disappeared within a fortnight after the tar was stopped, leaving roughened skin. At the end of 22 days another small flat wart was seen to the right of the site of the former, but after another week it too disappeared, and a rough irregular condition of the skin without further neoplasia continued till the death of the mouse, 71 days after cessation of tar painting. Histological examination of the skin showed irregular hyperplasia of the epithelium, with small nodules of epithelial cells isolated in the corium and surrounded by round-cell and fibroblastic reaction. Many of the epithelial masses had degeneration of the central keratin, and appeared as pseudo-cysts. The panniculus carnosus was not encroached upon. (Five months' treatment previously.)

2. A small wart the size of a pinhead was present, which increased slowly in size till 70 days after the tar was stopped, when it appeared as a conical horny wart a quarter of an inch in height. Pulled off, it left merely a small area of abraded skin, which showed no sign of tumour when the mouse died a week later. (Four months' previous treatment.)

3. After tar had been applied for 4 months a minute wart was observed which had grown to the size of a hempseed one month later, when the applications were suspended. It had not increased 13 days later, but a pinhead-sized wart had appeared in front of it, and a scab had formed immediately behind it. At the end of 22 days the scab had taken the place of the larger wart. It was difficult to determine whether there was horn formation or merely a scab. However, it seemed to increase in size and to show induration beneath. This proved to be a septic condition; an axillary gland became infected and the mouse was killed, but no sign of tumour could be detected, merely acute inflammation.

4. Tar had been applied for 5 months. When it was discontinued a minute wart 1 mm. in height, which had not been there a week previously, was found. For a month afterwards it increased slowly in extent, though remaining flat. At the end of 2 months it seemed to show a deeper area of induration, and another tiny wart had appeared near it. A week later it was found that the induration was inflammatory, and pus was evacuated. The animal died at the end of 71 days, and the wart came away at autopsy, leaving no trace of tumour formation underneath.

5. Tar had been applied for 5 months, and a small wart, which had been in existence for a month, showed commencing ulceration, when the tar was stopped. This ulceration had increased, when the animal died 13 days later, but histological examination showed only the necrotic remains of the wart.

* A paper communicated to the Pathological Society of Great Britain and Ireland, July 15th, 1922.

Simple Papillomata.

1. Tar had been applied for 4 months, and had produced a single wart of the size of a hempeed at the end of that time, when the applications were stopped. A fortnight later two others smaller warts appeared in the neighbourhood. Progress was slow: at the end of 48 days there were still three warts, two of the size of hempeeds and the third pinhead size. The mouse died at the end of 63 days, the tumours having shown little advance.

2. Tar applied for 4 months. A small wart appeared in the last 20 days, and when the tar was stopped there were two growing warts. One of these disappeared 20 days afterwards, but the other continued growing. The mouse died in 29 days with a papilloma histologically simple.

3. Tar applied for 4 months: in the last 20 days a wart appeared which had formed a small horn a week old when the tar was stopped. It measured then a quarter of an inch high by one-eighth of an inch thick, and a tiny wart had just appeared in front of it. Twenty days afterwards four warts were found. At the end of a month two of these had disappeared, but another was beginning. In 43 days a papilloma, the size of a large pea, had formed from the coalescence of two neighbouring warts. The warts diminished in number and size, and the mouse died 86 days after the cessation of tar applications. The papillomata were histologically simple.

Doubtful Case.

Tar applied for 5 months. A wart was noticed at the end of the fourth month, two warts in the last 18 days, and when tar was stopped there were four closely set warts all about the size of pinheads. They gave place 15 days later to a flat irregular plaque surrounded by hair. This disappeared, and at the end of 22 days a small pinhead-sized wart appeared in front of this. This in turn gave place to a shallow ulcer which seemed to be healing. At the end of 2 months there was very doubtful superficial induration, and this did not become more definite when the mouse died in 78 days after the tar had been stopped. The carcass had been eaten by the other mice and no histological examination was possible.

Malignant Tumours.

1. Tar applied for 5 months. During the last month the skin was very rough, and in the last 13 days two warts made their appearance. When the tar was stopped the larger was the size of a hempeed and the smaller less than half of that. Another papilloma, hempeed in size, appeared 20 days afterwards. At the end of a month there were three horns with doubtful induration beneath. The horns became flatter but the induration proceeded, and at the end of 43 days it seemed definitely to be malignant. The tumour became fixed to the deeper tissues. When the mouse died after 60 days it had a horn, five-eighths of an inch high, set on a broad indurated base. Examination proved the tumour to be a spreading internally in the subcutaneous muscles (Plate I, Figs. 1 and 2).

2. Tar had been applied for 5 months. A tumour arose during the last month, and formed a horny pedunculated wart about the size of an oatseed, with a tiny wart behind it, when the tar was stopped. Fifteen days afterwards three or four minute warts appeared in the neighbourhood. Progress was slow. At the end of 2 months there was an area of induration detectable at the edge of the warty masses. The growth thereafter was rapid, and the mouse died in 81 days with a warty mass which on the deep side was infiltrating the muscles of the back (Plate I, Figs. 3 and 4).

3. Tar had been applied for 4 months, and on its cessation there was found a hemispherical subcutaneous tumour with a central eschar measuring a quarter of an inch in diameter. It had not been observed 8 days previously. It reached a diameter of nearly half an inch 20 days after the tar had been stopped, and it showed central ulceration. The mouse died in 25 days, and microscopic examination showed the tumour to be an epithelioma infiltrating the muscles. This tumour was of rapid growth, extending over little more than a month, and may have been malignant even at the time when the tar was stopped.

4. Tar had been applied for 4 months. Within the last 20 days a wart appeared, and by the time the tar was stopped it had reached the size of a hempeed. It had increased 20 days later, and two in the neighbourhood. Progress was rapid. Days, and microscopic examination showed ing the muscles (Plate I, Fig. 5).

5. Tar had been applied for 4 months, and a wart the size of a milletseed had then been in existence for 8 days. It decreased somewhat 20 days after the tar was stopped. At the end of a month the top of the wart was accidentally removed. In 43 days there was a flat ulcer with slight induration. Progress was then slow. In 76 days there was a red ulcerated area in the centre, and the condition was now in 86 days the ulcer had scabbed over, marked, and two small warts had appeared in the neighbourhood. The mouse died next day. Histological examination showed an epithelioma penetrating the deep muscles (Plate I, Fig. 6).

6. Tar had been applied for 4 months; a small wart appeared during the last 8 days and had grown to the size of a small hempeed

when the tar was stopped. Twenty days afterwards there were two small warts and two flat each covered areas measuring three-eighths and a quarter of an inch in diameter respectively, and beneath these there was some irregular induration. This induration by the end of a month had spread underneath the adjacent warts. These warts lost their prominence as the induration extended, so that in 43 days a raised indurated area obscured their position. At the end of 7 weeks there was an extensive indurated area nearly three-quarters of an inch in greatest diameter, with two ulcerated patches on its surface, and it was now considered indubitably to be malignant. The mouse died in 63 days, and the carcass was eaten by the other mice, and therefore the histological confirmation is awaiting.

These experiments show that some warts will disappear, some will increase for a time and then diminish and disappear, some will increase but still remain simple, and others will go on to malignancy probably as rapidly as if the irritant had continued. We can make three deductions from this: (1) that the production of the cancerous state is not necessarily the result of the action of the irritant on neoplastic, as contrasted with pre-neoplastic, tissues; (2) that the bias towards malignancy is given to the cells probably during the pre-neoplastic stage; and (3) that the successful transplantation of a tumour in the histologically doubtful stage is not a sure proof of the malignancy of the tissue at that particular date, seeing that left alone in its natural environment it will tend to declare itself as an epithelioma.

Such conclusions would be rendered much more certain by observations in cases where the irritant had been suspended before any neoplastic reaction had taken place—that is, during the prodromal period. Cases are known where men have been exposed to the action of soot, paraffin, or aniline products for a length of time and have given up such employment, and yet years afterwards they have developed the particular kind of epithelioma associated with these irritants. These cannot be lightly dismissed as strange coincidences, and they would seem to show that the essential damage to the tissues, finally resulting in malignant proliferation, is done at a comparatively early stage.

A second batch of mice was taken which had been painted thrice weekly with tar for four or five months without any sign of tumour formation resulting, and the tar applications were stopped.

Result when Tumours were not Present.

At the time the tar painting was suspended there were 20 mice with no visible sign of neoplastic reaction. Of these, 6 remained negative till they died, 4 developed temporary warts, 4 developed simple papillomata, and 6 developed malignant tumours. The 6 negative cases lived for 29, 42, 43, 48, 65, and 75 days respectively after the tar was discontinued, and no sign of tumour was at any time observed.

Temporary Tumours.

1. Tar applied for 4 months. Twenty days afterwards a pinhead-sized wart was seen. This had disappeared a week later, and the mouse died in 63 days without further wart formation.

2. Tar applied for 4 months. A month afterwards a wart the size of a hempeed was found. This made slow progress for another month and then disappeared. The mouse died in 83 days without further wart formation.

3. Tar applied for 4 months. Two months later a tiny wart was found amidst the regrown hair. This persisted unchanged for nearly a month, then diminished in size and disappeared completely at the end of 100 days. The mouse died in 110 days without further wart formation.

4. Tar applied for 4 months. Twenty days afterwards a wart the size of a pinhead was found. It did not increase appreciably in size, and had disappeared when the mouse died in 48 days.

Simple Papillomata.

1. Tar applied for 4 months. The hair grew again. Forty three days afterwards a small, flat, pinhead-sized wart was noticed. For another month its progress was slow. In 86 days it was just palpable, having diminished for 10 days. A fortnight later it developed into a cutaneous horn. The mouse died in 112 days. Histologically a typical papilloma.

2. Tar applied for 4 months. Twenty days later a wart the size of a large hempeed was observed. This increased slowly till the mouse died in 42 days.

3. Tar applied for 4 months. Twenty days later two small warts were seen, one the size of a hempeed, the other of pinhead size. A week later the smaller had disappeared and the larger had grown no bigger. Progress was very slow. The mouse died in 63 days.

4. Tar applied for 4 months. Twenty days later four minute warts were found. Two of these coalesced a week later. Progress of all very slow. The mouse died in 42 days.

Malignant Tumours.

1. Tar applied for 5 months. The skin was rough when the tar was stopped, but the hair grew again. A month afterwards the skin was very rough and scabby. In 33 days there was doubtful growth under a scab which was pulled off. In 45 days there was definite horn formation, with doubtful basal induration. By the end of 2 months tumour formation had progressed, but the induration was still doubtful. The horn was broken off in handling. The mouse died in 71 days, and histological examination showed the tumour to be a large cornifying epithelioma definitely infiltrating the deep muscles of the back.

2. Tar applied for 4 months. Twenty days later a tiny wart was noticed. At the end of a month another wart appeared, and the first had grown to the size of a hempseed. In 43 days several warts were seen, one of them growing very well. At the end of 2 months progress had been maintained and induration of the base was suspected. A week later this induration was marked and the diagnosis of epithelioma was practically certain by 76 days. The mouse died in 98 days. Microscopic examination showed an epithelioma (Plate I, Figs. 7 and 8).

3. Tar applied for 4 months. Twenty days later there was found a wart the size of a hempseed with two tiny warts in front of it, all surrounded by hair. At the end of 27 days the larger had reached the size of a small pea. For another week it was stationary, though the base seemed somewhat indurated. Superficial ulceration commenced in 43 days and the basal induration extended. Another small wart now appeared. Five days later necrotic material was expressed from under the larger wart, and by the end of 63 days there was merely a flat scab half an inch in diameter, and it was thought that the greater part of the process must have been inflammatory and not malignant. The mouse died in 70 days, and histological examination showed an epithelioma of atypical cells deeply infiltrating the muscles.

4. Tar applied for 4 months. Twenty days later a hempseed-sized wart was observed. It increased in size and in 38 days another wart appeared beside it. Progress was then slow. In 70 days it was thought that the base of the larger showed signs of induration, but as the growth was very slow and the induration did not extend doubt remained until the mouse died in 90 days. Histological examination proved it to be an epithelioma with epithelial cell masses penetrating beyond the panniculus carnosus.

5. Tar applied for 4 months. The skin was then bald but smooth. From the 20th to the 34th day afterwards the skin was rough but again became smooth. In 63 days a small wart was detected. This increased in size and the skin grew rough. In 76 days there were two warts in this rough area. These progressed in size and the whole skin showed a verrucose appearance. The mouse died in 96 days. Microscopic examination revealed an epithelioma just penetrating the panniculus carnosus (Plate I, Fig. 9).

6. Tar applied for 4 months. One month afterwards minute raised points, hardly to be called warts, were found. A week later they might have been described as tiny warts set closely in a rough scaly skin. In 43 days they had coalesced to form a flat wart. Five days later serous fluid exuded from it and a crusted area took the place of the flat wart. In 63 days blood-stained serum exuded from this, and three small warts made their appearance. Sepsis became evident, and the resulting ulcer was taken to be merely a septic condition until the mouse died in 86 days, when microscopic examination revealed a typical epithelioma invading the deep muscles of the back (Plate I, Fig. 10).

These experiments clearly show that when tar has been applied repeatedly for a certain length of time and the irritant is then removed, tumours, even carcinomata, may make their appearance at a later date. It must be that the irritation produces in the normal cells subjected to its influence some profound change, undetectable by the microscope, so that they eventually proliferate in an unrestrained and in a harmful fashion. We may conclude that the neoplastic response to an irritant is a slow tissue reaction that exhibits no defensive property, that subserves no useful function. The internal changes in the cells in the earliest stages may some day be analysed: at present they are quite unknown. In the skin epithelioma we have a tissue which we have been taught to believe is constantly being shed and constantly regenerated, and one would imagine that the damaged cells would soon have been shed leaving a new and healthy race to take their place. Of course, in man the processes take a much longer time to evolve. In mice we can discover the minimum duration of exposure to a tissue irritant that will be necessary to produce cancers, and thus form an idea of the length of the latent period before they are evident, and it is possible that this will vary with different agents.

Professor ROBERT MUIR, M.D., F.R.C.P. Edin., F.R.S.,
President.

THE PRODUCTION OF CANCER BY SPECIFIC FORMS OF IRRITATION.

BY

J. A. MURRAY, M.D.,
Imperial Cancer Research Fund, London.

THE modern experimental study of cancer etiology begins with Fibiger's experiments with the *Spiroptera* cancer of rats. The specific irritant is introduced by feeding rats with cockroaches carrying the larval nematodes. The cycle is completed by feeding cockroaches with the faeces of infected rats. Squamous carcinoma of the rat's stomach and tongue follows in a variable percentage of animals. Some races of rats are apparently quite resistant, and never show any lesions graver than papillomatous thickening of the gastric mucosa. Analogous results have been obtained by feeding rats with ova of *Taenia crassicolis* from infected cats. In this case sarcoma of the liver is obtained in as many as 50 per cent. of young rats (Bullock and Curtis). Both methods are convenient in application, but have the disadvantage that the animals have to be killed to observe the result.

The external application of coal-tar, first successfully utilized by Yamagiwa and Ichikawa on the rabbit's ear, though much more laborious, permits continuous observation and experimental variation in the degree of irritation. The extension of this method to the mouse by Tsutsui, and later by Fibiger and Bang, Murray and Woglom, Bloch and Dreyfuss, Deelman and others, has put us in possession of a certain method of producing undoubted malignant growths (squamous-cell carcinoma) in a high percentage of the animals used. This is evidenced by progressive growths, local infiltration, and lymphatic and vascular dissemination. In addition, Murray and Woglom have shown that artificial metastasis can be carried out with these growths. In this way very strong evidence of their malignancy can be got at an early stage, before even local infiltration has had time to occur.

So far an interval of at least three months has elapsed before true malignant growth occurs, and in some animals tarring must be kept up for as long as eighteen months to produce this result. No one has succeeded with the rat or guinea-pig, and it is probable that success with the mouse is, in part at least, to be attributed to the short life cycle of that animal. The surmise is borne out by the fact that in tar distillers and pitch workers the interval is never less than ten years, and may extend to thirty and forty years before malignant disease is set up. These observations furnish a rational explanation of the characteristic age incidence of cancer, since it is probable that the irritational factors responsible are neither so continuously nor so energetically applied in these industrial forms of the disease as in the experiments with mice.

Bloch and Dreyfuss are of opinion that the active substance is contained in the anthracene fraction of coal-tar boiling at over 300°C. I have found that an extremely active extract can be prepared from tar by successive extractions with water, alcohol, and ether. The ethereal extract gave 50 per cent. malignant growths in twelve months, reckoned on the total number of animals which survived for four months.

Result of an experiment in which unaltered tar, alcoholic extract, and ethereal extract of tar were applied to separate areas of the dorsal skin of each of 60 normal mice. After four months, when the first tumour appeared, 50 mice survived, and

in these 25 presented malignant new growths distributed as follows:

No. of Mice.	Tar.	Alcoholic Extract.	Ethereal Extract.
11	—	—	+
10	+	—	+
1	—	+	+
2	+	—	—
1	—	+	—
25			

Twenty-two out of 25 animals bore carcinomata at the site painted with the ethereal extract, 12 had carcinomata at the site treated with the original tar, and 2 only at the site treated with the alcoholic extract. In one of these animals no tumours appeared at the sites treated with the apparently much more efficacious whole tar and ether extract.

The alcoholic extract only produced two new growths in the same series of animals, but other experiments raise the suspicion that this does not truly represent the power of the alcoholic fraction to produce cancer. The other experiments were carried out by tarring animals, which had already responded to tarring with carcinoma production, in another situation remote from the area in which the first growth was produced. So far no second initiation of cancer has been observed, although in several instances tarring has been continued for longer periods than were required the first time. Mice which had developed spontaneous mammary carcinoma have been operated and tarred for long periods without success, and the two sets of experiments seem to indicate that the previous existence of a cancerous growth may in some way hinder the production of a second primary tumour. Further experiments are in progress to test this possibility in unequivocal fashion, as it is obvious that, if proved, it furnishes an explanation of the rarity of multiple primary growths, and may lead to a rational diagnosis and prophylaxis of malignant disease.

PARAFFIN CANCER AND ITS EXPERIMENTAL PRODUCTION.

BY

ARCHIBALD LEITCH, M.D.,

Director of the Cancer Hospital Research Institute, London.

[With Special Plate.]

ABOUT the middle of last century the distillation of paraffin oils from the oil-bearing shales that exist in the West Lothian district of Scotland was begun, and the methods now employed universally in the refining of mineral oils originated there. The shale, as it is brought up from the mines, is a hard, black, non-crystalline substance which roughly resembles lumps of pitch. Heated in tall high-temperature retorts, it yields a dark viscid fluid, from which ammonia, naphtha, lubricating oils, illuminating oils, and solid paraffin are obtained by subsequent refining processes. The workmen engaged in the treatment of the cruder products are prone to various skin eruptions, affecting principally the arms, which are directly exposed, and also other parts, especially the scrotum, through their oil-sodden clothing. These skin affections comprise acute paraffin dermatitis, which most of the workers develop within a few days of starting employment, more chronic conditions which make their appearance later and may persist for years, and finally papillomata and true epitheliomata.

The occurrence of cutaneous cancers of the arms and scrotum in paraffin workers has been well recognized for over fifty years by medical men practising in that district of Scotland, though few of them have recorded their observations in medical journals. Ogston,¹ from his examinations of workmen employed in a small paraffin refinery in Aherdeen, was the first, in 1871, to publish an account of acute and chronic paraffin dermatitis, but his description was necessarily incomplete, though it is still worth reading if only to admire the beauty of his literary style. The first actual record of paraffin cancer, however, is to be found in a paper by Volkman,² who in 1875 reported three cases of cancer of the scrotum. The distillation of lamp oils from the German brown coal—a mineral closely allied to shale chemically and geologically—had then been in operation in the neighbourhood of Halle for some fifteen years. Indeed, all the cases of paraffin cancer recorded in German literature—and they are few—have occurred in that locality, whilst all the cases recorded in English have come from the above-mentioned

part of Scotland. It is possible that as the refining centres for crude petroleum multiply in this country we may encounter more cases unless special precautions are adopted. As far as I know only two cases have been reported from such refineries in the United States. In 1876 Joseph Bell of Edinburgh³ (the prototype of "Sherlock Holmes"), unaware of Volkman's communication, published a description of two cases of paraffin cancer. A case under the care of Hector Cameron of Glasgow was recorded in 1879, and his reporter noted that this was Cameron's third case, and stated that Longmuir and other practitioners in the Scottish shale country had long been familiar with the condition.⁴ The literature on the subject is meagre: Tillmanns of Halle in 1880,⁵ Longmuir of Bathgate in 1883,⁶ Schuchardt of Halle in 1885,⁷ George Buchanan of Glasgow in 1894,⁸ Kirk of Bathgate in 1903,⁹ and Franklin Davis of Chicago in 1914,¹⁰ are the only others who have recorded cases. The total number of cases in the literature, excluding the frequent repetitions of the same cases in Germany, is less than a score, although undoubtedly many more cases have occurred. Dr. Alexander Scott of Broxburn has had an unrivalled experience of paraffin cancers, and we look forward to his communications.¹¹

Some interesting facts emerge from a consideration of these cases. The subjects have been long exposed to the action on the skin of crude mineral oils, and though we refer to the lesions as "paraffin cancers" it is by no means certain that the particular harmful agent in the oils is a member of the paraffin series: both shale and German brown coal yield, in addition, olefines, naphthenes, aromatic compounds, and a host of other chemical substances in lesser amounts. The workers in the refineries who deal with solid paraffin or with the more refined oils are not prone to dermatitis or cutaneous tumours. But whatever the chemistry of the substances may be, we have in crude paraffin oils something that induces neoplasia. The skin cancers that they produce are all of an exactly similar type; they occur on sites unusual for squamous carcinomata unassociated with definite forms of irritation; they are frequently multiple; they are generally preceded or accompanied by warts or other hyperplasias; they are often of a low degree of malignancy; and it takes several years of exposure to the noxious substances before they develop—never less than ten years in the German industry and probably never less than fifteen in the Scottish oil works. Although the patients are usually of middle age or more, it is perhaps more a question of the length of exposure than of the age of the individual. Can we say that the substances under consideration are the actual cause of the epitheliomata? The generally accepted opinion has been to regard them as mediate or predisposing rather than as proximate causes: they bring about such a pathological condition of the skin that the soil is rendered suitable for the operation of some other and hitherto mysterious cause. It is impossible to controvert such an idea. But the success that has attended our efforts to produce cancer experimentally minimizes its cogency. No one doubts that the crude paraffin oil produces chronic as well as acute inflammatory reactions; no one has doubted the fact that it causes hyperplasias of the epithelium and even definite wart formation; why should one have to premise the intervention of a new factor in the succeeding development of the malignant stage?

In our previous experiments with coal tar we found, as other workers have found, that it was comparatively easy to induce cancer formation in mice by continuing the applications to the same area of the skin for several months. Generally, though not invariably, the epitheliomata passed through a preliminary stage of benign papilloma, and if the animals lived long enough they all developed malignant tumours. We wished, therefore, to see if we could obtain similar results by the use of shale oil. Thanks to the kind offices of Dr. Scott and the courtesy of the Pumpherston Oil Company and their chief chemist, Mr. E. M. Bailey, I obtained samples of the more unrefined oils, and the experiments were started in September of 1921. Four crude products were used, known as "green oil," "blne oil," "unfinshed gas oil," and "unfinshed lubricating oil"—representing a series advancing in purity, from each of which solid paraffins in decreasing amounts may be obtained. All these were applied by means of a camel-hair brush to a small area between the shoulders three times a week for several months, but naturally the oil diffused through the hair and affected a much greater area. This was an undesirable but unavoidable occurrence,

* See p. 1108 of this issue, and also p. 381, August 25th, 1922.

for the animals licked some of it off and we lost a large number of mice in consequence. At a later date we used rats, cavies, and rabbits in addition, but hitherto no tumours have been obtained in these animals. After one or two applications the hair falls out over the area affected; generally after some weeks it grows again, but by continuing the applications it becomes permanently lost, leaving a bald, shiny area of skin. Sometimes this bald skin shows a slight scaly eczema, and in a few animals there are small points of excoriation due to scratching, but in no cases have we ever found acute or chronic dermatitis of the types found in the human subject. Occasionally we have observed minute skin plaques, probably representing local hyperplasia of the epithelium, which have immediately preceded wart formations; at other times they seem to have disappeared spontaneously. By the end of the third or the beginning of the fourth month papillary upgrowth may be expected to make their appearance, increasing in size and number, generally forming extremely keratinized warts or horns, and progressing in the course of time to squamous-cell carcinoma.

Experiments with "Green Oil" (Fraction A).

This is a dark, thick, viscid fluid which contains a considerable amount of semi-solid paraffin in suspension. The crude distillate that comes from the rotors is treated with sulphuric acid and soda and again distilled, and the product is the first with which the workmen come in contact. A series of 100 mice was used. At the end of a hundred days only 29 remained alive; of these, 16 never developed tumours, 4 exhibited small warts which subsequently disappeared, 8 developed simple increasing papillomata, and 1 developed a malignant tumour.

Negative Cases.

The animals lived for periods lasting for 105 to 175 days. Histological examination of the skin showed extensive destruction of the hair follicles, irregular hyperplasia of the epithelium, often hyperkeratinization, and, not infrequently, round-cell infiltration of the cutis with increased vascularity. A common feature in these, as in many of the animals that died later, was an extreme degeneration of the liver parenchyma.

Temporary Tumours.

It was probable that in the majority of cases the small warts were scratched off by the animals themselves; possibly they sometimes disappeared spontaneously.

1. Two minute warts were formed in 98 days, but they disappeared within a fortnight, and there was no sign of tumour formation when the mouse died in 144 days.
2. A small wart was detected in 111 days, but no trace was left 16 days later, and the mouse died in 139 days without sign of tumour.
3. A papilloma appeared in 111 days, and a second in 127 days. The growth of both was very slow. The second had gone in 147 days and the first in 172 days. The mouse died in 180 days without sign of tumour.
4. Two warts were seen in 117 days, a third appearing in 140 days and a fourth in 147 days. In 172 days three of these had disappeared, and the fourth had gone in 181 days. The mouse died five days later with no visible tumour.

Increasing Papillomata.

The first tumours in all cases made their appearance before the end of twenty weeks, but their rates of growth varied considerably.

1. A wart was noticed in 98 days; in 111 days there were four warts, in 117 days five, and in 127 days six. The mouse died in 133 days. Microscopic examination showed multiple, strongly keratinized papillomata with hyperplasia of intervening skin and complete destruction of hair follicles.
2. Two warts were evident in 98 days; in 117 days there were five warts altogether. The mouse died in 141 days. Microscopic examination showed keratinizing papillomata with irregularity of adjacent epithelium.
3. Two warts were observed in 98 days. The animal died in 109 days and microscopic examination showed a branching papilloma with dilatation of the vessels of the corium.
4. Two warts were noted in 98 days. One remained a flat wart and the other formed an upstanding horn. Several more appeared in 147 days. The animal lived for 155 days. The tumours were simple papillomata.
5. The first wart was found in 98 days and another appeared in 111 days. In 140 days there were two large and several small warts and the number and size had increased in 147 days. The animal died in 166 days. Multiple benign papillomata.
6. A wart started in 140 days and had formed a thin tall horn when the mouse died in 155 days.
7. A small papilloma appeared in 111 days, but its progress was very slow, and it had only attained the size of a hempseed when the animal died in 163 days.
8. A single papilloma was noticed in 111 days, three in 127 days, and three or four more in 140 days. In 147 days the two largest had coalesced. There was marked horn formation in 153 days, and the oil applications were then stopped. Progress was maintained; in

158 days there were four large horns. The oil was resumed in 214 days, but without any resulting acceleration of growth. The animal died in 268 days with comparatively huge multiple horny papillomata that showed no basal induration. No microscopic examination of the tumours was made as the specimen was required for other purposes, but it is probable that they were all still in a benign stage (Plate II, Fig. 1).

Malignant Tumour.

This was the first animal in this series to develop a tumour. In 87 days two small warts were found; in 140 days there were seven warts (Figs. 2 and 3). In 181 days there were three large papillomata and one smaller on the back and another two on the left side (Fig. 4). Under the lower of the last two there was a suspicious basal induration. The oil applications were therefore stopped on this day. The suspicious patch of induration became more definite; it undermined the neighbouring small wart, and the two warts were lost by superficial ulceration. In 200 days this indurated area, raised from the surface and superficially ulcerated in the centre, was a good half-inch in diameter. The animal died in 206 days (Fig. 5). Microscopic examination of one of the horny warts on the back showed advanced papilloma, with considerable irregular downgrowth of the epithelium. It was impossible to say whether it was simple or benign; the fibres of the panniculus carnosus could not be found beneath the downgrown epithelium, but, judging from the position of remnants of that muscle on either side, it had not penetrated beyond that level; and if we take penetration of the panniculus as the histological criterion of malignancy we shall have to record this as a doubtful tumour (Fig. 6). But the ulcerating tumour on the side was of a different character; it was a spindle-cell sarcoma which infiltrated the deep muscles (Fig. 7). No metastases were found in the internal organs nor in the lymphatic glands.

Experiments with "Blue Oil" (Fraction C).

This substance differs from "green oil" only in the fact that it contains less of the solid and semi-solid paraffin, which has been removed by refrigeration. The workmen at the presses are continually in contact with this crude oil. In the experiments a series of 100 mice was used. At the end of a hundred days only 22 mice were alive; of these, 9 remained negative, 1 showed a temporary tumour, 10 had increasing papillomata, and 2 developed malignant tumours.

Negative Cases.

The animals lived for periods lasting for 111 to 281 days. It is remarkable that one mouse survived the thrice-weekly applications for over nine months without at any time showing any neoplastic reaction. The microscopic examination of the skin of these mice showed appearances identical with those in the negatives of the former series.

Temporary Tumour.

On one mouse which remained refractory for a long period a small wart arose in 186 days, but it never increased above the size of a pinhead. It had disappeared when the mouse died in 203 days, and histological examination of the site it occupied showed merely a healed scar.

Increasing Papillomata.

The tumours appeared in from three to six months and showed various rates of progress.

1. Three warts were observed in 98 days; in 111 days two of these had increased, but one remained stationary. The progress was now slow. In 140 days there was only one good wart. In 147 days another had just appeared. In 147 days there was a good-sized flat wart which in 181 days measured 7 mm. by 5 mm. The mouse died in 185 days. Microscopic examination showed a simple papilloma.
2. In 98 days a wart was seen which by 111 days had reached the size of a large hempseed. In 117 days another wart appeared beside it. These went on increasing and coalesced to form a good-sized flat wart in 140 days, at which time another smaller wart appeared. All progressed till the animal died in 164 days.
3. A small wart appeared in 98 days; in 111 days there were two papillomata growing well; in 127 days these had formed two adjacent horny warts; in 147 days these were separated only by a very narrow cleft beside them. Gradually all three coalesced. The mouse died in 179 days. Histological examination showed an excessively keratinized papilloma with downgrowth of epithelium which reached but did not actually invade the panniculus carnosus.
4. A small wart was seen in 93 days, which reached the size of a hempseed by 110 days, when the animal died.
5. In 98 days a wart appeared which grew till the animal died in 111 days. Microscopic examination showed a small branching papilloma which was markedly cornified. The tissues of the corium, the panniculus carnosus, and even the subjacent muscles, were domed upwards towards the stalk of the papilloma. The hair follicles in the vicinity were lost, and there was no evidence of round-cell infiltration in the corium.
6. A small wart was discovered in 111 days; in 127 days it had formed a tall, slender, horny papilloma; in 140 days it had grown larger, and a second but flatter wart had appeared. The mouse died in 144 days. Microscopic examination showed a simple papilloma with considerable hyperplasia of the epithelium in the neighbourhood.

7. Only at the end of 140 days was a small pinhead-sized wart disintegrable, but this showed progressive growth till the animal died in 172 days.

8. In 140 days a very small pointed wart made its appearance on the right posterior part of the exposed area. In 147 days other two small warts appeared on the opposite flank, and these coalesced in 181 days. In 186 days there were three warts, one on the right flank, one on the left flank, and one on the right shoulder. In 201 days there were two warts on the left flank and one on the right, but the wart on the shoulder had disappeared. Progress was now very slow. The mouse died in 236 days with three fairly large, and several small, horny warts. Microscopically they were simple papillomata.

9. The first sign of a wart was not seen for 172 days. Its succeeding progress was very slow, and it never exceeded 2 mm. in diameter. It disappeared entirely in 201 days. A second small wart appeared at another situation and measured 1.5 mm. by 2 mm. in 214 days. The mouse died in 222 days. Histological examination showed a small but typical cornifying papilloma.

10. Not until after 181 days did a minute wart make its appearance. The progress was exceedingly slow. In 294 days it had formed a little horny papilloma about an eighth of an inch in height. The mouse died in 299 days. Histologically it was a simple wart, but it was remarkable that the adjacent epithelium showed neither hyperplasia nor irregularity.

Malignant Tumours.

1. The earliest tumour formation in any of the oil experiments occurred in this animal. In 83 days there was found a spherical semi-sessile wart of the size of a hemipseed. By 111 days it had shown considerable increase. In 117 days there were three papillomata; in 127 days several minute thickened plaques of skin were also evident; in 140 days there were five separate papillomata, and another had appeared in 147 days. Increase in size was very slow now for a long time (Plate II, Fig. 8). Thus in 201 days there were still six papillomata. In 208 days another wart appeared on the right foreleg. In 214 days it was thought that there might be basal induration of one of the warts situated on the neck behind the left ear (Fig. 9). The other warts were then short and not progressive. In 247 days it was certain that the tissues under the post-aural wart were being infiltrated; in 257 days the subcutaneous infiltration extended under the skin of the ear; in 264 days this tumour showed cracks on its surface and it was infiltrating subcutaneously towards the occiput. Another smaller wart situated over the left shoulder showed suspicious basal induration. Besides these there was a good horn in the mid-line, a wart over the right shoulder, and three other flat warts on the back. The animal was killed on the 265th day (Fig. 10). Microscopic examination of the post-aural tumour revealed an epithelioma with somewhat atypical cells and comparatively little keratinization; the tumour cells infiltrated the deep muscles (Fig. 11). The smaller tumour situated over the left shoulder was also an epithelioma infiltrating the muscles, and it was entirely separate from the former. Thus there were two distinct epitheliomata produced in this mouse. No metastases were seen.

2. In contrast to the last case, no lesion of any kind could be detected before 186 days, when a very doubtful minute plaque was seen behind the left ear, but this had disappeared entirely within a fortnight. In 208 days a tiny wart was noticed in the mid-line behind the shoulders, but it did not increase in size. In 238 days a small wart appeared behind the left ear; in 239 days it had shown little or no progress, and the wart in the mid-line had disappeared. In 264 days the post-aural wart measured less than a quarter of an inch in diameter and in height; in 295 days it was no larger than a hemipseed, though it grew later into a horn which curled towards the mid-line, and the base indurated shortly before the animal died in 339 days (Plate III, Figs. 12 to 14). During manipulation at autopsy the horn was broken off, leaving an area of basal induration. No metastases were seen. Histological examination of the basal part showed, to our surprise, a spindle-cell sarcoma infiltrating the deep muscles (Fig. 15). The surface of this where the horn had been detached was covered by a rather indefinite hyaline material, but the surface epithelium on either side of this was not much altered. Examination of the broken-off horn showed the usual highly cornified epithelium. There was no transition between the epithelial cells and the underlying sarcoma. The picture, including the superficial hyaline material which I take to represent degenerated keratin, was identical with that given by the sarcoma produced by the "green oil" above.

Experiments with more Refined Shale Oils.

From "blue oil" which has been treated with sulphuric acid and caustic soda and then distilled three products are obtained—unfinished gas, cleaning, and lubricating oils. I am not aware that cutaneous cancers have developed in workmen dealing with these products. Two series of fifty mice were painted with unfinished gas oil and unfinished lubricating oil. These were started in the beginning of this year. The death rate, as with the cruder oils, has been very high, and as the experiments are still going on only an imperfect account can be given. With both substances we have succeeded in producing tumours.

Unfinished Gas Oil.—With this oil, which is a golden-yellow transparent fluid, but from which solid paraffin can still be extracted, only one temporary tumour was obtained amongst

A papilloma was observed in 102 days, and it reached the size of a hemipseed in 110 days. Its progress was slow. In 135 days it had been scratched flat. In 145 days it had gone, leaving a small excoriated area. In 152 days there was another wart on a different site measuring 1 mm. (thick) and 2 mm. in height; in 180 days it had grown laterally somewhat but had not increased in height, and it slowly disappeared.

Unfinished Lubricating Oil.—This is a dark green oil still containing solid paraffin in solution. With this three tumours have been produced amongst 10 mice which survived for a hundred days.

1. Two minute warts close together were found in 124 days, but they were still small when the mouse died in 183 days.

2. A tiny wart was discovered in 180 days, but it disappeared entirely. Another started in 255 days, and measured 2 mm. high by 1.5 mm. broad a week later. The mouse is still alive.

3. A small papilloma appeared in 123 days, and had reached the size of a lentil 12 days later. In 145 days there were three separate warts which showed fair growth (late III, Figs. 16 to 18). When the mouse died in 235 days it showed three tumours—one a large horn about three-quarters of an inch long growing from the back of the neck, a small wart about the size of a hemipseed, and a circular superficially ulcerated wart on the left flank. Microscopic examination of the left flank wart showed it to be a typical epithelioma infiltrating the muscles. No metastases were seen.

[The dates for the appearance or disappearance of tumours in all the experiments are correct to within seven days.]

By the frequent application of crude shale oils containing paraffins we have thus produced tumour formations in no less than 30 out of 74 mice which survived the treatment for over a hundred days. Owing to the increasing death rate after that time it is impossible to say how many more would have developed tumours had they lived long enough, or how many of the simple tumours produced would have gone on to malignancy. Certainly one animal resisted for over nine months. The disappearance of some of the simple papillomata corresponds with what is found in man. In many of the older papillomata considerable difficulty has been encountered in forming a judgement of their benignity or malignancy; the boundary line between them is nebulous, and I have adopted the convention of not reckoning a tumour as malignant no matter how extensive the heterotopy of epithelium or the lack of differentiation of the cells, unless the panniculus carnosus has been definitely penetrated. I have not used the method of transplantation as a criterion of malignancy because I do not believe it gives any surer, or even additional, information on that point. But in the two epitheliomata I have produced the invasion has gone far deeper than the panniculus carnosus and the evidence, even though metastases have not occurred, is clear beyond doubt. The sections of the two sarcomata have been seen by several pathologists of distinction, and all agree with the diagnosis. It might be thought that the cells composing these latter tumours are much altered, undifferentiated epithelium, but careful examination and the use of special staining methods seem to put this interpretation out of court. The sarcomatous development which in these two cases occurred underneath previously existing papillomata is probably due to the entrance of the carcinogenic agent into the subcutaneous connective tissue through small fissures in the overlying epithelium. Sarcomatous formation has not been found in the workmen in the paraffin refineries, but the observation in mice is of interest in that it demonstrates that the same causal agent may produce two such widely different kinds of malignant tumours as epithelioma and sarcoma. If we reckon that the life of a mouse is roughly one-twentieth that of man and that its reactions, as far as neoplasia are concerned, are correspondingly speeded up, we may conclude from our experimental evidence that it takes at least ten years of exposure to paraffin oils to produce cancer in man—which corresponds to actual experience. And the result of our experiments, in which we have cut out as far as is humanly possible all the accessory factors that disturb the deductions in the human subject, goes far to show that we are dealing with an actual, in contradistinction from a predisposing, cause of cancer.

LEITCH: EFFECT OF CESSATION OF IRRITANT ON DEVELOPMENT
OF EXPERIMENTAL TAR CANCER.

FIG. 1.—Large horny wart with basal induration. Tar had been applied for 5 months, and for the last 13 days a wart was present. Photo on day before death, 60 days after cessation of treatment.

FIG. 5.—A very cellular epithelioma with little keratinization, spreading laterally beneath the panniculus carnosus, which may be seen crossing obliquely upwards from the middle of the

FIG. 7.—Tar applied for 4 months. Tumour started 20 days later. Photo a week before death. A large cornified mass with basal induration.

FIG. 2.—Section of No. 1. An epithelioma showing lateral subcutaneous spread. Musculo fibres were easily identified amongst the epithelial cell masses. Age of tumour 73 days.

FIG. 3.—Multiple cornified warts, the larger with deep infiltration. Tar applied for 5 months; tumour formation started at end of 4 months. Photo on day before death, 80 days after cessation of applications.

FIG. 6.—An epithelioma infiltrating muscle, part of which is seen below. Age of tumour 95 days. Tar applied for 4 months, and tumour started 8 days before cessation of applications.

FIG. 8.—Section of No. 7. Epithelioma with moderate keratinization. Age of tumour 78 days.

FIG. 4.—Section of No. 3—an epithelioma with large cornifying cell masses infiltrating the deep muscles of the back. Age of tumour 121 days.

FIG. 9.—An epithelioma just penetrating the panniculus carnosus. Tar applied for 4 months. Tumour started 2 months later. Age of tumour 33 days.

FIG. 10.—An epithelioma. Epithelial cell masses can be seen amongst the fibres of the deep muscles of the back. Tar applied for 4 months. Tumour started one month later. Age of tumour 55 days.

PLATE II.

LEITCH: PARAFFIN CANCER AND ITS EXPERIMENTAL PRODUCTION.

FIG. 1.—Large multiple horny warts over the shoulder region produced in 9 months by applications of crude shale oil (fraction A).

FIG. 2.—Tumours produced by crude shale oil (fraction A). Warts on neck and left flank. Photo on 115th day.

FIG. 3.—Same mouse after 151 days. More warts on shoulder and much scaly dermatitis.

FIG. 4.—Same mouse after 177 days. View from right side.

FIG. 5.—Same mouse after death, 206th day. The large tumour on the left flank had developed within a month. Note the horny warts on the neck and shoulder.

FIG. 6.—A section of the tumour behind the ear. Much downgrowth of proliferated epithelium reaching level of panniculus carnosus—a doubtful epithelioma. Age of tumour 119 days.

FIG. 7.—A section of the tumour on the left flank—a spindle-cell sarcoma. Low power photo. Compare with Plate III, Fig. 15. Age of tumour 25 days.

FIG. 8.—Tumours produced by crude shale oil (fraction C). Warts on neck and shoulder after 180 days.

FIG. 10.—The same after 265 days. The dorsum of the ear is infiltrated, and beneath this tumour there is another smaller tumour which shows basal induration.

FIG. 9.—The same after 212 days. Suspicious induration noted beneath the growth immediately behind the ear.

FIG. 11.—Section of the tumour infiltrating the ear—a very cellular epithelioma with very little keratinization. Remnants of muscle fibres can be detected amongst the invading cells. Age of tumour 151 days.

LEITCH: PARAFFIN CANCER AND ITS EXPERIMENTAL PRODUCTION.

FIG. 12.—Tumours produced by crude shale oil (fraction C). Photo of wart at base of left ear after 265 days.

FIG. 16.—Tumours produced by more refined shale oil (fraction G). Warts after 170 days.

FIG. 17.—The same after 185 days.

FIG. 13.—The same after 282 days, showing practically no progress.

FIG. 18.—The same after 225 days.

FIG. 14.—The same after 297 days, slightly larger.

FIG. 15.—Section of tumour when mouse (Figs. 12, 13, 14) died on the 329th day. High power. It is a spindle-cell sarcoma similar to that in Plate II, Fig. 7. Age of tumour 111 days.

FIG. 19.—Section of the larger tumour on the left flank (Figs. 16, 17, 18). It is a typical epithelioma infiltrating the muscles, fibres of which can be detected amongst the epithelial cell masses. Age of tumour 112 days.

PLATE IIIA.

LEITCH AND KENNAWAY: EXPERIMENTAL PRODUCTION OF CANCER BY ARSENIC.

FIG. 1.—Photo taken after death at the end of 3 1/2 months, showing large tumour at back of neck with small wart in mid-line directly behind it.

FIG. 2.—The same from above.

FIG. 4.—Section of the metastatic nodule in the left lung.

FIG. 3.—Section of larger tumour showing typical cellular epithelioma on right side. On the left side may be seen the subcutaneous tissues with evidences of chronic inflammation. Age of tumour 76 days.

SCOTT: OCCUPATION CANCER OF PARAFFIN AND OIL WORKERS.

FIG. 1.—Recent papular dermatitis occurring after a few weeks' service in paraffin departments. This eruption had almost completely disappeared three weeks after its onset.

FIG. 2.—Advanced dermatitis orythematoses, after over twenty-four years' service as paraffin worker. Note warts, scars, scales, and patches of atrophied skin.

FIG. 3.—Horny papule in midst of indurated skin. Note leathery appearance of skin.

FIG. 4.—Horny warts on hand. Paraffin worker 83 years of age, sixty years' service as paraffin worker.

FIG. 5.—Large paraffin wart, with central necrotic area, approaching malignancy. Paraffin worker for thirty years.

FIG. 6.—Large ulcerating epithelioma. Paraffin worker for over forty years.

EXPERIMENTAL PRODUCTION OF CANCER BY ARSENIC.

BY
ARCHIBALD LEITCH, M.D.,
Director,
AND
E. L. KENNAWAY, M.D., D.Sc.,
Chemical Pathologist,
Cancer Hospital Research Institute, London.

[With Special Plate.]

A FEW cases had been recorded previously of epithelioma of the skin occurring in patients the subject of psoriasis without any definite relationship between the two diseases having been suspected. Jonathan Hutchinson was the first to attach an important significance to the association. In a communication to the Pathological Society of London in 1887,¹ in which he reported with illuminating details six cases that had come under his care, he maintained that the bond of connexion between the skin disease and the cancer was to be found in the influence of the drug (arsenic) given for the cure of the skin affection. His careful observation and his extensive experience enabled him to detect in these cases a new appearance that was absent in the ordinary phenomena of psoriasis; this was the occurrence of keratoses and warty formations on the palmar surfaces of the hands and feet. "By the prolonged use of arsenic," said he, "the nutrition of the skin may be seriously affected, and, amongst other changes, warty or cornlike indurations may be produced, and if the drug be continued these 'arsenic corns' may assume a tendency to grow downwards and pass into epithelial cancer." He suggested that the effect of the arsenic on the skin was to render it less able to withstand friction and the common kinds of irritation. The striking illustrations which he brought forward in support of his contention excited much interest, and it was not long before more cases were reported from various parts of the world in corroboration. In succeeding years Hutchinson's convictions grew stronger, and he endeavoured, not very convincingly it may be, to attribute many other forms of cancer to the operation of the same agent. Thus, the presence of arsenic in soot explained the occurrence of chimney-sweeps' cancer of the scrotum; the finding of arsenic in beer accounted for the undue prevalence of cancer in brewers and publicans and its frequent incidence in the general population; and even cancer of the tongue might be traceable to the arsenic contained in cured tobacco. He rode the idea with a loose rein. The quest of a single cause of cancer has always led to much speculation, much especial pleading, and much disappointment. Certainly arsenic is widely distributed in nature and is present in traces in many of our foodstuffs. Professor Bayet of Brussels is a strong supporter of the "arsenic theory"; he thinks that practically all our industrial cancers are due to the action of the arsenic contained, even in excessively small amounts, in the substances with which the workmen come in contact—soot, tar, pitch, paraffin, and aniline derivatives.²

Apart, however, from cases of psoriasis and other skin diseases in which arsenic has been taken in medicinal doses over long periods, there is little clinical evidence in favour of the theory that arsenic can induce cancer. In this country there are only two instances on record which could reasonably be attributed to employment in arsenical works—two workmen who dealt with sheep-dip; miners dealing with ores of high arsenic content show no special liability to cutaneous cancers. The reputed prevalence of lung cancer amongst the Schneeberg miners in Saxony, where the ores contain arsenic, has never been satisfactorily verified. The semi-mythical arsenic eaters of Styria have not been known to furnish any examples. The amount of arsenic in coal tar and paraffin is very small, and there is no evidence that it is the tumour-producing agent in these substances; nor is there any good reason for the belief that arsenic, amongst all the various substances employed in the preparation of dyes, is responsible for the typical bladder cancer of aniline workers.

Nevertheless, a consideration of the reported cases of epithelioma arising in psoriatic patients who have been treated with arsenic must impress one with the possibility that this substance may induce cutaneous cancer. A few years ago Pyo-Smith³ collected most of the reported cases. In all the known instances arsenic, generally in the form of Fowler's solution (containing 1 per cent. As_2O_3), had been

taken by the patients for long periods—two to thirty years; in more than half of the cases the epitheliomata were multiple, and on different parts of the body; in more than two-thirds the hands or feet were affected, and several were quite young people. Still, the number of cases recorded, some thirty in all, must be very small in comparison with the large number of patients who have taken arsenic medicinally, and certainly no one has yet suggested that the wide use of arsenical preparations in the treatment of syphilis has been productive of cancer. It might be argued that psoriasis is merely one form of reaction to an unknown agent which may otherwise induce epithelioma.

In the hope, therefore, of determining experimentally if arsenic might act as a tumour-producing, or carcinogenic, agent, but realizing that the chances of obtaining a positive demonstration were against us, we fed a series of rats and mice on bread containing arsenic. The bread was soaked in a weak solution of potassium arsenite and then dried, and a ration of dried bread was given to each box of animals, so that each rat would receive approximately the equivalent of 0.075 c.c.m. of Fowler's solution, and each mouse 0.05 c.c.m. of the same, on each of three days in the week. Even with such small quantities the death rate was unusually high, and the experiments were unsuccessful in the matter of tumour production, although in the rats there was clear evidence that the skin was affected by the elimination of the arsenic. In order to avoid constitutional effects as much as possible, and to give us more latitude in the quantity of arsenic we could use with safety to the animals, we applied the arsenical solution directly to the skin in 100 mice. An area between the shoulders was epilated with sodium sulphide, and a drop of the solution—potassium arsenite in alcohol—was applied by means of a camel-hair brush thrice weekly. The particular site was chosen in order that the mice should not lick off the arsenic, and an alcoholic solution was used so that it might evaporate rapidly without spreading through the adjacent hair. The first applications contained 1.8 per cent. of arsenious oxide, but the quantity was reduced on account of the high death rate to 0.12 per cent. in a fortnight and continued at this strength. Thus for the most part of the time we used a solution of arsenic eight times weaker than Fowler's solution. The exact quantities are of no importance, because the concentration on the skin, owing to evaporation of the solvent, would be relatively high. In three months' time we had lost two-thirds of the mice, but we had succeeded in producing a growing tumour in one of the survivors.

In 85 days a tiny wart appeared on the small area to which the arsenic was applied. In 93 days another small wart arose behind the former, which had now attained the size of a hempseed. The larger wart increased quickly in size, so that in 140 days it was a centimetre in diameter, forming a disc-shaped tumour, freely movable over the deeper structures, raised about 2 mm. above the surrounding skin, and slightly excoriated on the surface, whilst the smaller tumour showed little increase in size. The larger growth increased, becoming more ovoid and extending laterally, and definite subcutaneous induration was observed. As there seemed little doubt about the malignancy of the tumour the animal was killed at the end of 5½ months (162 days). The principal tumour, situated on the back of the neck between the shoulders and the ears, measured 2 cm. across by 1.25 cm. from before backwards, and stood well up from the skin level. It was a hemispherical whitish growth, with a reddish, slightly ulcerated dome, hard and white on section, spreading under the adjacent normal skin, and apparently infiltrating the deep muscles (Plate IIIA, Figs. 1 and 2). Close behind it was a simple wart. In the left lung there was a hard white spherical nodule, 2 mm. in diameter, and another nodule half that size in the gastro-hepatic omentum. The cervical and axillary lymphatic glands and portions of liver, spleen, and other organs were taken for examination. Microscopic examination of a section through the large tumour showed it to be a typical squamous-cell carcinoma with cell-nest formation, though not markedly keratinized, spreading underneath the panniculus carnosus for a distance on each side and infiltrating the deeper muscle (Fig. 3). The nodule in the lung was a metastatic deposit repeating the histological features of the parent growth (Fig. 4). The nodule in the omentum was merely a structureless calcified node, and no deposits were found in the lymphatic glands nor in the organs examined.

The experiments are being repeated in order to obtain further examples, but there is little room for doubt, owing to the situation of the tumour on the exact spot where the

arsenic had been applied, the time of its appearance, the fact that another wart appeared also beside it, and the extreme rarity of epithelioma of the skin in mice, that this is an experimentally produced cancer. Rarely induced in man, it may not be more easily induced in mice.

ON THE OCCUPATION CANCER OF THE PARAFFIN AND OIL WORKERS OF THE SCOTTISH SHALE OIL INDUSTRY.

BY

ALEXANDER SCOTT, M.D.,

Certifying Factory Surgeon: Surgeon to Broxburn and other Oil
Companies; Medical Examiner of Paraffin Workers for
Scottish Oils, Ltd.

(With Special Plate.)

WHILE the term "paraffin cancer" has become classic, it is not so generally known that the paraffin workers of the Scottish shale oil industry suffer from various well-defined skin lesions, due entirely to their employment, and arising from the handling of and coming into contact with paraffin materials over lengthened periods.

The lesions may be enumerated as follows:

1. Occupation comedones.
2. Folliculitis and perifolliculitis.
3. Pastular dermatitis.
4. Simple erythema.
5. Dermatitis papulare (erythema papulatum).
6. Dermatitis erythematos.
7. Epithelioma.

The first four of these conditions need not be referred to further, so far as this discussion is concerned, as they play no part in the production of malignant conditions. The other conditions, being of importance in this respect, may be briefly described.

Papular Dermatitis.

This consists of an eruption of small rounded elevations of a reddish colour, varying in size from that of a small peppercorn to that of a small pea. They are solid, superficial, rounded in shape, and contain no fluid. There is as a rule no inflammatory areola around the typical papule; there is neither itching nor irritation; the papules do not tend to coalesce, and as a rule heal spontaneously. They may be present singly or in twos or threes, or in larger numbers until there may be a diffuse eruption of discrete papules. Between 40 and 50 per cent. of the workmen are affected with this type of eruption, and of these affected approximately 50 per cent. show not more than three or four papules, 45 per cent. have a limited extent of eruption confined to a small area, and 5 per cent. have a diffuse eruption. The distribution of the papular eruption is very typical. In the great majority of cases it is confined to forearms, especially over the ulnar aspects, though it is also prevalent over anterior and posterior aspects, around wrists, and on backs of hands. Less frequently a few papules are present on the shoulders, legs, and dorsal aspects of feet. In old-standing cases they are seen over the lower thirds of arms and around elbow-joints. Approximately 75 per cent. of those affected have eruption on hands and arms only, 20 per cent. have both arms and legs affected, and about 5 per cent. have some eruption on the body, as well as on either arms or legs. The earliest appearance of papules after men begin work in paraffin sheds occurs in from ten to twelve days, and they may persist throughout the duration of employment.

Occasionally in old-standing cases the papules assume a warty appearance, due to proliferation of superficial layers of epidermis, forming scaly warts, at first soft, but gradually becoming harder and more indurated, this warty appearance being of a permanent nature. As a general rule this indurated type of papule is first observed on workmen who have been continuously employed in paraffin departments for over eight years or so, and they are present at first singly or in small numbers, and only after fifteen or twenty years of service as paraffin workers are they present in greater numbers, especially over backs of wrists and hands. They may persist in this condition indefinitely.

In the most chronic types of this condition of warty papule

there is occasionally a tendency to increase in size, accompanied by the formation of a central necrotic area, which may separate and be followed ultimately by the disappearance of the warty growth, with the formation of a scar. These more chronic types are, as a rule, associated with an old-standing induration of skin. Occasionally a warty papule, instead of disappearing, grows until it assumes the characters of an epitheliomatous growth, with the usual clinical and pathological features of that condition.

Dermatitis Erythematosa.

This is a chronic inflammation of the various layers of the epidermis and cutis vera, followed by induration and, in the most advanced stages, by partial or complete destruction of small areas of the skin in the affected parts. The early appearances are first seen on workmen who have been in contact with paraffin substances for seven or eight years. In the first stages the lesion consists of dull red erythematous patches distributed irregularly over the forearms, giving a mottled or honeycombed appearance. At first the condition is limited to small areas, but, as it becomes more old-standing, involves larger areas, the whole surface of the forearms being frequently affected. This erythematous stage may persist for long periods without further change, or healing may take place, the redness disappearing, being replaced by some induration of the superficial layers of the skin, with a characteristic dry scalliness which is practically permanent. Frequently the erythematous dermatitis progresses so that the deeper layers of the skin are infiltrated and, as the inflammatory process subsides, small patches of atrophied skin, white in colour, appear, or there may be scar formation, according to the depth of the inflammatory changes. There is frequently a tendency to the formation of small, flat, scaly warts, usually oval or circular in shape, which are very typical of old-standing dermatitis due to paraffin. The advanced condition of dermatitis may persist for many years or for a lifetime, with permanent roughness and wartiness of skin and a chronic desquamative process going on.

Chronic dermatitis as described above usually coexists with old-standing papular dermatitis, in which the papules are of the indurated type, being hard and scaly. Thus in an advanced stage the forearms show pigmented patches, small white areas of atrophied skin, scars, scaly warts, and indurated papules. The distribution of erythematous dermatitis is confined solely to parts in contact with paraffin substances. The forearms principally are affected, either in parts (especially over ulnar aspects) or generally. In advanced cases the lower thirds or halves of arms are usually also affected. While a considerable proportion of the older workmen show evidence of healed or old-standing dermatitis the condition has become less evident in recent years, and is practically confined to those who have been paraffin workers for years, the recent employees being free from this type of skin lesion.

Epithelioma (Paraffin Workers' Cancer).

Epithelioma, as seen among the paraffin workers of the Scottish shale oil industry, occur only in those about or over middle life who have been so employed for twenty years or more. They usually arise from warts due to a chronic dermatitis or from indurated papules, and therefore usually coexist with an advanced dermatitis erythematos in which wartiness is a predominant feature, or with numerous indurated papules of a simple nature. The usual appearance is that of a gradually growing epithelioma in the midst of a chronic indurated dermatitis, with numerous simple warts or indurated warty papules, only one of which has become malignant. I have never seen more than one epithelioma at one time on the same individual, though it is not uncommon for the same workman to have several different growths at various times over a period of years. The warts or papules from which this condition arises have as a rule been present for many years in a benign form, until the epithelial covering begins to proliferate more rapidly, with increasing growth of the primary lesion, until the characters of malignancy develop. These epitheliomata are only met with on those who have been paraffin workers for many years, and, indeed, those which I have seen have occurred after twenty or more years' work among the paraffin materials, the majority being seen after between twenty-five and thirty years of such service. In the early stages of the degeneration the naked-eye appearances vary according to the primary condition, so a short outline of the development from a wart and an indurated papule may conveniently be given.

(a) *Arising from Scaly Wart.*—In the benign condition the wart is somewhat oval or circular, about the size of a sixpence. It is covered by small scales, which are readily removable, leaving a somewhat indurated base. The wart does not protrude to any extent above the level of the surrounding epidermis. As the epithelium undergoes proliferation the wart increases in area, and also becomes more raised above the level of the surrounding skin, until it gradually assumes the size of half a crown in area, raised about a quarter of an inch or more above the surface and covered with thick horny scales. On reaching this size there is a tendency for the formation of fissures, or abrasions of the surface, from which a serous fluid exudes, causing crusting of the surface. The crusts are readily removed by any slight injury, but re-form. This appearance persists for some months, the area gradually increasing until the incrustation and warty covering of the growth eventually slough and disappear, leaving a superficial ulcer, from which sero-sanguineous fluid exudes. Subsequent growth of the ulcer in depth and size takes place slowly.

(b) *Arising from a Papule.*—An indurated papule has been already described as occurring in old-standing erythematous dermatitis. The papule as a rule persists in this benign form for many years. A central necrotic area may form, accompanied by the gradual growth of the primary lesion. After separation of the slough it may grow until it assumes much larger proportions than formerly, the growth having a central ulcer surrounded by indurated edges. The growth of the ulcer extends peripherally and also in depth, the edges being indurated and undermined until all trace of elevation of tissue above the level of the surrounding skin disappears, so that a large open ulcer is formed, with a base of red, angry-looking granulation tissue, bleeding profusely on the slightest touch. When the growth is situated on the scrotum there is, as a rule, in the ulcerative stages, an overgrowth of epithelial tissue forming large masses, protruding above the surrounding surface, giving the appearance of a cauliflower excrescence, and, being very vascular, they bleed profusely. Ultimately the lymphatic glands are involved in this excrescence, so that in the latest stages the whole inguinal region is invaded by a large ulcerating cauliflower-like mass. The malignancy for a long time is not great, as the lymphatic glands do not become involved till a late stage, but thus varies according to the situation, the glands being involved earlier when the lesion is situated on the scrotum than when the site is on the arm or forearm. I have seen occasionally quite advanced tumours and ulcers removed without recurrence, though sometimes amputation of a limb has been necessary, the after-results being satisfactory. In cases terminating fatally death is as a rule due to extensive ulceration with exhaustion, rather than to metastases. I have known very extensive ulceration of the scrotum and inguinal glands, ending in death, unaccompanied by any gross secondary lesion as far as clinical investigation or symptoms indicated. The most common site is on the back of the hand or on the lower third of the forearm, but it is also common on the scrotum, especially among oil workers and labourers, a fact which will be considered later. Epitheliomata have been seen on the face, and at the outer and inner angles of the eyelids, in which latter case the features of a rodent ulcer may be assumed.

Epitheliomata also occur among retortmen, oil workers, stillmen, and labourers, these being a large group of workmen, approximately five thousand in number, quite distinct from the group of paraffin workers. These men do not come into such intimate contact with paraffin substances in the course of their work and accordingly do not suffer from any of the papular or inflammatory lesions which occur among the paraffin workers. On these workmen they do not arise from pre-existing warts or papules, but generally begin as a reddish pea-shaped nodule, in which the typical "cell nests" are present practically from the onset; or they may occur at the site of a simple papilloma or small cyst or mole—simple conditions found frequently on the scrotum under ordinary conditions apart from any occupation cause—but in the great majority of cases the growth is a primary lesion. There is epithelial proliferation, accompanied later by the degenerative changes associated with an epitheliomatous growth. The epitheliomata which occur in oil workers and labourers, as distinguished from paraffin workers, without any primary condition of dermatitis, are as a rule found among those men—such as retortmen, labourers, stillmen, oil workers, etc.—who come into contact with ash, coke, or other gritty material. The scrotum is most frequently the site of such

lesions, this being due to the difficulty of ensuring cleanliness of this region.

I have made a list of all cases of paraffin epithelioma which have occurred during the twenty-two years from January 1st, 1900, to December 31st, 1921. In all 65 cases have occurred, of which 19 have been on paraffin workers proper, most of which cases have been seen by me, and 46 among the other grades of labour employed, such as retortmen, stillmen, etc., many of these cases having come under my observation. Since 1918 I have periodically inspected the paraffin workers proper and so have been able to observe the gradual development of malignant features from simple primary lesions, and to have growths removed at an earlier stage than formerly.

In the oil works comprised under Scottish Oils, Ltd., there have been employed approximately five thousand workmen annually for many years, which number includes all forms of labour necessary in the distillation of oil shale and the refining of its products. It will be thus seen that the cancer incidence is approximately $1\frac{1}{2}$ per cent. in twenty-two years, or under 0.1 per cent. per annum. Nineteen of these cases have occurred among those definitely known to have been employed in green sheds (paraffin sheds or crude paraffin departments), there being approximately two hundred men thus employed annually by Scottish Oils, Ltd., during those years. The incidence of this condition among these workers is thus 0.5 per cent. per annum approximately. The ages of the cases recorded vary from 37 to 79 years.

Three were under 40 years of age.

Thirteen were between 41 and 50 years.

Twenty-three were between 51 and 60 years.

Sixteen were between 61 and 70 years.

Ten were between 71 and 79 years.

Of the 19 cases among paraffin shed men the lesions were most prevalent on the arms, forearms, and hands, thus:

Hands, forearms, and arms	12 = 63 per cent.
Face, neck, and ear	3 = 15 "
Scrotum	3 = 16 "
Groin	1 = 5 "

Of the 46 cases occurring among oil workers and labourers the sites were:

Scrotum	28 = 61 per cent.
Arms, forearms, and hands	9 = 20 "
Face, neck, and ear	7 = 15 "
Leg	1 = 2 "
Anus	1 = 2 "

These figures are in accordance with the facts stated that among oil workers, retortmen, and labourers the tendency is for the primary lesion to occur on the scrotum, being malignant practically from its early stages; while among paraffin shed workmen, as a general rule, the lesion occurs as a degenerative stage of warts or papules, which are most commonly situated on the forearms.

The chief etiological factors predisposing to the formation of paraffin workers' cancer are age, length of service in paraffin department, and idiosyncrasy.

Age.—Age has an important influence on the occurrence of epitheliomata, these being practically never seen under 40 years of age, and as a rule appear at more advanced ages than this. This will be seen from the age incidence already given.

Length of Service.—The importance of a long period of service in paraffin departments as a predisposing cause of chronic indurated dermatitis and epitheliomata is apparent from the following figures. Of twelve paraffin workers who had extensive indurated dermatitis (dermatitis erythematosa) at one examination, the individual lengths of service were 39, 38, 36, 34, 33, 29, 28, 27, 22, 21, 18, 18 years respectively. As epitheliomata of paraffin workers are associated with this indurated dermatitis, the importance of long service is apparent.

Idiosyncrasy.—This plays an important part as a predisposing cause of paraffin epitheliomata. Many workmen have indurated papules and warts due to occupation, from which epitheliomata may develop, but only a small percentage of these undergo malignant degeneration, and, on the other hand, several workmen have had primary growths at different sites on different occasions showing a tendency towards this condition. I have frequently had under observation large warty growths, with a central necrotic area, suggestive of the stage immediately preceding malignancy, which instead of degenerating have healed after separation of the central necrotic area. Cases such as these may be considered as only lacking in the "personal factor."

EPITHELIOMATOUS ULCERATION IN INDUSTRY.

BY

T. M. LEGGE, M.D.,

Medical Inspector of Factories.

EPITHELIOMATOUS ulceration in industry was brought prominently to the notice of the Committee on Compensation for Industrial Diseases in 1907, by Mr. J. Wignall (then organizing secretary of the Dockers' Union, and now M.P. for the Forest of Dean), who cited 38 cases as within his knowledge at that time among the patent-fuel workers in South Wales. The Committee visited Swansea, and in their report said: "We have no doubt that the lesions are specific to the trades mentioned, and that they should be made the subject of compensation." The disease was scheduled under the Workmen's Compensation Act, 1906, as "Epitheliomatous cancer or ulceration of the skin . . . due to pitch, tar, or tarry compounds"; but owing to failure of a workman in one of the shale oil works in Scotland to recover compensation when suffering from this condition, the description was widened to read as it now stands: "Epitheliomatous cancer or ulceration of the skin . . . due to tar, pitch, bitumen, mineral oil, or paraffin, or any compound, product, or residue of any of these substances."

Fuller information of the effects of pitch was obtained at a public inquiry made by Mr. A. H. Lush in 1911 into certain proposed regulations of the Home Office requiring, among other things, washing and bathing facilities in factories or workshops for the manufacture of patent fuel (briquettes) with the addition of pitch, other than blast-furnace pitch. On the strength of the evidence given by the workmen as to the increased pain caused by exposure to sun and wind immediately after washing, these requirements of the regulations could not be made obligatory. The evidence was convincing that no class of worker suffers so much discomfort from his employment as does the patent-fuel worker.

When regulations are proposed under the Factory Act they must first be issued in draft, so affording an opportunity to employers and employed to object. The exclusion of blast-furnace pitch was made as the result of such objection by the occupiers of two factories in Scotland manufacturing blast-furnace pitch. They alleged that blast-furnace tar was free from anthracene and naphthalene, and of entirely different composition from that of gasworks tar. In twenty-three years during which they had been distilling blast-furnace tar in the making of briquettes they had not been aware of a single case of disease from handling pitch.

As every piece of evidence on this point is now desired, I think it right to publish the slender evidence (extracted from my report) on which exemption from the proposed regulations was granted.

"At the two works about 32 men altogether are employed in the manufacture and 6 are engaged solely in the digging of pitch." Of these 38 I examined 20 and satisfied myself that the objections had substance. No history of any case of epitheliomatous cancer or of any wart requiring surgical treatment could be obtained. The men had not the same degree of swarthiness of skin noted in the Swansea workers, nor did they complain to the same extent of the sun's rays in causing smarting of the face. Apart from a certain darkening of the skin, all that I could find pointing to effect of the pitch was in one man, aged 60, employed in the pitch bin fifteen years, marked freckling, dryness of the hands, and a wart (not characteristic) on a finger; in a second (a pitch digger) slight thickening of the backs of the hands with hyperæmic patches; and in a third a few acne spots at the angle of the jaw. While no doubt bathing and washing is desirable for these workers, the evidence as to injury to health is not strong enough for regulations."

This point was followed up in an interesting way by H. O. Ross and J. W. Cropper, who showed, on the assumption that a substance is mischievous or otherwise according as experiments did or did not indicate the presence of anæsthetics and kinetics, that—

- (1) Pitch obtained from gasworks tar is mischievous, but not that from tar of blast-furnaces.
- (2) If the distillation of gasworks tar is carried to a temperature of 365° C. the resulting pitch is no longer mischievous.
- (3) Pure anthracene oil is not mischievous, but the commercial rough anthracene cake is so.

- (4) The bituminous coal from which gasworks pitch is obtained contains agents of the same mischievous character as those of the pitch, but these are rarely found in the Scottish splint coal, which is the main source of supply for blast-furnace pitch.

From later experiments Ross concluded that the dangerous principles were not anthracene or anthracene oil, but probably some substance intimately mixed with them which distilled over at the same temperatures.

Between 1911 and 1918 the Factory Department was kept informed voluntarily by the principal occupiers of patent-fuel works of the men requiring medical treatment for pitch warts or epitheliomatous ulceration. Reports on these cases were obtained from the certifying factory surgeons. In this way, between the years 1911 and 1919 inclusive, information was received of 158 attacks with three deaths among pitch workers, 12 with two deaths among tar workers, and 12 among the paraffin refinery workers in the shale oil factories in Scotland, making altogether 182 attacks with five deaths. I say "attacks" advisedly, because during the years in question 2 men were included for recurrences five times each, 3 four times each, 10 three times each, and 15 twice each. The number of men affected, therefore, was 130.

In January, 1920, the Secretary of State added epitheliomatous ulceration and chrome ulceration, contracted in a factory or workshop, to the diseases enumerated in Section 73 of the Factory and Workshop Act, 1901 (lead, phosphorus, arsenical, or mercurial poisoning, toxic jaundice, and anthrax), notification of which is obligatory on medical practitioners. The following table shows the number of attacks so reported:

	1920.	1921.	1922, Jan.-June.	Total.
Pitch	32	24 ²	10	66 ²
Tar	16 ¹	8	3 ¹	21 ²
Paraffin	3	—	5 ¹	8 ¹
Total	45 ¹	32 ²	18 ²	95 ⁵

The number of persons affected is 89,* as one man had three and four men two recurrences.

The distribution according to age of the men affected is as follows:

	Pitch.	Tar.	Paraffin.	Total.
Under 20 years ...	—	—	—	—
20 to 30 " ...	3	—	—	3
30 to 40 " ...	8	—	1	9
40 to 50 " ...	20	4	1	25
50 to 60 " ...	23	7	3	33
Over 60 " ...	5	9	3	17
Not stated	1	1	—	2
Total	60	21	8	89

The duration of employment of these men at the time of notification is shown in the following table:

	Pitch.	Tar.	Paraffin.	Total.
1 to 5 years ...	6	—	—	6
5 to 10 " ...	9	1	—	10
10 to 15 " ...	8	2	—	10
15 to 20 " ...	5	—	1	6
20 to 30 " ...	18	6	3	27
30 to 40 " ...	10	5	2	17
Over 40 " ...	—	2	—	2
Not stated	4	5	2	11
Total	60	21	8	89

* Twenty-one of the 89 were men of whom we had already knowledge as suffering from epitheliomatous ulceration prior to January 1st, 1920.

The situation of the lesion may be stated thus:

	Pitch.	Tar.	Paraffin.	Total.
Scrotum	19	8	2	29
Eyelid	9	2	1	12
Cheek	7	1	—	8
Forearm	—	4	4	8
Lip	7	—	—	7
Hand	3	2	—	5
Neck	3	1	—	4
Wrist	1	2	—	3
Ear	2	—	—	2
Chin	2	—	—	2
Head; forehead; nose; penis; scrotum and nose; scrotum and neck; scrotum and face; scrotum and arms; scrotum and eyelid; scrotum, chin, and leg; lip, face, and hands; arm, leg, and cheek (1 case each)	10	1	1	12
Not stated	3	—	—	3
Total	66	21	8	95

The following table gives the occupation of the men affected and the number employed in 1920, so far as this can be given:

Precise Occupation.	No. Employed in 1920.	No. of Attacks, Jan., 1920, to June, 1922.	No. of Men Affected.
1. Patent-Fuel Industry.			
Coal tipplers, trimmers, blamers, millmen, pugmen, pressmen, factory labourers	810	24	19
Trolley-men, yardmen, slingers, crane-men	420	6	6
Shippers, pilers, etc.	720	19	18
Fitters, enginemmen, firemen, etc. ...	550	6	6
Total	2,500	55*	49
2. Tar.			
Gas stokers and labourers	Not available	10	10
Tar distillers	"	4	4
Anthracene purification	"	2	2
Other (repairing barges, boats, creosoting, net fixing, etc.)	"	5	5
Total	—	21	21
3. Paraffin.			
Paraffin refinery	200	5	5
Retortmen	Not available	2	2
Total	—	8	8

* The remaining eleven attacks due to pitch were contracted by men handling pitch in other industries than patent-fuel works—for example, gasworks.

The total number engaged in the patent-fuel industry was therefore 2,500. This number includes several who run little risk. Roughly, those included under the first heading work inside sheds and are exposed to pitch dust; under the second in the open air; under the third inside ships stowing briquettes, and exposed to much dust; and under the fourth in the factory premises with occasional exposure to dust. The number exposed to constant risk from tar cannot be given. My impression is that the figure must be a higher one than that for patent fuel, but that as the industry is widely distributed over the country the requirement to notify is not yet sufficiently known. The number employed in the paraffin refineries of the shale oil works is 200. Throughout the period 1920 to 1922 it should be remembered there has been much broken time, several of the works having been at a standstill for months together.

In 1919 the trade unions in South Wales asked for voluntary medical examination to prevent pitch warts becoming inoperable. This was arranged for those over the age of 30, with a duration of employment of over ten years—about 20 per cent. of the total number employed. Owing to the very slow onset of the disease, and trade depression, men have been slow to avail themselves of the opportunity. It is, however, open now to any workman to consult Dr. Scholberg, the pathologist of the Royal Infirmary, Cardiff, and Dr. Sladden in a similar position at Swansea. Dr. Scholberg thus describes, from his examination in 1920 of 213 men, the two clinical varieties of pitch warts:

"(a) The pendulous papilloma, having a slender pedicle, which varies in length from about one-tenth to a quarter of an inch. Such warts may be present for a considerable length of time and give rise to no trouble so far as my observation goes. They are often situated on the upper eyelids and give rise to inconvenience. These for the most part get rubbed off.

"(b) The flattened papilloma, but slightly raised from the surface of the skin, having a broad base and a smooth top. They may occur singly or in groups. They will often be seen on the back of the neck or along the sterno-mastoids. The men are often not aware of their presence, owing to their small size, which is as a rule about that of the head of a small pin. This is the type of wart which may increase rapidly in size, and which on cauterization will recur and if left unexcised become epitheliomatous. However, speaking generally, as far as I have observed the percentage of warts that become large and require treatment is relatively small."

No case of anilino tumours of the bladder has been reported. Since January 1st, 1920, notification has been received of 175 cases of chrome ulceration, 93 in the manufacture of bichromates, 69 in dyeing, and 7 in chrome tanning. It is clear from the reports that cases of chrome ulceration from the use of the salts in dyeing take much longer to develop and are much more chronic than those in the manufacture. In none of the cases has there been any suggestion of epithelioma.

X-RAY CANCER.

BY

CECIL ROWNTREE, F.R.C.S.,
Surgeon to the Cancer Hospital, London.

X-ray dermatitis and x-ray cancer are well-recognized occupational diseases to which radiographers and the manufacturers of x-ray tubes are peculiarly liable. It would appear that as early as 1896 Marcuse¹ described a case of dermatitis and drew attention to the dangers attending the use of x-rays. However, not very much attention seems to have been attached to this warning, and x-ray experiments and investigations continued to be prosecuted during the next few years with great energy and enthusiasm and little or no protection. But in 1903 Sick reported the startling fact that one of the already numerous cases of x-ray dermatitis had developed a malignant growth on the affected part. This dramatic complication emphasized the dangers of the work and resulted in great development in the methods of protection. But it was too late to help those already affected with dermatitis, for the damage was done, and during the next few years cases of x-ray cancer occurred with a frequency which was a matter of grave concern to those who were exposed to this special risk.

In 1909 for my Hunterian lecture on x-ray cancer² I found it possible to collect the records of eleven English and nine American cases, and at that date four American and one English case had already terminated fatally, the English case having died as early as 1904. Since 1909 there have been at least three further deaths in this country, making four altogether. Two of them were medical men, one an x-ray tube manufacturer, and the other an x-ray assistant. It is sincerely to be hoped that we have now reached the end of the fatalities and that x-ray cancer will soon be an unknown disease.

I have not had the opportunity to investigate the present position of affairs in other countries, but it would appear that in England only two new cases of x-ray cancer have occurred since I investigated the subject in 1909, although of course many of the sufferers—in fact, nearly all of them—have had to submit to the amputation of additional fingers as further growths have shown themselves. I think the smallness of the number of additional cases is probably to be explained by the fact that practically every one of the early cases of severe dermatitis has now developed cancer, and that the

methods of protection in use during the last twelve or fifteen years have prevented the occurrence of new cases of dermatitis of a severity likely to develop into cancer.

There is no need to describe the clinical appearances of x-ray dermatitis, but it may be of interest to emphasize some peculiarities of its distribution. In the first place, it is practically confined to the backs of the hands and fingers, particularly the latter. The dermatitis stops abruptly at the wrist at the level of the coat sleeve, showing how slight a measure of protection is necessary and affording proof of the fact that it is the soft non-penetrating rays that do the damage. As might be expected, in those who wore a ring the narrow zone of skin so protected remained absolutely unaffected.

In two instances the dermatitis was not confined to the hands. One of these patients developed changes over an area of the chest corresponding to the V-shaped opening of the waistcoat and also a malignant growth on the chin. The second patient developed one growth on the eyelid and another on the toe.

The clinical history of all the cases is very similar. In nearly every instance there is a definite history of a severe burn, usually as the result of prolonged manipulation of a fluorescent screen. Healing of the burn was followed by the development of x-ray warts, and in the course of time one of these warts came to be differentiated from its fellows by growing larger and increasingly painful. Sooner or later the wart came away, leaving a superficial ulcer, which, when removed, generally proved to be an early carcinoma.

In many of the cases the ulcerated areas were so superficial and so harmless-looking that a good deal of doubt was at one time expressed as to the exact nature of the lesions. But examination of the microscopic slides leaves no possible question that we are dealing with a typical squamous-cell carcinoma. I may say, however, that even in the light of earlier experience it was sometimes impossible to form any opinion as to the malignancy or otherwise of a lesion without the aid of the microscope. Several quite innocent-looking warts proved to have epitheliomatous bases, and I suspect that microscopic evidence of malignancy frequently precedes any of the accepted clinical signs by a considerable period of time, just as we see in the tongue and elsewhere.

In neglected cases the growth assumes the usual infiltrating and fungating character seen in other forms of epithelioma. In the most striking case of the kind that I have seen the finger became converted into a huge lobulated mass of growth which infiltrated and destroyed the underlying bone. This patient lost several fingers and then the arm, which is preserved in the museum of the Royal College of Surgeons. When death took place there was also an extensive growth involving the chin and lower lip.

Infection of the lymphatic glands would seem to be uncommon, for although all the four fatal cases had their axillary glands involved, yet the remaining nine cases have had no glandular infection, and in seven of them a period of at least fourteen years has elapsed since the removal of the first growth. And as it must be remembered that nearly all these patients have had multiple tumours and therefore multiple opportunities of developing metastases, it is, I think, fair to assume that x-ray cancer may be classed as of relatively low malignancy. Moreover, local recurrence has not been met with even after the very limited excisions that have been sometimes practised. Any further development has been on another finger, or at any rate on a part sufficiently remote from the original growth to establish its independence. There is no such immunity in other forms of cancer, and I have often wondered whether the general changes in the connective tissues, and presumably in the lymphatic vessels, which are characteristic of x-ray dermatitis, can have any influence in staying lymphatic permeation.

It is very interesting to speculate as to the amount of irradiation necessary for the production of x-ray cancer, and another point of great interest is the intensity of dosage required. Can cancer follow one large dose or a short series of such doses? I believe not, for in spite of the very large number of patients who have been burned in the course of screening or of treatment I have not been able to find a single case of epithelioma arising as the result of such a burn. Of course in x-ray workers the conditions of exposure are impossible to analyse, but I believe I am right in stating that those of the earlier workers who have escaped serious trouble were never burnt, while those who have developed cancer

have all had either a burn or at least a severe erythema in addition to their small daily exposures.

There are in London now two men who in the early days were constantly exposed for a year or two and were badly burnt in consequence. They gave up x-ray work absolutely nearly twenty years ago and have remained entirely free from cancer. The complete immunity of these two men and of the numerous burnt patients proves, I think, that one burn alone is not sufficient to cause cancer; while the immunity of the few x-ray workers who have escaped burns but who must for years have been exposed to small daily doses suggests that it is to a combination of one or more burns plus a long succession of quite small exposures that x-ray cancer must be attributed. For how long these small doses must go on it is impossible to say, but I think it certain that very numerous exposures spread over a considerable period of time must be required. In none of the cases of x-ray cancer I investigated was there a shorter period than four or five years between the first exposure and the first epithelioma. In most of them the interval was much longer—in fact, in two cases it was no less than seventeen years. But it is not suggested that continuance of exposure during these long periods is essential, for it appears to be a fact that the changes of x-ray dermatitis, when once they are well established, are of a progressive character, and that cancer may develop long after any exposure to x-rays has occurred.

This long latent period is of great importance from the clinical point of view, for it shows us that no case of x-ray dermatitis can be considered safe—at any rate for many years after the last exposure. It is also of interest from the pathological point of view, having regard to Leitch's observations on the progressive nature of the skin changes resulting from the action of other specific irritants.³ This raises the question as to how far x-ray cancer can be regarded as of specific character. Let me recapitulate its clinical features. It is a cancer occurring in young men, some of them only 30 years of age, far below the average age for other skin cancers. Practically every patient has his original growth upon the dorsal surface of the finger, a site where other forms of cancer are so rare that I have been unable to discover an example. There is none even at the College of Surgeons' Museum. In most of the cases the growths were multiple. Porter⁴ records one case where ten separate epitheliomas were removed during five years. In every case the growths arose in areas the seat of x-ray dermatitis, and finally nearly every case of x-ray dermatitis arising in the years 1899–1906 has developed cancer.

I think it is fair to conclude that x-ray cancer is caused by the application of a specific irritant, and that in view of its high incidence and special character it may be regarded as the most specific of all human cancers. In fact we might go farther and claim that in x-ray cancer we possess the only clear-cut and well-defined example of the experimental production of cancer in man.

Consideration of human x-ray cancer naturally invited an attempt at its production in animals, and numerous experiments on rats and rabbits were the result. Varying degrees of dermatitis were readily obtained, but nothing further eventuated, and my experiments were abandoned. I think we were too impatient and had not sufficiently realized the importance of the latent period factor now proved to be so important in the other experimental cancers. A further series of experiments now in progress may perhaps be followed by more success.

EXPERIMENTAL SOOT CANCER.

BY

R. D. PASSEY, M.C., M.D., D.P.H.,
Guy's Hospital, London.

EARLY in 1920, with a view to the finding of some means of producing carcinoma in animals, both quickly and in a reasonably high percentage of cases, an attempt was made to select an active fraction out of soot. Ordinary household chimney soot was chosen for the purpose, its source being that coal known in the trade as "best house." The soot used was from the same source throughout the experiments. Three fractions were selected, and were labelled I, II, and III.

Fraction I.—This was merely an ether extract of the soot. The soot was stirred into ether and filtered through ordinary filter paper, fresh ether being added till the washings came away the colour of a light sherry. The filtrate was distilled and the ether evaporated off until a residue, of the consistency of a thin syrup and still smelling strongly of ether, was left. This was then stored in glass-stoppered bottles till required.

Fraction II.—Three parts of soot and one part of quicklime were intimately mixed with distilled water into a fairly thick paste and spread in thin layers on large glass plates to dry. Lime was selected as the base solely because it gave a mixture which dried readily and did not cake too hard. This mixture produced an abundance of free ammonia. When dry and free from a smell of ammonia the caked mixture was broken up finely and extracted with ether until the final washings were of the same colour as the final washings of Fraction I. This extract was filtered and the ether distilled off and stored as in the case of I.

Fraction III.—One part of Fraction II was added to ten parts of a weak acid (N/10 HCl was used) and shaken thoroughly in a large glass separating funnel. The watery solution was run off and filtered, and fresh weak acid added, the process being repeated until the watery solution came off nearly colourless. This bulky watery solution, which was strongly acid, was filtered and then rendered slightly alkaline with normal caustic soda solution. This produced a precipitate of a yellowish colour which microscopically was seen to consist of oily droplets. The whole neutralized filtrate was then extracted with ether repeatedly till the ether came away nearly colourless. The same procedure was then adopted of distilling off the ether and storing.

Watery extracts of Fractions II and III were faintly alkaline and of Fraction I faintly acid, though neither was appreciably soluble in water. Fractions II and III smelt strongly of the pyridine group, especially III. Fraction I, when freed of ether, was almost black tarry liquid which, when cold, nearly solidified. II was of the consistency of a very thick treacle and very dark, but was browner in colour than I. III was somewhat more fluid, but still very thick, and much lighter in colour than either of the others. Fraction II contained the ether-soluble bases and neutral substances in soot together with colouring matters. III consisted mostly of the ether-soluble bases of the water-soluble salts of Fraction II, also some colouring matter. As previously stated, the pyridines were present in large quantities.

Three groups of young adult white mice were taken, two of twenty in each and one of forty. Care was taken to divide them equally as regards size and colour. One lot of twenty was painted with soot Fraction I, the other with Fraction III. The group of forty were painted with II.

The hair was removed from the back by an epilatory containing barium sulphide. The fractions were applied along the epilated back by means of camel-hair brushes along an area about 2 cm. long by 5 mm. in width. Applications were made two or three times a week. The fractions were usually diluted with a minimum of ether sufficient to render them easy to apply—the ether, of course, evaporated at once on application. The advantages of this were: (1) ease in working; (2) a film was produced on the skin which appeared to stay on the animals longer; and (3) better penetration into the interstices of the skin (and perhaps even into the hair follicles). It was hoped that the lipid-solvent properties of ether might result in better penetration of the fractions into the cells themselves.

At the outset one can dismiss Fractions I and III. The former produced warts in only three animals by the end of six months, and the latter in only one. Neither had produced definite malignant changes, so at that point they were discarded as not giving the results aimed at. Undoubtedly I was the fraction which produced the most ulceration, whereas III seemed the least destructive. It would be beside the point to discuss whether Fractions I and III would have produced malignancy if application had been continued. Anyway, the method of preparation was too crude to exclude the presence in them of traces of substances (which might indeed be the active ones) present in II.

Applications of Fraction II—the basic ether-soluble fraction—were commenced on December 16th, 1920, and the first wart appeared on February 25th, 1921—in ten weeks and after thirty-one applications. By March 18th, 1921, 16 mice (88 per cent. of the survivors, which numbered 18) had developed warts, and of the survivors at the end of the third

month 50 per cent. subsequently developed malignant tumours. The first date malignancy was established microscopically was June 12th, 1921.

In April, 1921, as the second fraction seemed to promise so well, it was decided to see if, perchance, the fat-soluble A vitamin is an additional factor in the production of primary tumours. At this stage a second investigator, Mr. J. L. Woodhouse, joined in the experiment.

Two groups of white mice, fifty in each, were selected, as nearly identical in size and colour as possible. One group was fed on a diet very rich in the fat-soluble factor and the other on one in which that factor was eliminated as completely as possible. It is not claimed to be free of it—it was question of a fat-soluble-rich versus a fat-soluble-poor diet.

The vitamin-poor diet consisted of plenty of bread soaked in water, slices of orange once or twice a week, and oats once every ten days or a fortnight. To this diet was added breadcrumbs dipped in olive oil to make the diets comparable as to their fat content. The vitamin-rich diet was the same, except that in place of the olive oil, butter (grass-fed) and cod-liver oil were substituted.

The mice were painted with soot Fraction II as in the first experiment, the conditions being identical in every way throughout the experiment, excepting that of the diet.

Of the survivors at the end of the fifth month of the experiment in the case of the fat-soluble-rich diet, 42.3 per cent. subsequently developed malignancy, and in the case of the fat-soluble-poor diet the corresponding figure was 47.3 per cent. The only noticeable difference in the two groups was that the warts appeared a little earlier in the vitamin-poor diet animals. The tumours were identical in type, and, as far as one could tell, in their rate of growth.

This experiment would suggest that the fat-soluble A vitamin is not a factor in the induction of tumours, as the difference between the two figures is not sufficiently striking, especially as the numbers are not large; furthermore, the death incidence was higher in the vitamin-rich animals, owing to an epidemic in two boxes of this group. But this experiment confirmed the first in showing that this soot fraction is an active one, producing tumours fairly rapidly and giving a high percentage of malignant growths. The malignant tumours were of the same types, mostly keratinizing carcinomata, as are obtained in experimental tar cancers. Forms suggesting sarcomata occurred, but were considered really to be carcinomata.

Malignancy was determined (1) where possible, by auto-plasty, as suggested by Dr. Murray; (2) by secondary deposits or recurrence after wide excision; or (3) by deep invasion of muscle where the animal had died before 1 or 2 had time to occur.

It would seem that this is the first time that cancer has been produced experimentally by means of soot, and possibly the lack of success in the past was due to (1) its application in a form which had not much chance of long contact with the tissues and of penetration; (2) an insufficient length of time over which the inoculum was applied; (3) a choice of unsuitable animals; or (4) an unsuitable sample of soot. In connexion with this last, Ross¹ has shown that soot, as pitch, derived from the more bituminous coals is much the most active.

REFERENCE.

¹ *Journal of Cancer Research*, 1918.

THE Dentists Act, 1921, came into force on November 30th, 1922, after which date all practice of dentistry by persons not on the *Dentists Register* is illegal and subject to heavy penalty. The Act was passed as a result of the report of a departmental committee, appointed in 1918, which inquired into the conditions of dental practice prevailing in this country, the competition of unregistered persons practising dentistry in an unrestricted and unprofessional manner having resulted in a serious decrease in the numbers of those willing to obtain a dental diploma or degree. Some 8,000 names of dental practitioners have been added to the *Register* under the new regulations, and no person can now enter the dental profession except by going through the dental curriculum and obtaining a diploma or degree. The only exceptions are in the cases of registered medical practitioners, urgent extractions of a tooth (without an anaesthetic) by a registered pharmacist, and minor dental work in a public service under conditions approved by the Ministry of Health. Persons who passed the examination before July 28th, 1921, but were prevented from registering owing to delay on the part of the licensing body, may be excused the annual fee now payable if immediate application is made to the Registrar.

ADDER BITE.

BY

SIR THOMAS OLIVER, M.D., F.R.C.P.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE,
UNIVERSITY OF DUBLIN AND COLLEGE OF MEDICINE,
NEWCASTLE UPON TYNE.

PERHAPS it may not be out of place if I draw attention to a subject which is seldom touched upon in medical literature—I refer to the effects of, and the dangers incidental to, adder bite. In June last I saw, on the recommendation of Dr. E.H. Grant Morris of Dalbeattie, a lady living in South Durham, on her way home from Scotland. She had been bitten on the ankle by an adder.

An adder strikes suddenly, and, in the act of striking, the venom is pressed through the hollow fangs into the tissues of the victim. In India snake bite exacts every year a heavy death toll, but we have no exact information of the number of people bitten by adders yearly in Scotland. It may, I think, with safety be said that the number of fatal cases of adder bite is small. While walking over heather-clad moors in Ayrshire it has been my privilege to see adders, also my good fortune never to have been bitten by one. Adders are timid creatures and generally glide rapidly out of sight; they do not bite unless trodden upon or when attacked.

A married woman, aged 54, no children, inclined to stoutness, whose menses ceased at 40, and who occasionally had headache and slight functional cardiac trouble following influenza seven years ago, was in June last, when walking on a moor close to the Solway, bitten by an adder above the left ankle. She saw the reptile escape. On turning down her stocking two small punctures were observed; these were bleeding. She was assisted to a cottage a little distance away; there the wound was not bathed, but the limb was kept elevated. An hour afterwards she was seen by Dr. Morris, by whom the wound was dressed and a stimulant administered. Meanwhile severe vomiting and diarrhoea had developed. A stretcher having been obtained, the patient was carried across the moor half a mile to a point where a motor bus had been brought, and in it she was conveyed to her room. These she reached in a condition of collapse. When the limb was again examined it was found to be swollen up to the knee; it was red, but not very tender. She felt, however, extremely ill. The limb was dressed with ichthyol and glycerin. That evening and for the first few nights she slept very well. The vomiting and diarrhoea referred to only lasted a few hours. By degrees she got better, but dependency of the limb caused much pain.

When I saw the patient ten days after the bite she was fairly well generally; her emunctories were acting normally, the pulse was 94, the blood pressure 120 mm. Hg, and the urine was free from albumin. The heart and lungs were normal. The left foot and leg, to within four inches of the knee, were red and considerably swollen; the instep was particularly red and swollen; the calf was oedematous, the veins not enlarged, and the knee-jerks were normal; the two minute punctures of the skin were still visible. A film of blood was sent to Professor Stuart McDonald, who reported the absence of abnormality. The patient, after resting in Newcastle for two days, reached her home all right, but it was nearly three months after the injury before the swelling of the ankle disappeared.

In his letter Dr. Morris reminds me that when he first saw the patient the symptoms were entirely local, but soon afterwards there were the gastro-intestinal troubles I have mentioned, attended by collapse and by an almost imperceptible pulse. The vomiting occurred every ten minutes and the diarrhoea was frequent. Dr. Morris, who has seen other cases of adder bite, considered the symptoms unusually severe. He had not met with diarrhoea in other patients, although in the case of a dog bitten by an adder he had observed vomiting.

Several medical men in the Highlands of Scotland to whom I wrote for facts bearing upon adder bite have replied that they had not seen any cases. Dr. Donald McDougall of Brodie, Arran, gave me details of a lady visitor to Arran whom he had successfully treated for such an injury. The Marquess of Ailsa informs me that, in the case of one of his dogs who was bitten on the pad of one foot by an adder, the limb swelled enormously, and that shortly afterwards the animal appeared to be dead, but that after one of the gamekeepers had slit the wound open with a penknife, squeezed the foot and bathed it with whisky, the beat of the heart and respiration were re-established, and in three days the dog was quite well.

Dr. Lachlan Grant of Ballachulish, to whom I had also written, kindly referred me to ex-Sergeant Morrison of Campbeltown, who is a recognized authority on adders. To Mr. Morrison I am indebted not only for the loan of his typed copy of the pamphlet he intends to publish, but for

permission to make use of some of the information it contains.

There are three different species of snakes in Great Britain: the ring snake, the smooth snake, and the adder. The ring snake is olive grey in colour and measures 2 feet or more; the smooth reptile is usually just a little less than 2 feet in length and is reddish-brown; while the adder is about 21 inches in length. The first two types are non-poisonous. The head of the adder is rather flat and tends to broaden towards the neck. The tail differs in the two sexes, that of the male being short and blunt, while the tail of the female is long and pointed. It is owing to the reproductive organs of the male being contained in the tail that the terminal portion of his body is broader than that of the female. Clothed in a coat of mail of scales and plates with a succession of dark inverted V-like markings stretching from head to tail, and with patches of yellow colouring running into the apex of the incomplete triangles, the reptile can be thus recognized and differentiated from the snakes already mentioned. The adder is found widely distributed over the west of Europe—from Spain, through Great Britain, to the north of Europe. It is common in Scotland. The disputational statement of its absence from Ireland, and from some of the western islands of Scotland, such as Iona, does not for the moment concern us. Like the snake tribe generally the adder hibernates in winter. On the approach of winter adders retire into crevices, and therein they remain in a state of torpidity until February or later. Although cold-blooded they are sensitive to cold; they like to bask in the warmth of the sun. Once, at least, during the year they cast their outer covering. The adder produces its young alive. Mating in April, the young are born four and a half months afterwards, towards the end of August or the commencement of September. Little is known of the family life of the adder, for it does not breed in captivity. Morrison on one occasion captured a female adder, took it home, and in about a week afterwards she gave birth to a family of seven, all of whom died within a week afterwards. These animals were 6½ inches long at birth.

Although the phrase "stung by an adder" is frequently used, an adder does not sting, but bites. There is nothing to fear from the forked tongue, which is repeatedly being shot out and retracted again; it is an organ of touch, and is constantly in requisition, since, owing to the fixed orbits of the animal, the range of vision for objects immediately in front of it is extremely limited, especially on the inner half. The fangs of the adder are two slender sharp-pointed teeth on each side of the upper jaw, curving inwards, and barely three-quarters of an inch in length. They are hollow, and lie in a sheath in the palate; in this sheath is also contained a reserve of another pair of fangs ready to be used should the first be destroyed through accident. The poison glands lie behind the eyes; they secrete a clear fluid, like saliva, which is carried by ducts into the fangs. When the animal is about to strike it opens its mouth to nearly an angle of 90 degrees, erects the fangs, darts its tongue out and in with a hissing noise, and then, all at once, the tongue is swiftly withdrawn and the fangs are plunged into the victim. In the act of biting the poison glands are compressed by muscular contraction, and as a consequence two or three drops of venom are driven along the ducts into the fangs, from the tip of which the poison is injected into the wound inflicted, two minute punctures marking the site of the injury. Although the bite of these animals is dangerous, and must never be lightly considered, yet Morrison has frequently removed the fangs from living adders—a dangerous procedure, and an operation never to be undertaken by any person who is not familiar with the handling of snakes, for, if an adder strikes, it does so with unerring certainty.

In confirmation of the severity of symptoms due to adder bite I can hardly do better than refer readers to the story told by Dr. R. S. C. Edleston of Baslow¹ of the sufferings experienced by Dr. H. Peck, Medical Officer of Health for the Ghorstfield District of Derbyshire, who was bitten by an adder, first on the right thumb and hand, and immediately afterwards on the left thumb, when near a reservoir, testing water for poaty acids. Seeing a snake on the ground he picked it up and was bitten. He at once sucked the wounds. Shortly afterwards he felt as if his head was bound by a tight girdle; he became faint and vomited; his lips, tongue, and fauces swelled and breathing became difficult. When seen three hours afterwards by Dr. Edleston there was great

exhaustion, for which stimulants were given, followed by the hypodermic administration of digitalin and strychnine. For several hours the patient was extremely ill. The right arm swelled considerably, and at one time it seemed as if it might become gangrenous. It was three weeks before the swelling of the arm disappeared.

Probably some persons are more susceptible to the influence of adder bite than others, but no one is altogether immune, nor are such animals as the horse, dog, and sheep. Morrison carried out a series of experiments with frogs and toads, and he found that these animals were immune to the bite of an adder which had been five weeks in captivity. The immunity does not appear to be due to the fact that these animals are cold-blooded, for a lizard bitten by the same adder died twelve minutes after being bitten. Morrison, after raising the question as to whether the immunity possessed by frogs and toads may not be due to the presence of an antitoxin in their tissues, states that he has submitted the results of his experiments to the Wellcome Bureau of Scientific Research.

Treatment.

All writers upon the subject are agreed that since symptoms rapidly supervene, and quickly assume an alarming nature, treatment should be prompt; but as the accident occurs usually in out-of-the-way places, and often at considerable distance from a human habitation, help is often not readily obtained. Such constitutional symptoms as difficult breathing, attended by collapse and a small and irregular pulse, call for the immediate use of stimulants, and upon the value of the prompt administration of whisky or brandy there is complete unanimity of opinion. So far as I know, there is no antivenom treatment for adder bite. Since the poison rapidly produces constitutional effects, an attempt should be made to prevent it being absorbed by sucking the wound, if there are no cracks on the lips, by incising the wound and allowing it to bleed rather freely, also by applying an alcoholic lotion or a fairly strong solution of potassium permanganate. In the case of many persons who have been bitten by an adder a ligature has been tightly applied round the limb on the cardiac side of the injury. Dr. McDougall of Brodick successfully treated his case of adder bite by freely incising the bitten part, cauterizing it with pure carbolic acid, and dressing the wound with permanganate solution. In his patient very few constitutional symptoms followed, notwithstanding the swollen state of the foot. In Dr. Morris's patient the constitutional symptoms were already severe before he arrived on the scene, or at any rate shortly afterwards, but, combating the collapse by means of stimulants, subsequently dressing the swollen limb, first with ichthyol and glycerin, followed later by warm lead lotion, and the internal administration of quinine and phosphoric acid, the patient was placed out of immediate danger in the course of a few days.

Natives of East Africa are extremely afraid of snakes. Discussing this subject with Dr. A. R. Cook, the well-known medical missionary of Uganda, he told me that the number of persons bitten by snakes in Uganda is small, also that he had found the application of a ligature on the cardiac side of the wound, incision, and the application of permanganate crystals gave the best results. The various methods of treating snake bites form interesting reading. The old European method of treating snake wounds in India was to incise the wound, pack it with gunpowder, and ignite the powder. In tropical countries the bites used to be treated by the natives by means of a charm—the serpent's stone—which was said to adhere to the wound and later on to fall off.

Incidental to what has just been stated in regard to adder bite, and bearing upon the collateral subject of snake bite, there have recently appeared in the *Times* abstracts of letters relating to the African puff-adder. The writer of one communication states that he himself had been bitten by an African puff-adder and that he knew of four other white men who had been similarly injured, also of nine natives and Indians. He himself suffered agonies until he was relieved half an hour afterwards by a Kaffir witch doctor; with an experience of thirty cases the fatalities, he said, were 80 per cent.

Snake bites are extremely fatal, and frequently with great rapidity. One of my nephews who has recently returned from Burma informs me that when in that country he saw an American oil-well driller who, on dismounting from his horse, inadvertently trod upon a small snake. The reptile struck him upon the inner side of one of his ankles. The accident occurred in the interior of the country. My nephew,

who is not a medical man, but who had witnessed the accident, at once applied Condy's fluid to the wound, dressed the limb, and advised the American to go to the nearest hospital three miles away. The patient did not then feel sick, neither was he collapsed, nor did he feel ill. He remounted and galloped off to the hospital, but he had only gone about half a mile when my nephew, who was watching, saw him fall from his horse, and running forward he, on reaching the spot, found that the American was dead. Death occurred in this instance within half an hour after the injury.

In alluding to the African puff-adder mention was made of the rapid cure of snake bite by a native witch doctor. My nephew told me an interesting story which I simply reproduce, in the hope that it may be corroborated or refuted by those concerned, should they perchance ever read this article. One afternoon he went to Pakokku to spend a few hours with the British doctor at the hospital. In the hospital compound at the time were several snake charmers with whom conversation sprang up. Although these charmers can apparently force snakes to do almost anything they wish yet occasionally the men get bitten. At any rate they showed several minute scars on their hands and arms, which might, or might not, have been caused in the manner they stated. On being asked if they had ever been affected by the poison the men replied in the negative, but they would not say why they had not suffered. Ultimately the snake charmers agreed to a suggestion of the doctor that three experiments should be tried: (1) a chicken was to be bitten by a snake and treated by the snake charmers; (2) a chicken was to be similarly bitten and not treated; and (3) a chicken similarly affected was to be treated by the doctor. The results were as follows: the chicken which was not treated died in twenty minutes; that treated by the doctor died in about the same time. Chicken No. 1 was taken by the men to behind some brushwood quite close at hand, but where their movements could not be seen; they returned with the animal after being absent about ten minutes, and on the following day the fowl was quite well and remained thus. Nothing could draw from the natives the method of treatment they had adopted.

A SIMPLE METHOD OF TREATING CLUB-FOOT (CONGENITAL TALIPES EQUINO-VARUS).*

BY

A. S. BLUNDELL BANKART, M.C.CANTAB., F.R.C.S.,
ORTHOPAEDIC SURGEON, MIDDLESEX HOSPITAL; SURGEON, ROYAL
NATIONAL ORTHOPAEDIC HOSPITAL.

THE following is a simple method of treating club-foot that I have employed for the last ten or twelve years.

It is, of course, well known that the apparent correction of the deformity of club-foot does not in itself constitute a cure. It is necessary after the deformity has been corrected to employ some means of keeping the foot continually in the corrected position until growth and adaptation have changed its anatomy and rendered the correction permanent. This end was attained formerly by putting the child into a walking instrument or apparatus designed to keep the foot in the corrected position during the day—a splint being used at night. Such an instrument is expensive in the first instance. It requires constant adjustment in the case of a growing child, frequent repairs to make good breakages and wear and tear, and an amount of intelligence, which is not always forthcoming, on the part of the parents or guardians to see that it is put on properly and is doing its work efficiently. One has seen many relapses and poor results owing to the failure of instruments to act efficiently from one cause or another, and such causes are often beyond the control of the surgeon. But, apart from this, it is a most unfortunate thing to have to put a healthy child into "irons" for some of the best years of its life.

In recent years a good deal has been done to eliminate instruments from the treatment of club-foot. Some surgeons treat these cases in a succession of plaster casts until they judge that the correction is permanent. Others have done simple or elaborate tendon transplantation or other operations. No orthopaedic surgeon nowadays does drastic bone operations on club-feet in children. The method here described appeals to me because it is simple, efficient, and

* Demonstrated before a meeting of the British Orthopaedic Association in London on October 20th, 1922.

it does not interfere with the anatomy of the child's foot. The procedure is as follows:

Correction of the Deformity.

The apparent deformity is first fully corrected in the ordinary way by tenotomy, manipulation, and splinting. I personally always divide the two tibial tendons and frequently some of the ligaments on the inner side of the foot, because I believe that better correction is obtained after tenotomy than without it, and I have never seen any ill effect follow the division of these tendons in club-foot. We prefer gradual correction, by daily manipulation and the use of a splint, to forcible redressment under an anaesthetic, because a much more natural and supple foot is eventually obtained by the gradual method. When the varus part of the deformity has been completely corrected or overcorrected I divide the tendo Achillis and frequently the posterior ligaments of the ankle-joint, and again I have never seen the slightest ill effects from this tenotomy in club-foot cases. The equinus deformity is now completely corrected, and the foot is put on a trough splint with a footpiece at a right angle ("tin shoe"), or it may be put in plaster. It is allowed to remain thus for at least a week or two—sometimes it is convenient to wait some months—before the fixation operation.

Fixation Operation.

The object of this operation is to secure permanent fixation of the foot in a corrected position by means of an artificial ligament attached to the outer border of the foot below and to the outer side of the tibia above.

Pearshall's No. 3 pearl silk is prepared according to Lange's formula.* A suitable length is taken out of the melted paraffin with forceps, and the excess of paraffin is removed with a sterile swab.

An incision a quarter of an inch long is made down to bone on the dorsum of the base of the fifth metatarsal bone. A drill with an eye near the point is passed through the base of the fifth metatarsal and thrust out through the sole of the foot. A guide loop of salmon-gut is threaded into the eye of the drill, and by means of this one end of the silk is pulled into the sole, through the base of the fifth metatarsal, and out through the incision on the dorsum. The drill is again passed into the same incision, but this time round the outer side of the metatarsal, and it is made to emerge through the same puncture in the sole. The eye is again threaded with a loop of salmon gut, and the other end of the silk is pulled through to the dorsum. The two ends are pulled out to an equal distance, so that the middle of the silk surrounds the outer half of the base of the fifth metatarsal.

On pulling the loop tight it will often be found that the skin of the sole is dimpled at the point where the silk was passed through, and we have found that when the dimple is allowed to remain the patient sometimes complains of pain afterwards at this spot. So it is well at this stage to give the middle of the loop a few sawing movements—like using a Gigli's saw—and the dimple will then disappear. This also ensures that the loop lies close to the bone and prevents subsequent slackening. A single hitch is now tied in the middle of the loop of silk.

Next a long special probe with an eye near the tip is thrust into the incision on the dorsum of the foot and is carried deeply in the subcutaneous tissues up the outer side of the leg. The tip should be kept well back, and it is made to project beneath the skin somewhere in the lower third of the leg, just in front of the plane of the fibula. A stab incision is made over the tip, which is then thrust out of the leg. The eye is threaded with a salmon-gut loop, and this is pulled down to, and out of, the incision on the dorsum of the foot. Both ends of the silk are then passed into the loop and pulled up to, and out of, the upper incision.

The last step is to pass both ends of the silk separately through the tibia, and to tie them on the inner side. The bone drill is therefore passed into the upper incision and bored straight through the middle of the shaft of the tibia until its point projects beneath the skin on the inner side of the leg. A curved incision is made down to bone, so as to turn back a small flap over the point of the drill. The drill is then pushed out of the wound and its eye is threaded

with a loop of salmon-gut. This loop is pulled through to the outer side of the leg, and one end of the silk is passed into it and pulled through to the inner side. The other end of the silk is passed in exactly the same way, but through a separate drill hole at a slightly higher level.

An assistant now holds the foot firmly in an overcorrected position—that is, abducted and everted. The two ends of the silk are pulled tight, first separately, and then together. Finally, they are tied very tightly in a triple knot on the inner side of the tibia. The little wounds are all closed with fine horseshair stitches.

The foot is now held permanently in the corrected position by a stout ligament attached to bone above and below. It is put on a tin splint for a week or ten days. The stitches are then taken out, and the foot and leg are put in plaster. The plaster is kept on for two months, then it is cut off, and the patient is allowed to walk in ordinary boots or shoes. It should, however, be seen that the boot or shoe is made flat on the inner side.

Instruments.

One or two special instruments will be found useful for this little operation. One is a steel probe for passing the silk up the leg. This has a straight shaft about seven inches long mounted on a handle. The tip is smooth and rounded and slightly turned up (condé), and there is an eye near the end. The other is a bone drill with a cylindrical shaft. Most of the bone drills on the market have a shaft which expands more or less from the point towards the handle, so that when they have penetrated some distance one is attempting to drive a cone into the hole made by the point. I have therefore had drills made with straight cylindrical shafts, so that they can be passed easily for their whole length. The best form of point is, I think, the miniature gouge, but there should also be a slight groove on the convex side, otherwise the salmon-gut loop is cut as it is pulled back through the bone. These instruments have been made for me by Allen and Hanbury and Krobac and Sesemann.

Remarks.

Failures are nearly always due to faulty technique. Failure to obtain complete correction or overcorrection of the deformity before the fixation operation is the worst mistake. The silk should play no part in the correction; it should merely hold the foot in the corrected position. A certain amount of "give" must be anticipated, and the assistant must hold the foot well everted while the silk is being tied. The amount of correction often looks rather excessive at first.

Failure to keep the silk close to the bone, and to pull it tight enough, is another mistake. If a considerable amount of the soft parts is included in the loop in the sole this will subsequently be absorbed, and the silk will slacken.

The base of the fifth metatarsal is a small thing in a small child, and if the drill strikes it too near its outer side, or if the drill is too large, the thin slip of bone which is caught by the silk may give way. On the other hand, it is not satisfactory to pass the silk round the metatarsal, instead of through it, as I found in some of my earliest cases.

In working through small stab incisions it is impossible to avoid all contact with the skin, as one would like to do in silk operations. So that occasionally there is a mild infection, and a sinus forms, and the silk has to come out. This risk is not great, and I have preferred to take it rather than elaborate the operation.

In passing the probe up the leg the tip should be kept as deeply as possible in the subcutaneous tissues. It should not, however, pass under the annular ligament. The skin is very intolerant of pressure on its deep surface, and if the silk is placed too superficially the skin may slough over it where it crosses the angle between the foot and the leg.

When the silk has been in place for two months or more it will be found that the foot retains its position even though the silk be removed. I have shown by dissection that this is due to the formation of a fibrous cord around the silk, and that this fibrous cord acts in just the same way as the original silk ligament. The silk itself I have found to be absolutely unchanged after nearly two years. For this reason when a sinus forms, either from mild infection or sloughing, the silk should not be removed at once unless the discharge is excessive. When the silk has to be removed one of the cords is cut and the other is forcibly dragged out with Spencer Wells forceps. It nearly always comes out intact, knot and all.

* The silk is first boiled for twenty minutes in 1 in 1,000 mercury perchloride solution. It is then dried aseptically between sterile towels for two days. It is next put into a jar of melted soft paraffin (white vaseline) and cooked in this in a water-bath for two hours. It is kept in the paraffin, which solidifies on cooling, and it is melted down before each operation by standing the jar in an ordinary sterilizer.

In mentioning these causes of failure I may perhaps add that a little practice and familiarity with the operation goes far to eliminate them, and I see far less of them now than formerly. With these few exceptions I have found the operation entirely satisfactory. The children have nice supple active feet, permanently corrected, and they are from the beginning freed from the burden of instruments.

PNEUMOCOCCAL INFLUENZA.

BY

O. F. T. EAST, M.A., B.M., B.Ch. Oxon., M.R.C.P. Lond.,
OUT-PATIENT MEDICAL OFFICER, KING'S COLLEGE HOSPITAL.

THE name "influenza" is applied to a variety of ailments. In the recent great pandemic *B. influenzae* was shown to be the infecting organism in a very large number of cases; there may be, however, small local epidemics, influenzal in type, which are caused by other organisms. Clinically the cases have the appearance of influenza, and one might class them, as Sir William Osler suggested, under the head of "influenza nostras."

The series of cases here described occurred among the nursing staff and students of a hospital during the early part of this year. The epidemic began early in January and went on till March, and comprised some forty cases. The pneumococcus was the organism found in overwhelming predominance on examination of throat swabs by direct smear and culture in every case. *M. catarrhalis* and streptococci also occurred, but were in the minority, and *B. influenzae* was not seen. Pneumococci were also the cause of such complications as occurred. Clinically the cases varied from a slight headache, sore throat, and fever to very severe prostration.

In almost every case the first symptoms were referred to the upper air passages. Some complained of having had a cold for a day or two, or a sore throat; in others the onset was more sudden. Then followed headache, which was usually frontal, and attacks of shivering, with pains all over the body, especially in the back and limbs. Such symptoms are similar to those described as the nervous symptoms of influenza. The headache in some instances was intense. Most cases had more or less photophobia, and in some there was considerable conjunctival injection. The tongue was coated with white fur as a rule; in four instances there was vomiting, which persisted for three days in one case. There was no marked diarrhoea or constipation. Fever appeared with the other symptoms. The temperature in some cases reached 104° F.; in others there was only a slight rise. As a rule there was in uncomplicated cases no fever after four or five days.

Sore throat was the most common complaint, and there were patches on the tonsils in most cases; injection was acute in all. The throat and nasopharynx seem to have been the points of attack of the infecting organism. In five cases there appeared on the fauces and soft palate, and on the uvula to a varying degree, a whitish, shining exudate, which had a glazed look; it gradually spread over the surrounding parts, was very thin, almost transparent, and easily detachable. From each of these cases almost pure cultures of pneumococci were obtained. The parts of the throat not covered by the exudate were very injected. The presence or absence of tonsils did not appear to have any influence on the incidence of the infection, but the patients without tonsils got off more lightly. Only three slight cases of adenitis occurred, and the glands at the angle of the jaw were only affected to a small degree in the most severe cases of throat infection. There was not much tendency to downward spread of the infection; bronchitis occurred twice, and there were two cases with pulmonary consolidation; one of the latter ended in widespread bronchopneumonia which proved fatal.

In six of the most severe cases a scarlatiniform erythema appeared early in the illness. It showed itself uniformly on the limbs, trunk, and face at the same time. The extensor surfaces of the limbs tended to be most affected. There was no itching. As the temperature fell the rash faded, leaving the skin rather yellow. There was a very slight powdery desquamation afterwards in two cases. The appearance of the rash was the signal of acute infection, and the patient was soon very ill. The throat was always markedly affected in these cases, and four of them showed the distinctive exudate described above.

Direct spread of the pneumococcus caused such complications as there were. The pus from a double mastoid infection, which set in on the fourth day, gave a pure culture pneumococci. The same was true of three cases of empyema of the antrum, as also of an acute case of conjunctivitis which began three days after the onset of the origin infection.

Clinically these cases exhibited the rather protean symptoms of influenza, although *B. influenzae* was not the cause. The pneumococcus was often present as a secondary infection in cases of true influenza in the recent epidemic but this outbreak illustrates the observation of Palfrey⁵ that a primary pneumococcal infection may cause an epidemic with all the clinical appearances of true influenza. This has also been noted by Peset,⁴ who found the pneumococcus to be the cause in 62 per cent. of cases in an epidemic.

Toxic erythematous are seen in acute infections, general streptococcal in origin. They may occur in pyaemia. Such rashes have been described in cases of influenza by Hainiss² and others. Sir W. Osler mentions them¹ occurring occasionally in pneumonia. No doubt in the outbreak here described they were caused by the absorption of toxins from the throat; it may be noted that they were seen only in the worst cases. The appearance of the throat exudate described above was very striking and distinctive. It would appear to be characteristic of acute pneumococcal infection in the throat.

These few cases serve to show how closely true influenza may be mimicked by an infection due to another organism. My thanks are due to Dr. Harold Wiltshire for his kindness in allowing me to publish this account.

A CASE OF BRONCHO-BILIARY FISTULA.

BY

A. G. YATES, M.A., M.D., M.R.C.P.,
PHYSICIAN TO THE SHEFFIELD ROYAL INFIRMARY.

THE following case is an unusual one, and at the same time of sufficient practical clinical interest to merit its being placed on record.

A labourer, aged 47, went to his doctor in June, 1921, complaining of some loss of weight and of feeling generally weak and ill. A few days later a severe hiccup commenced which lasted for nine days and then ceased abruptly. It was so severe that it deprived him of sleep and seriously interfered with eating, and even with speaking. On its disappearance he complained of nothing beyond general weakness, but three weeks later a cough began with copious expectoration which he described as being "like brown jelly and sometimes streaked with blood." This continued for a month, when the colour of the sputum suddenly changed to yellow. It was now intensely irritating and associated with violent paroxysmal cough which sometimes led to vomiting.

Such was his condition on admission to hospital on November 5th, 1921. His previous record included scarlet fever at 8, pneumonia at 16, and gonorrhoea at 19. He had never been abroad, and had never had any illness resembling dysentery.

He was found on admission to be coughing up large quantities of clear bright yellow fluid, which consisted almost entirely of bile. It contained a few Gram positive cocci and one or two cells, but no pus. No traces were found of amoebae or the hooklets of *Thelazia rhinoceros*. He was emaciated and weighed 7 st. 4 lb. Before his illness he weighed 9 st. 2 lb. He was not jaundiced.

Examination of the chest revealed a small area of impaired resonance at the base of the right lung over which medium crepitations could be heard. The breath sounds over this area were harsh and vesicular in character; the vocal fremitus and resonance were not altered.

The liver was a little enlarged and just below the right costal margin could be felt somewhat rounded and hard. There were several dilated veins in the abdominal wall, chiefly on the right side both above and below the umbilicus. The spleen was not enlarged, there was no ascites, and examination of the faeces failed to reveal any evidence of amoebae. The Wassermann reaction was negative and radiograms showed nothing abnormal.

It was clear that a communication had in some way been effected between the bile passages and the bronchi, and as the condition was causing acute distress Professor A. M. Connel operated on November 25th. Portions of the eighth and ninth ribs were resected on the right side and the upper surface of the diaphragm explored. Dense adhesions were found between the base of the lung and the upper surface of the diaphragm, but no opening through the diaphragm was seen. The adherent surfaces were

separated as completely as possible and a drainage tube inserted from which for a few days a small amount of bile escaped.

After the operation the coughing of bile ceased completely for five days and then began again. He continued to cough up a considerable quantity for some time, but it steadily diminished and ceased altogether about a month after the operation. He was discharged on January 9th of this year, feeling well, free from cough, and having gained several pounds in weight. The wound was quite healed, the ereptions at the right base had gone, but some dullness remained. The signs in the abdomen were unchanged.

When examined again, six months later, he felt perfectly well and was doing full work. He had regained his former weight, the enlarged veins in the abdominal wall had disappeared, and there were no abnormal signs in the chest with the exception of slight persistent dullness.

It is an uncommon event for bile, at any rate in quantity, to find its way into the thoracic cavity. When an abscess of the liver ruptures it does so most commonly upwards through the diaphragm, either into the pleura or into the lung, and in the latter case large amounts of pus may be evacuated via the bronchi, and sometimes the pus is mixed with bile. In the present case an abscess of the liver appears to have penetrated the diaphragm and discharged itself into the lung, and at the

same time to have effected a communication with one of the larger bile passages, with the result that pure bile continued to escape long after all pus had disappeared. This seems altogether more probable than the alternative supposition that the primary focus was an empyema which burrowed through the diaphragm and deeply into the lung.

T. R. Elliott and H. Henry¹ described some cases of internal biliary fistulae—one into the lung and one into the pleura—which resulted from gunshot wounds. They noted particularly with regard to the latter, in which pure bile was aspirated from the pleural cavity, the absence of any evidence of an inflammatory reaction on the part of the pleura. The expectorated bile in the present case was similarly lacking in inflammatory products. There was no pus visible either to the naked eye or microscopically during the whole period of observation, though a few organisms were found in it.

RESTORATION OF THE ROUND LIGAMENTS.*

BY

ARTHUR J. NYULASY, M.R.C.S. Eng.,

Gynaecologist to the Perth Hospital, Australia.

IN one of his many moments of inspiration Lawson Tait fixed the fundus of a retroverted uterus to the anterior abdominal wall by a silk suture. Out of this inspiration to meet a sudden emergency during a pelvic operation was evolved the independent operation of hysteropexy—an operation which by its very simplicity captured the imagination of gynaecologists and very largely held the field a couple of decades ago in the surgical treatment of retroversion of the uterus. But with the progress of the years evil sequelae were reported, and then came the reaction from the early enthusiasm—a reaction threatening to relegate hysteropexy to the surgical scrap-heap.

Meanwhile the popularity of the Alexander-Adams operation had necessarily waned, in spite of its proven value, and in spite of Goldspohn and Stewart McKay having both shown that during the course of the operation limited access to the pelvic abdomen might be obtained through the same skin incision. It was not, however, until after the year 1900, when the intra-abdominal operation of Gilliam had entered the field, that the prestige of the Alexander-Adams operation was seriously imperilled. But with the advent of the Gilliam operation was ushered in a wave of enthusiasm for the free intra-abdominal method of curtailing the over-stretched round ligaments, and to-day the Gilliam procedure or one of its modifications appears to be that most commonly employed in British communities, although it must be admitted that the Baldy-Webster operation has many warm advocates. This latter operation, as with certain others (Mann, Dudley, Murphy) shortens the over-stretched round ligaments by eliminating its inner portion, while the Gilliam type and the Alexander-Adams cuts out the outer portion of the ligament.

Long simply puckers up ("shirring") as much of the intra abdominal portion of the ligament as may be necessary to produce anteversion of the uterus.

Genesis of the Operation.

With the exception of hysteropexy most of the numerous operations for retroversion are based on the view that the excess in length of the over-stretched round ligaments should be eliminated by excision or by looping. This view is obviously opposed to the fundamental surgical principle that the ideal treatment of an acquired abnormality is that which restores it to the normal. The ideal treatment then of an over-stretched round ligament would be the restoration of the ligament to its original dimensions. How was this end to be achieved?

It first occurred to me that, in retroversion, hysteropexy (Kelly) might be carried out, and the "false ligament" cut away a year or two later. I had seen cases in which this had been done, and in which the uterus had subsequently maintained its anteversion. In such cases the abdomen had been opened on the second occasion to deal with some fresh condition. To re-open the abdomen, however, solely to cut away the "false ligament" seemed to me, on consideration, unlikely to be practicable, and I abandoned the idea,

although the fundamental principle as to the ideal treatment of acquired abnormalities still dominated my outlook.

Meanwhile I had been employing the Montgomery-Gilliam operation, but towards the end of 1913 I began a new procedure, sewing up a loop in the round ligament reached by a short incision parallel to it in the anterior leaf of the broad ligament. One day I noticed that when I had tied a purse-string to close the opening in the broad ligament the uterine anteversion was increased beyond that produced by the loop in the round ligament. In subsequent cases I applied this observation, when necessary, by deliberately extending the incision (and the outer and inner limits of the purse-string). But during this period I made two other observations: (1) that the material of the anterior leaf of the broad ligament generally appeared to be stronger than simple peritoneum; and (2) that in many cases of retroversion this leaf of the broad

Restoration of the round ligaments. A, Fold of anterior leaf of broad ligament, between round ligament and bladder; C.C., forceps and cut edges of incision in anterior leaf of broad ligament; P, purse-string; U, uterus; N, bladder; I.N., internal abdominal ring. Drawn from a dissection made in the Perth Hospital, with photographs by Dr. G. W. Barker.

* Read before the West Australian Branch of the British Medical Association on September 20th, 1922.

ligament was unduly lax. Whether this laxity was cause or effect I was unable to decide. It seemed plausible that it might represent a result of frequent overdistension of the bladder; but, on the other hand, it might represent an effect of long retroversion of the uterus, the primary fault being softening of the round ligaments from congestion extending from the uterus. However, whether the laxity was cause or effect, it appeared reasonable to think that by removing it and placing the uterus in anteversion the overstretched round ligaments would be given physiological rest and thus put in the best position for restoration to the normal.

By this time (about June, 1914) the meaning and force of my observations had become fairly well crystallized. I was satisfied that the material of the anterior leaf of the broad ligament was elastic and strong enough to hold the uterus anteverted, without direct interference with the round ligaments, and, furthermore, that by adequate extension of the incision (and purse-string) in the broad ligament the undue laxity of the anterior leaf of the broad ligament must be reduced.

The Operation.

The way was now clear to put these views to the test of practice, and on July 9th, 1914, I deliberately carried out the operation of restoration of the round ligaments in a case of retroversion in the Perth Hospital. This operation consists in splitting the anterior leaf of the broad ligament parallel to the round ligament, between the round ligament and the bladder, undermining the opening, and closing it by a purse-string, the outer limit of the purse-string being in the vicinity of the internal abdominal ring and the inner limit being towards the uterine cornu. The immediate effect is to bring the uterus into anteversion, and to demonstrate the round ligaments contracted down to their normal length—an interesting physiological experiment performed directly under the eye. Furthermore, the undue laxity of the anterior leaf of the broad ligament is seen to be reduced.

Results.

I have carried out the operation of restoration of the round ligaments in over two hundred cases, many of them subsequently going through pregnancy and parturition, so that I am in a position to speak with some little authority as to the value of the operation. In one case the operation was performed in about the sixth week of gestation, and there was no subsequent trouble, parturition being quite normal and the uterus remaining anteverted. In another case, recently reopened for some fresh morbid condition a few years after the operation, there was no obvious evidence of the primary operation, the uterus being in anteversion and having its normal motility, although there had been an intervening parturition. On the other hand, in another recent case, in which the Montgomery-Gilliam operation had been carried out some years earlier, hysterectomy proved exceptionally trying on account of the anatomical disorder in the pelvis caused by the first operation.

Standard of Efficiency.

The conditions to be fulfilled by an ideal operation for retroversion of the uterus may be stated as follows: (1) It will conform with the principles of rational surgery in that it restores the abnormalities to the normal; (2) it will permit of adequate access to the pelvic abdomen; (3) it will leave no condition which may prove a source of future disability or danger; (4) it will stand the strain of pregnancy and parturition; and (5) it will not complicate future operations on the pelvic abdomen.

I know of no operation which appears to fulfil these conditions so completely as restoration of the round ligaments. This restores the round ligaments to their original condition as nearly as is ever likely to be possible, while at the same time it reduces undue laxity of the anterior leaf of the broad ligaments. It practically restores the abnormal to the normal without introducing any factor that might prove a source of trouble either of itself or in case the abdomen should need to be reopened in the future. In none of the cases subsequently coming under my notice have pregnancy and parturition been attended with difficulty from the operation or with recurrence of the retroversion.

Operative Technique.

A good light and the Trendelenburg position are almost essential. The suprapubic abdominal incision may be the ordinary vertical or the transverse. Retraction of the wound edges should be adequate to expose the round ligament in its whole length in the abdomen. For the incision in the anterior leaf of the broad ligament a fold is raised between the round ligament and the bladder, snipped into, and the opening

freely undermined, and extended outwards and inwards. The commencement (outer limit) of the purse-string suture (silk or Pagenstecher) is made near, and a little on the pelvic side of, the internal abdominal ring. The suture terminates just beyond the inner end of the incision. If the free ends of the purse-string are now caught together and pulled on, the tissue in which the thread is placed will be drawn somewhat inwards. This new point marks the outer limit of the purse-string when tied, and thus permits us to fix on the inner limit necessary to produce the desired amount of anteversion of the uterus. (The round ligament and the bladder must be avoided in passing the purse-string; when the purse-string is tied the raw edges of the incision should have been buried.) If, when the purse-string is tied, the uterine anteversion is found insufficient, it may be readily increased by the same suture either by taking in the uterus near the cornu or by taking a fresh bite farther outwards in the broad ligament. It is convenient to work from the side (of the patient) opposite to the round ligament being dealt with. When the operation is completed a narrow raised fold of the broad ligament is noted extending across the utero-vesical interspace; this can prove in no way a detriment to the patient.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

A POSSIBLE CASE OF BRONCHO-PULMONARY SPIROCHAETOSIS.

In the discussion on the differential diagnosis of pulmonary tuberculosis at the Glasgow meeting of the British Medical Association Dr. James Lawson referred to broncho-pulmonary spirochaetosis, and instanced a possible case under observation at Tor-na-Dee Sanatorium. The results of further investigation of this case are, I think, worthy of record, since the evidence is conflicting and leaves the diagnosis doubtful.

The patient was a lady aged 40, who had never been abroad except for a year at school in France and Switzerland. Down to five years before admission she had always had good health except for otitis media as a child. At the age of 33 she had whooping-cough, which left her with a cough and a little sputum for about four months. The sputum was streaked with blood once; it was repeatedly examined for tubercle bacilli, with negative results. She had an attack of influenza four years later, which was followed by a persistent cough with sputum, and on three occasions at intervals of about three weeks she had small but definite haemoptyses. She was seen by a consulting physician, who diagnosed pulmonary tuberculosis and advised sanatorium treatment.

There was no history of tuberculosis in her blood relations, but her husband had died of pulmonary tuberculosis six years before her admission. She complained of a rather troublesome cough with copious sputum, and slight huskiness of the voice on waking. The sputum was copious, thin, and very fetid, and on standing separated into an upper clear watery layer and a lower layer of yellowish-grey pulaceous material. Repeated examination by ordinary and concentration methods of twenty-four hours' samples failed to reveal tubercle bacilli, but numerous septic organisms were present, along with large numbers of spirochaetes which at first we thought were the spirilla of Vincent's angina, since she had severe pyorrhoea alveolaris, and the tonsils were a little enlarged, congested, and cryptic. The mucous membrane of the nose and nasopharynx looked unhealthy, but the larynx was normal. The physical signs in the lungs were those of definite infiltration (with râles) of the upper half of the right lung, and doubtful infiltration (without râles) at the left apex. The x rays confirmed these findings, and in addition showed some calcareous deposit at the roots of both lungs, with two small dilated bronchi near the root of the right lung. Her general condition was quite good, and there was practically no systemic disturbance except slight tachycardia. The blood was normal, and the Wassermann reaction was negative.

A provisional diagnosis of pulmonary tuberculosis, with spirochaetal infection of the mouth and fauces, was made. After local treatment the consulting rhinologist declared the upper air passages healthy, and dental treatment was equally successful in clearing up the septic condition of the teeth and gums, but there was practically no diminution of the fetid sputum, and the spirochaetes were as numerous as ever. We therefore formed the opinion that broncho-pulmonary spirochaetosis was a possible diagnosis. An independent bacteriologist was asked to examine the sputum, and he reported that "the spirochaetes are certainly not *S. pallida*, and if infection from the mouth can be excluded it is very possible that they are of the type described by Castellani; they closely resemble the spirochaetes described by him, but similar organisms may be found in the mouth, so that it is not possible to say definitely that they are pathogenic in this case."

The von Pirquet test was inconclusive, only a slight reaction being obtained. Injection of samples of the sputum into guinea-pigs gave negative results as to tuberculosis, and no lesions of any sort were produced. Two successive samples of blood were sent to Drs. Gosse and Pouch for the complement fixation test, and both were "positive."

On the above evidence it is very difficult to make an exact diagnosis, but taking all the facts into consideration I think it

is probable that the case was one of arrested pulmonary tuberculosis, with secondary infection of the mouth, upper air passages, and possibly the lung, with septic organisms and spirochaetes.

The spirochaetes were of the type described by Castellani as producing the pathological condition named by him "broncho-pulmonary spirochaetosis," and may have been responsible for the peculiar fetid sputum. The positive complement fixation results were unexpected by us since, according to Dr. Gosse,¹ a positive result is "an almost infallible guide to the presence of active tuberculosis," though he qualifies this by saying that "the blood may give a positive test for perhaps a year after the disease is arrested." Is it possible that Castellani's spirochaetes may, like *S. pallida*, sometimes produce substances in the blood which fix complement in the presence of tuberculous antigen?

The patient improved greatly under treatment with arsenic and antiseptic inhalations, but on discharge there was still a small quantity of sputum containing spirochaetes, and at the apex of the right lung a few rales after cough.

ESERINE POISONING PRODUCED BY INTRAVENOUS INJECTION: RECOVERY.

The following case, which was seen by me recently, is of interest:

M. S., aged 32, was admitted to the London Hospital suffering from psoriasis. Inadvertently the patient was given a quarter of a grain of eserine sulphate in 15 minims of water by intravenous injection. Within a minute she became unconscious, with laboured breathing, imperceptible pulse, and cyanosis, fibrillary twittings of all muscles, and wide dilatation of the pupils. There was incontinence of urine and faeces, and a great flow of saliva, and the throat and larynx were filled with secretion. Immediately the mistake was recognized an injection of atropine 1/100 grain and strychnine 1/60 grain was given, and oxygen was administered by inhalation. An hour later the pulse could just be felt, the throat was clearer, but breathing was still laboured. A second injection of atropine 1/100 grain was given, and the inhalation of oxygen continued.

Shortly afterwards the patient began to regain consciousness, but it was at least an hour later before she spoke. She complained of deafness and blindness. The breathing was now calm and deep, and the twittings had almost stopped. The pulse was weak and irregular. The oxygen was stopped; saline (2 pints) was injected by the rectum and retained. Gradually the sight and hearing returned, and the general condition steadily improved. The following day the patient felt rather weak, but was otherwise none the worse.

The course of the psoriasis appeared not to be affected by the incident.

COLLOIDAL GOLD FOR THE LANGE TEST.

In view of the difficulties so often experienced in the preparation of reliable samples of colloidal gold for the Lange test and the consequent limitation in usefulness of this valuable reagent, it may be of service to describe a greatly simplified technique for the preparation of the reagent, which in our hands is giving encouraging results.

Into a perfectly clean hard-glass flask, washed out several times with distilled water, take 100 c.cm. of distilled water and 1 c.cm. of $\text{AuCl}_3 \cdot \text{NaCl}$; bring to the boil, and from a Dreyer pipette add ten drops of 1 per cent. formaldehyde (23 per cent. formalin); remove the flame to the edge of the wire gauze and from another Dreyer pipette add sixteen drops of a 2 per cent. solution of K_2CO_3 ; and then at intervals of fifteen seconds add one or two more drops—eighteen in all usually suffice, red streaks appearing at the seventeenth drop, converted at the eighteenth into a smart bluish; cease now. There is no need to shake.

The sample as it cools in the flask will assume a rich old-rose colour to transmitted light, throwing on to white paper a red colour, with a violet tinge; it will have a marked fluorescence to reflected light; 5 c.cm. of it will be rapidly decolorized by 1.7 c.cm. of a 1 per cent. solution of NaCl ; and it will give isoelectric curves with appropriate positives and negative results with known negatives.

The reagent should not be used quite fresh; we do not use a sample prepared more recently than the evening before. On the other hand, the sample may not keep more than a

week or ten days; hence the advantage of preparing it in small quantities.

The usual precautions as to scrupulous cleanliness of apparatus are taken, every single piece of apparatus used being reserved for this work and no other. Triple distilled water is not used; we use a fresh sample of water distilled in a copper retort which has been in use for some time.

GENERAL PARALYSIS.

THE DISCOVERY OF GENERAL PARALYSIS.

At the ordinary quarterly meeting of the Medico-Psychological Association of Great Britain and Ireland, held on November 23rd at the Bethlem Royal Hospital, London, the President, Professor G. M. ROBERTSON of Edinburgh, read a paper on the discovery of general paralysis, from Haslam to Bayle (1798-1822). On November 21st, 1822, he said, a young man named A. L. J. Bayle presented a thesis for the Doctorate of Medicine to the Faculty of Paris, entitled *Recherches sur les maladies mentales*. In it he recorded the opinion that "general and incomplete paralysis" and disorder of the mind, developing side by side, were caused by chronic arachnitis; in other words, that these two groups of phenomena were the associated symptoms of a definite disease having a distinctive pathological anatomy. This was an opinion which had never been expressed before by anyone, and it had since been proved in its essential features to be true. The disease was the one now generally known as general paralysis of the insane. According to Baillarger, the recognition of the association of these two orders of symptoms signified the greatest advance ever made in the history of mental disease.

The first case of undoubted general paralysis recorded in medical literature was described in 1793, by an Englishman named John Haslam, who was apothecary to Bethlem Hospital from 1795 to 1816, and was at one time President of the Edinburgh Royal Medical Society, and one of the original members of the Medico-Psychological Association of Great Britain and Ireland. Haslam was an acute observer, and he had the gift of literary expression. Less than three years after entering Bethlem Hospital he published the first edition of his *Observations on Insanity*. Professor Robertson then quoted verbatim Haslam's celebrated Case xv.

It was that of a man aged 42, whose illness suddenly developed on a hot day while he was working in the garden. Some years previously he had travelled over the greater part of Europe with a gentleman, and after the onset of his illness he received himself the King of Denmark, France. Though lacking education, of all the dead and living languages, recollection of having come over to t Conqueror. He was irritable and quarrelsome. In the hospital he became tranquil, relinquished his absurdities, and was "discharged well" in June, 1796. But in six weeks he relapsed and was readmitted. He now had a paralytic affection, and his speech was inarticulate. Then he became stupid, his legs swelled and afterwards ulcerated, his appetite failed him, he became emaciated, and died. Haslam made a post mortem examination, and minutely described all that he found.

Probably, Dr. Robertson said, the man was infected with syphilis while travelling abroad, and he had the typical delusions of grandeur. Even at that early date Haslam believed that madness was always connected with disease of the brain and of its membranes. The great Pinel spoke very highly of Haslam's character.

In Paris the clinical symptoms of general paralysis were undoubtedly discovered by Esquirol, and in 1826 Bayle and Calmeil gave a complete picture of the symptoms, the course, and the naked-eye pathology of general paralysis. It was Pinel who insisted on a study of the symptoms of insanity on strictly scientific lines, and on a daily visitation of the patients, and a record of their symptoms and the progress of the cases. He appeared to have practised towards the patients the greatest consideration and kindness. Paris was in a fortunate position for the study of the disease, as at this period it possessed three large mental hospitals, and some years after the Napoleonic wars there arose a large crop of cases of general paralysis; no doubt there was a large infection of the soldiers with syphilis while passing through the various European countries. Still no one seemed to have thought of syphilis as a cause of general paralysis; the

¹ BRITISH MEDICAL JOURNAL, October 21st, 1922, p. 741.

latter was rather regarded as resulting from anxieties and alcoholic and venereal excesses.

Esquirol's thesis on the emotions, in 1805, recorded the existence of paralysis among insane persons, and said paralysis was a common complication of insanity, and when it was present added to the seriousness of the prognosis. His ideas, as set forth in the article on "Dementia" in the *Dictionary of Medical Sciences*, showed a conception of general paralysis nearer to the truth than that of Pinel. He certainly seemed able to diagnose the condition with precision.

At the Salpêtrière was a man only 25 years of age, Georget, who published a book on madness (*De la Folie*); it contained the most complete clinical picture of general paralysis so far given by any of Bayle's precursors. The disease was now named "chronic muscular paralysis." Down to this time the disease had been studied mainly from the clinical side, but Pioul, in 1800, touched on pathology. He considered that the primitive seat of insanity generally was in the region of the stomach and intestines, that it was from there the disorder of the intelligence propagated itself. Esquirol was a believer in the doctrine of sympathy.

A. Foville and J. B. Delaye, who were working at the Bicêtre mental hospital, won Esquirol's prize for an essay on the causes and the seat of mental diseases. They concluded that the grey matter of the convolutions was the organ of the intelligence, and that the white matter and the basal ganglia presided over locomotion; they also said that the disorders were of the brain, the organ of the mind. But there was no reference to lesions believed to be distinctive of and peculiar to general paralysis. Delaye believed that a particular modification of the white matter of the brain was the organic alteration which produced paralysis; whereas Bayle thought the primary change was a chronic arachnitis, and the former worker was the first to employ the term "general paralysis" for the disease.

Bayle commenced to study medicine in Paris in 1815, when he was but 16 years of age, and he concluded that mental diseases depended for their elucidation on anatomical and pathological researches. He performed over 400 *post-mortem* examinations in less than five years. He gave very minute descriptions of the changes he found, and added one or two symptoms to the disease; in fact he gave an accurate and almost complete description of the pathological anatomy of general paralysis. The inflammation of the meninges which he discovered he named "chronic arachnitis." Professor Robertson considered that the French were amply justified in calling the disease "la maladie de Bayle." In spite of illness Bayle also published a treatise on maladies of the brain and its membranes, a great classic, for which the Academy of Sciences awarded a special prize. Professor Robertson spoke of the commotion in medical circles which followed Bayle's contribution, and of the plain-spoken criticisms which emanated from Pinel and Esquirol.

In conclusion, Professor Robertson said that the hundred years had produced a band of hard-working and devoted followers, who had assisted to draw aside the veil which concealed the most terrible disease which afflicts humanity. Their successors had discovered its cause, and it remained for the present generation to either discover a remedy for it or to prevent it altogether.

On the motion of Dr. PERCY SMITH, a cordial vote of thanks to the President for his address was accorded by acclamation.

THE TREATMENT OF GENERAL PARALYSIS BY MALARIA, AND THE USE OF SPEECH INSCRIPTIONS FOR EARLY DIAGNOSIS.

Dr. EDWARD WHEELER SCRIPTURE said that there were on record undoubted cases in which general paralysis seemed for a time to have been cured, so as to enable the patients to return to their work; and although they afterwards relapsed the fact seemed to indicate the possibility of stopping the progressive paralysis. Attempts which had been made with mercury and salvarsan had not been encouraging. Tuberculin and mercury, used in the way described at the Buda-Pesth Congress in 1909, were said to have produced good results. The tuberculin treatment was a substitute for the method by which nature had been known occasionally to cure general paralysis—namely, by adding a fever to the disease. Wagner-Jauregg, in 1917, inoculated nine cases with tertian malaria, and six of them showed favourable results, three being still at work more than four years afterwards and showing no signs of the disease. For the inoculation, blood was taken from the vein of an untreated patient during the fever, and of this

2 to 4 c.cm. were injected under the skin of the back of the neck paralytic. As a rule, the patient was allowed to have eight chills, after which the malaria was cut short by giving, for three days, twice a day, 0.5 gram of quinine bisulphate, and then for fourteen days once a day 0.5 gram. In nearly all cases there was no fever after the first dose. At the same time neo-salvarsan injections were carried on, an injection being made once a week for six weeks, the neo-salvarsan acting not only against the syphilis but the malaria also. Latterly silber-salvarsan was used instead of neo-salvarsan. The results had been very favourable, and the clinical signs of general paralysis were said to have often completely disappeared during the treatment. Incomplete cures with persistent marked abnormalities occurred in fourteen cases, the disease having endured for several years. Professor Wagner-Jauregg considered the malaria treatment was the best, but that where this could not be applied the tuberculin treatment was to be recommended. Emphasis was placed on the patients being treated if possible early in the disease, and Dr. Scripture described the method of making speech inscriptions, which served to reveal the earliest abnormalities of speech and present them in graphic form. The patient spoke into the mouthpiece of a wide tube leading to an apparatus which registered the puffs of air and the waves of speech on a drum; these records were then studied under the microscope. The cases of general paralysis showed the most varied bulbar, cortical, and mental signs, and of all degrees of severity. One sign was never missing in general paralysis—namely, asaphia (lack of precision in regard to type). With the normal person there was no variation in his speech, in the relative energy of the explosives, etc., but in the general paralytic this uniformity was lacking. The absence of asaphia could not yet be asserted to be a proof of the absence of general paralysis, though it was highly probable.

THE PRESIDENT, in thanking Dr. Scripture for his paper, said that the vast majority of cases of the affection were diagnosed with great ease, but every now and then one was seen which, in spite of every care, could not be labelled general paralysis as against ordinary tertiary syphilis, and this additional means of testing, if its value were confirmed, would be a valuable addition. He would like to try the treatment of general paralysis by malaria in some cases, but he did not at present feel convinced on the subject. Still, the course of the disease was so relentlessly downhill that any promising treatment should be tested.

SURGICAL TREATMENT.

A MEETING of the Surgical Section of the Royal Academy of Medicine in Ireland was held in the Royal College of Physicians on November 17th, with Sir ARTHUR CHANCE in the chair, when the President, Sir WILLIAM L. DE COURCEY WHEELER, delivered his opening address, entitled, "What makes for success in surgical treatment." He referred to the part played in the development of Irish surgery by his predecessors in the chair, and to the presidential address of his father in 1883. In a plea for better team work in surgery, he emphasized the fallacy of sending specimens for report to a pathological laboratory at a distance, the surgeon never seeing the pathologist and the pathologist never seeing the patient. He described visits to various clinics in Europe and America, and thought that team work could be carried on without extra staff and without extra cost, to an extent sufficient to change antiquated and defective into modern and safer methods. He urged the necessity for travel for those about to undertake hospital appointments.

The preparation, the "ritual of the operation," and the after-treatment of patients were then discussed. It was his own practice to give patients alkalis for several days before operation, and glucose was added when any anxiety was felt. No laxatives to cause purging were ever given to patients preparing for operation, and no enema was given on the morning of operation. As a rule, surgical cases free of fever and non-drainage cases were allowed up two or three days after operation. All reports went to show that the healing of the wound was not interfered with by early movement; that probably the danger of pulmonary embolism was rendered less, and ventral hernia did not occur. Very hot operating theatres were condemned, and he advised that the head of the patient should be covered over with a blanket to prevent the inhalation of cold unfiltered air while being taken from the theatre to the wards. Sir William Wheeler said that he had experienced the calamity of pulmonary embolism in four cases. The part played by morphine,

the Trondelenburg position, the Fowler position, and the immunity of children were discussed. Moynihan's opinion was quoted to emphasize that all grades of infection might occur in wounds without the actual formation of abscesses. The aim should be the healing of a wound without any local or general reaction whatever, followed by a convalescence with little or no pain or discomfort. Union by first intention could be easily obtained, but that might be far from the finality of perfection. The combination of local anaesthesia with general anaesthesia as a routine in surgery was urged. He had adopted that method for almost the past twenty years.

Dr. Lewis Cassin thought that what was needed in Dublin was an institution to deal purely with problems of research. He appealed strongly to the President and the other leaders of the profession to take steps to try and remedy this defect. He himself hoped to establish a biochemical laboratory at the Coombe Hospital, which would help towards the solution of those problems which demanded research work.

Dr. T. T. O'Farrell said that in regard to team work where they failed in Dublin was in applying it. A pathologist was sent a specimen, but was given very few instructions, and knew nothing about it except what the microscope showed. He then sent in his report, and never heard anything more about the case. In his opinion the pathologist should be told how the case progressed. Dr. Percy Kirkpatrick said that, speaking as an anaesthetist, the first thing that made for success at an operation was that everyone concerned should remember that they were treating a sick person. He thought that the anaesthetist should be given an opportunity of examining the patient before the operation. Very often the anaesthetist knew nothing about the patient, and that did not make for success in surgical operations.

Dr. T. G. Moynihan thought that surgeons did not realize, in the same way as physicians, the extremely important part an operation played not only in a patient's physical welfare, but also in his mental welfare. In every case undergoing surgical treatment, except minor operations, it was essential for the patient to take things easily for three or four months at least. An operation was a shock to the nervous system. A patient made up his mind to be operated upon, and then was not given full time to recuperate, and so a great many people suffered from neurasthenia. Nearly every day he came across patients suffering from post-operative neurasthenia. Dr. Milne Henry said that combined forethought should be used in every case, and that every minutest detail should be thought over before operation.

Sir Arthur Chance wondered whether it was well for them to be so well satisfied with their work. They heard great praise of Irish surgery, and he wondered if this praise was really deserved. He would like to know if there was any team work done in Ireland. He believed that isolated team work was done, but that was not his conception of real team work. One point about operations was the after-result. Was any genuine inquiry made in the majority of cases as to the progress after operation? He did not think there was.

THE ENTERIC-SALMONELLA GROUP OF BACTERIA.

The Pathological Section of the Royal Academy of Medicine in Ireland met on November 10th, when the President, Dr. W. D. O'Kelly, read a presidential address entitled "Some observations on the enteric-salmonella group of bacteria." He reviewed the position of the more important members of the salmonella and enteric groups of organisms in the light of recent work, and expressed the opinion that the trend of English bacteriologists was towards the grouping suggested by Tenbrook in America, while he thought that German workers were moving in the same direction. The great difficulty with regard to members of the salmonella group was to apportion the relative importance of cultural and serological differences, and also to determine how far varying degrees of virulence for animals assisted in the differentiation of the organisms concerned. Was, he asked, Hirschfeld's *B. paratyphosus* C to be classed with *B. suispestifer*, with which it was serologically identical, or with Schottmüller's bacillus, with which it corresponded in its fermentation reactions, or with the paratyphoids of animal origin, on account of its agreement with the latter organisms in cross-immunization tests against *B. suispestifer*? He suggested that the two groups of *B. suispestifer* described by Andrews

and Neave corresponded to "super-" and "sub-strains" which Schlitzke had worked out. Instances of the Gaertner and Aertrycke organisms causing affections other than gastro-enteritis were recalled, and stress was laid on the fact that the enteric-salmonella organisms were more frequently responsible for affections of the respiratory tract than was hitherto believed. The importance of such cases in the search for the cause of an outbreak was emphasized, and the difficulty of isolating the organisms under review from the intestines of carriers was dealt with. The employment of larger amounts of faeces in fluid media by enrichment methods was advocated, and it was considered that the urine should be investigated, and perhaps also the sputum. The difficulties were increased by the occurrence of atypical varieties such as non-motile typhoid bacilli and the mucoid paratyphoid bacilli described by Walker and Fletcher. Even sluggish fermenters gave rise to a good deal of unnecessary work. These atypical varieties had been met with in "raw" strands as well as amongst stock laboratory cultures. The time had come for settling some, if not all, of the points raised, and the hope was expressed that Irish bacteriologists would devote some of their time to the solution of these problems.

Dr. Bragan said that with reference to the sugar test he thought that the great difficulty was in getting many of the rarer materials in a pure state. If one relied on chemical tests one organism alone was found—namely, paratyphoid. It was only when serological tests were introduced that one could distinguish between paratyphoid A and paratyphoid B, and later between them and the other members of the group.

Dr. O'Farrell and Dr. Wigham also spoke, and Dr. O'Kelly replied.

THE BLADDER IN GYNAECOLOGICAL CASES.

A MEETING of the North of England Obstetrical and Gynaecological Society was held at Sheffield on November 17th, with the President, Mr. HAROLD CLIFFORD (Manchester), in the chair, when Mr. ALFRED GORAN (Leeds) read a paper on the bacterial flora of the bladder in gynaecological cases.

Mr. Gough said that his observations were based on the examination of catheter specimens of urine from 100 unselected cases in which no complaint of urinary symptoms had been made. The specimens were obtained by the routine catheterization of patients before operation and were examined in the following manner: With the least possible delay a single drop of urine was placed in a tube of agar culture medium and, after incubating for forty-eight hours the number of colonies was noted; the deposit obtained by centrifuging was also submitted to microscopic examination. No search was made for tubercle bacilli, gonococci, or anaerobic organisms, but nevertheless the limited inquiry had yielded results of some interest. Of the specimens examined, 30 were sterile, in 39 the number of cultures was under 10, in 21 under 100, and in 10 over that figure. The organisms found were the *Staphylococcus albus* in 56 specimens, the diptheroid bacillus in 17, coliform bacilli in 12, and a streptococcus, the *Staphylococcus aureus*, and *Bacillus proteus* in one each. Taking the 10 cases where the number of cultures was over 100, coliform bacilli were found in 8, this being in accordance with the predominant part played by these organisms in the causation of the more severe infections of the urinary tract. His numbers were too small to justify an analysis of different morbid conditions, but as a general rule most organisms had been found in cases of prolapse and pelvic infection. The only accurate and scientific method of determining the bacterial content of the urine in the bladder was to withdraw a specimen with a syringe through a suprapubic puncture. Catheter specimens were always liable to be contaminated during the passage of the instrument, and this fact might account for some of the cases in which small numbers of cultures had been found. It would not, however, explain the 10 cases where the cultures were numerous, so he felt justified in concluding that organisms were present in the bladder in 10 per cent. of gynaecological cases without urinary symptoms. He thought this would explain many of the cases where cystitis followed operation, as the retention of urine frequently met with after operation, and the diminished resistance of the patient, would give an opportunity to germs already present. Similar considerations would account for the occurrence of cystitis and pyelitis during pregnancy and in the puerperium.

Rebickus:

THE THYROID GLAND.

PROFESSOR CRILE and his associates intend to publish a series of volumes on clinical subjects in order to present the knowledge by which the theory and practice of the Cleveland clinic is guided from day to day. "Both theory and practice, therefore, will be constantly subject to revision, and possibly reversal of opinion."

This first volume is on the thyroid gland.¹ It is a remarkable product of the work of fifteen men co-operating as a team and dominated by a refreshingly inspiring mind. The general outlook on the subject is always wide, and may be illustrated by the following three excerpts from the introduction written by Professor Crile:

1. "We wish," he writes, "first of all to express our sense of the obligation of medicine to Theodore Kocher in Europe for the secure foundation laid by him for surgery of the thyroid gland."

2. "Endemic goitre is a geologic deficiency disease due to a lack of iodine in the organism."

3. "We shall offer the general hypothesis that the body is an electro-mechanical mechanism in which the electric conductivity, hence oxidation, is controlled by the thyroid."

All will agree with No. 1, we believe No. 2 is not the whole story, whilst No. 3 is one of those "Crilean flashes" we look for from the author of *Mechanistic Views of Life and War*.

Although the volume starts its flight "as an ephemeral publication representing to-day's view-point of this clinic," there are in it many valuable contributions which will help to lighten the anxieties of those concerned (the surgeon, anaesthetist, and nurse) in performing operations on the thyroid gland, more especially for cases of hyperthyroidism.

Full details are given of how to guard "these sensitized patients" against "psychic, traumatic, biochemic, and anaesthetic stimuli," by pre-operative management, in which the nurse plays an important part; full instructions are likewise given as to the arrangement of instruments and also for the post-operative treatment. There is one statement which if given as an order by a general in charge of an army during battle would forthwith mark him as *great*, and that is—stop operations when matters go against you. "In performing thyroidectomies, the extent of the operation will depend entirely upon the condition of the patient, and therefore he may be sent back to his bed at any moment . . . with the wound dressed open with flavin gauze."

In the Cleveland clinic preliminary ligations are made in about 40 per cent. of the cases, and are performed in the patient's bedroom on his own bed without his being informed of it beforehand. The patient is daily introduced to the use of the anaesthetic "nitrous oxid-oxygen," and on the psychological opportunity the operation is done. "The average reaction following ligation is practically the same as the reaction which follows admission to a hospital." Either as an anaesthetic is tabooed.

On the burning question of treatment in hyperthyroidism, "x rays versus surgery," Crile favours the latter because "surgery now undertakes every case; the mortality is practically eliminated; much time is saved, and a more certain cure is achieved." "Since the adoption of the methods described in this volume we have performed 1,783 thyroidectomies, including 1,022 thyroidectomies for exophthalmic goitre, with a mortality of 1.4 per cent.; and 783 ligations, with a mortality rate of 0.76 per cent. No case has been rejected as inoperable, although some have been practically *in extremis*, with oedema of the extremities and with ascites." A truly remarkable achievement when one considers past records of operations in these perplexingly dangerous cases.

It is interesting to note that the plan of treatment so carefully and fully described in this volume is founded on experiments and on clinical studies of 3,535 thyroidectomies, among which 1,958 were for exophthalmic goitre. Although this is a big record of cases in one clinic, from our point of view, nevertheless it recalls a letter I (the reviewer) received from Dr. Albert Kocher of Bern some ten years ago, containing a postscript requiring no comment: "My father yesterday performed his 5,000 goitre operations. 12, iii, 1912." There is an interesting chapter on the "role of the radiologist in diagnosis of goitre," which is illustrated by many excellent figures well reproduced on thick paper.

¹ *The Thyroid Gland*. Edited by Amy F. Rowland. Clinics of George W. Crile and Associates. Philadelphia and London: W. B. Saunders Co. 1922. (Med. 8vo. pp. 288; 105 figures, 21s. net.)

A chapter on the "value of basal metabolism studies in goitre" brings this subject quite up to date; men of the old practical apprenticeship school will read with pardonable self-satisfaction that "the increase in pulse rate represents a fairly accurate index in lieu of actual metabolic measurements."

In connexion with the prevention of goitre, about which the reader would have been glad to hear more, reference is made to the use of iodine, sodium iodide, and mercuric iodide; as to this I cannot, I think, do better than quote the following passages from a letter I have received less than a couple of months ago from Dr. Albert Kocher, showing that the late Professor Kocher was of opinion that iodine was of value as a prophylactic, and was in the habit of using it for this purpose some forty or more years ago.

"As to the questions about goitre etiology you want to know, it is quite true that my father believed that the cause of goitre is either a hitherto unknown micro-organism, or more probably a chemical agent mostly transferred by water and made inoffensive by boiling the water. That is why he proposed, forty years ago, to boil all the drinking water, especially at the schools, to prevent goitre. But at the same time, forty years ago, he proposed to give the children twice or three times a year during some weeks a small dose of iodine to prevent goitre. He had then a malt preparation made with iodine and iron. The proof is that we were given it as boys three times a year, and at the same time were not allowed to drink any more boiled water at home or at school. The result is that we three brothers have absolutely normal thyroid glands, in size and consistency like the thyroid of Spaniards, etc., although my mother, grandmother, grandfather, uncles and aunts had goitres. On the other hand, I do not believe that it was my father's idea to give the school children the whole year round such doses of iodine as are given in America, and also here. . . . I believe this is dangerous, because it can give Graves's disease."

I have seen much of the late pioneer of our knowledge of thyroid gland surgery, the man who is commemorated in his native town (Berne) by the Theodor Kochergasse, and many times was told that goitre is a water-borne disease due to one of two causes, either (1) a subtle chemical compound which disappears on boiling, or (2) an elusive micro-organism, and he felt confident that one day the one or the other would be run to earth.

J. LYNN-THOMAS.

DISEASES OF THE BLOOD, KIDNEYS, DIGESTIVE ORGANS, AND METABOLISM.

We have received two volumes (IV and V) of the *Précis de Pathologie Médicale*,² which is being issued in Paris by the firm of Masson. Inasmuch as one of these volumes contains 628 pages and the other 800, it may be that the word "précis" has changed its connotation in France while retaining it in this country. The two volumes deal respectively with diseases of the blood, blood-forming organs, and kidneys, and diseases of the alimentary tract and metabolic disorders.

The section on diseases of the blood and haemopoietic system is by MM. P. EMILE WEIL and MARCEL BLOCH. It is divided into two parts, the first concerned with biological and the second with clinical aspects. The important part played by the liver in blood formation in the adult, especially its influence on coagulation, is emphasized. The clinical pictures of the various types of anaemia, it is needless to say, are well drawn, but the paragraphs on treatment are, on the whole, sketchy and disappointing. X-ray or radium therapy is advised in myelocytic leukaemia in "large doses," but no reference is made otherwise to strength or frequency of application. The skin lesions in lymphatic leukaemia are fully detailed and well illustrated. But our French friends have no greater success in differentiating the various types of lymphatic glandular enlargement than have British and American writers.

In discussing the site of elimination in the kidney of the various constituents of the urine, M. VALLERY-RADOT, who is responsible for this section, expresses the view, in spite of a footnote reference to the work of Richards in Philadelphia, that secretion of urine takes place entirely in the convoluted tubules, the glomeruli being merely pumps. The discussion of the various theories as to the causation of orthostatic albuminuria is followed by the warning that in certain cases it may be the first sign of a developing nephritis or the last

² *Précis de Pathologie Médicale*. Tome IV: *Maladies du Sang et des Organes hématopoïétiques*, par MM. P. Emile Weil et Marcel Bloch. *Maladies des Reins*, par M. Pasteur Vallery-Radot. (Cr. 8vo. pp. 623, 150 figures, 4 plates.) Tome V: *Maladies de l'Appareil digestif et de la Nutrition*, par MM. Marcel Labbé et G. Villy. (Cr. 8vo. pp. 800; 316 figures, 2 plates.) Paris: Masson et Cie. 1922. (Price of each volume—paper, fr. 20; cloth, fr. 25.)

stago in the process of healing, but we are not told the globulin-albumin ratio in these circumstances. The subject of nephritis is well handled and it is clearly pointed out that the dominant feature of the disease is due either to chloride or to nitrogenous retention, the latter usually associated with a raised blood pressure, the former with oedema. In discussing urea retention, the author mentions that it may occur in conditions other than nephritis—in cardiac disease, lead poisoning, icterus gravis, and urinary obstruction among others—yet in such conditions a pathological state of the kidneys is surely the rule. We are told that in nephritis a blood urea between 1 and 2 grams per litre indicates death within two years; above 2 grams several weeks or months only will elapse; while above 3 grams death cannot be long delayed. The author urges that the term "uraemia" should be abandoned, and the syndromes designated "chloride retention," or "nitrogen retention," or "hypertension," as the case may be.

Diseases of the alimentary tract, including the pancreas, peritonemum, and liver, metabolic disturbances and "deficiency diseases" are well expounded in volume V by MM. MARCEL LABBÉ and G. VITRY. The work includes descriptions of several conditions usually regarded as surgical rather than medical in this country, and many surgeons would profit by reading Marcel Labbé's lucid account of malignant disease of the intestine, of haemorrhoids, and of fissure.

Each section contains a review of the anatomy and physiology of the organ under consideration, a description of methods of examination, and an account of the general etiology and main symptoms of disorder of the part, before the particular diseases are discussed. As in the previous volume, the paragraphs on treatment are apt to be disappointing, and methods in advance of those described which have stood the test of time in this country—for example, Lénhartz diet for peptic ulcer and the Graham-Allen treatment for diabetes mellitus—are not mentioned.

These two volumes are intended for students reading for examination and for practitioners; they are well illustrated, and contain more detail than an English student requires for the qualifying examination in medicine and medical pathology, but those reading for higher examinations cannot fail to find them of great assistance. We look forward with interest to the publication of the remaining four volumes in the expectation that the high standard of excellence reached here will be maintained.

THE TECHNIQUE OF PSYCHO-ANALYSIS.

Though the literature of psycho-analysis has assumed considerable proportions, there has hitherto been no book which provides a clear and adequate account of the practical details of analytical therapy. Dr. DAVID FORSYTH aims to supply this want in a small volume entitled *The Technique of Psycho-analysis*.³ The book is based upon the author's experience of psycho-analytical therapy, and it supplies in a compact form the practical information it is essential to those who propose to take up the method of treatment with which it is concerned should possess. The difficulties which confront the would-be analyst are not minimized nor concealed, and it may be that some readers will feel that their vocation lies in other directions before they have reached the end of the volume. The initial difficulties concern the analyst himself, a topic which is discussed in the opening chapter. It is shown that in psycho-analysis the physician must assume an attitude towards his patients which involves a complete reversal of the habits and procedure acquired in ordinary practice. Thus he must be impersonal, passive, and no more than a shadowy figure in the background to whom the patient can reveal his temperament with complete freedom. As Dr. Forsyth observes, such an attitude of emotional detachment is more easily written about than achieved, and he considers that the analyst must acquire a knowledge of himself by being psycho-analysed, or, if this is not feasible, by psycho-analysing himself, in order to deal adequately with his patients.

The second chapter deals with the various details and precautions which must be heeded if the analytical work is to go forward in the most favourable circumstances. These details are included under the heading: "The pre-requisites of the treatment," and amongst the subjects discussed are the duration of the treatment (at least several months) and the type of case in which a favourable outcome may be antici-

pated. The remainder of the book deals with the analytical work itself, and in successive chapters the various stages of the treatment are described up to the termination of the analysis. The book is written with commendable clearness and brevity, and the author would appear to have achieved his aim and provided a useful guide to the practice of psycho-analysis.

INJURIES OF PERIPHERAL NERVES.

Dr. BYRON STOOKY'S *Surgical and Mechanical Treatment of Peripheral Nerves* is a welcome addition to the list of truly authoritative monographs which have appeared during recent years in response to the stimulus of the experience of the reconstructive surgery of the war. This work may be justly regarded as representing American views and teaching in this special surgical field, and amongst the younger American surgeons the author is pre-eminently fitted to undertake such an exposition. Considerable space is devoted to those anatomical and physiological considerations which form the basis of a rational surgical treatment of the various lesions of peripheral nerve trunks. Professor Carl Huber has contributed a chapter on nerve degeneration and regeneration which constitutes one of the most valuable sections of the book, although we must confess to a little difficulty in extracting a broad conception of these processes from the histological minutiae described.

In discussing the general principles of nerve repair the author has everywhere adopted a sane and judicious attitude. He writes more confidently perhaps than British surgeons of the efficiency of nerve grafts—particularly of the "cable" grafts which have proved so popular in the United States—but he is emphatic that anything short of end-to-end suture is at the best a most imperfect method of repairing a nerve injury.

The chapters dealing with the lesions of the individual nerves are well planned. It is interesting to note that in discussing the advisability of exploring the brachial plexus in cases of obstetrical paralysis the author's conservative advice runs counter to that of certain other American neurological surgeons—most notably Taylor and Sharpe. But Dr. Stookoy will here receive the support of the majority of surgeons who have had an extensive clinical experience of this type of nerve injury.

The many beautiful illustrations throughout the book have been carefully selected from various sources, and in its production of this book Messrs. Saunders have shown no deviation from their usual high standard.

QUESTIONS AND ANSWERS FOR DENTAL STUDENTS.

SINCE few of those who superintend the education of dental students have sufficient leisure to converse with or question each one separately, and since on this account the needs of the dental student are not disclosed, nor his mind directed in the manner best calculated to facilitate his studies, Messrs. W. and A. T. BARRITT have compiled *Questions and Answers for Dental Students*,⁴ hoping thus to stimulate in the student a desire for further knowledge.

That a teacher in a dental school should feel the need of such a book and write such a proface as is to be found in it is a serious indictment both of the teaching of dental students and of the dental curriculum. There are probably other dental teachers who share the uncomfortable feeling disclosed by the authors that the medical side of the dental student's education is seriously defective.

As has just been indicated, the scope of the book is limited to the medical side, and of that to such only as strictly applies to the mouth. The questions and answers are short and definite, and if the student be not spurred to inquire for further knowledge, at least he will have learned something. As a special example of a question which might spur to further inquiry we may quote, "Why does nature provide periods of rest during eruption?" with its answer, "To allow for recuperation and prevent exhaustion." A thoughtful student might ask whether nature has any need for recuperation during growth! He might also ask whether fluctuation

³ *Surgical and Mechanical Treatment of Peripheral Nerves*. By Byron Stookoy, A.M., M.D. New York: Neurological Institute. Co. 1922. (Sup. roy. 8vo. pp. 475; 217 figures. 48s. net.)

⁴ *Questions and Answers for Dental Students: Dental Surgery*. By Wesley Barritt, O.B.E., L.D.S. Eng., and Alfred Tomplar Barritt, L.D.S. Eng. London: Henry Kimpton. 1922. (Cr. 8vo; pp. 177. 6s. net.)

⁵ *The Technique of Psycho-analysis*. By David Forsyth, M.D., D.Sc. Lond., F.R.C.P. London: Kegan Paul, Trench, Trübner and Co., Ltd. 1922. (Cr. 8vo, pp. viii + 133. 5s. net.)

is the peculiar property of a chronic alveolar abscess, and what is the meaning of the phrase, "The stimulation of the salivary secretion acts as a prophylactic and curative agent." Ho may also marvel at the structure of the tongue, which is described as "covered with a mucous membrane resembling the skin in structure, together with a corium, a layer of papillae, and a superficial epithelium."

Whether such a book as this will stimulate the thirst for knowledge or be taken as the source itself of knowledge depends on the individual into whose hands it falls; but the student who desires to learn will find in it many a peg whereon to fix his first chaotic impressions of medicine as applied to dentistry.

A DOCTOR IN THE ARCTIC.

Dr. HARRIS has done well to edit for publication his late father's diary, for it tells a story of adventure and endeavour, of human endurance strained almost to the breaking point, worthy to rank with any narrative in the language. Dr. Charles Edward Smith was surgeon on board a whaler, and though many doctors have lived adventurous lives (the great war did not find the profession wanting, the only bars to the V.C. being bestowed on doctors, and was not Dr. Jameson of South Africa famous one of the most remarkable adventurers in history?) yet no man could have borne and survived greater privation than he. The tale, appropriately called *From the Deep of the Sea*,⁶ is told with an unaffected simplicity which fits the elemental nature of the subject and throws into strong relief the conduct of a devoted band of men in circumstances of extremest hardship. When reading it the mind naturally flies to the immortal story of Scott and Oates and Adrian Wilson in the Antarctic, and one marvels that Dr. Smith and his companions did not suffer a similar fate in the frozen north.

On Monday, February 19th, 1866, the *Diana*, a screw steamer of 355 tons, set sail from Hull for the Davis Straits on a sealing and whaling expedition. From the outset bad weather was encountered. It seemed, in the words of the diary, "that the spirit of the north was determined to do his utmost to dishearten us or delay our approach to his icy regions." Ill luck continued to follow the expedition. The sealing was an absolute failure, the ship arriving too late, delayed by bad weather and the ice, and the whaling, although not entirely barren of result, was also disappointing. It is this failure to reap material reward that makes the spiritual qualities of the men of the *Diana* shine the more brightly. There was a long continued struggle with imminent death. They were continually threatened with destruction by the elements, and, most terrible of all, by starvation. Once they had the mortification of seeing the ship which could have rescued them from a perilous place apparently abandon them to their fate. But in the end they survived, and eventually reached home, though in a most wretched condition, and their company sadly depleted by death. The diary breaks off suddenly before the completion of the voyage; the surgeon-diary became too busy attending the sick and dying, the crew being smitten with scurvy. Not only this, he was one of the few able-bodied men remaining, and he took his share in the routine work of the ship.

It is impossible to do full justice to this book in a review; it must be read. Not only does it tell a story of almost superhuman endurance, moving as all such stories must ever be to a sea-loving people; it brings us into contact with an inspiring personality whose courage and simple faith never deserted him.

PHYSIOLOGY AND BIOCHEMISTRY IN MEDICINE.

PROFESSOR J. J. R. MACLEOD and his collaborators are to be heartily congratulated on the appearance of the fourth edition of their book *Physiology and Biochemistry in Modern Medicine*.⁷ The third was reviewed in our columns so recently as April 30th, 1921. The fact that a new edition of so expensive a work has been called for in less than two years certainly demonstrates that the profession is taking a real interest in the application of physiology to medicine.

⁶ *From the Deep of the Sea*. Being the diary of the late C. E. Smith, M.R.C.S., Surgeon of the whaler *Diana*, of Hull, edited by his son, C. E. Smith Harris, M.B., Ch.B., Surgeon, Cunard Steamship Company, late Surgeon-Lieutenant R.N. London: A. and O. Black, Ltd. 1922. (Demy 8vo, pp. vii + 288; illustrated. 10s. 6d. net.)

⁷ *Physiology and Biochemistry in Modern Medicine*. By J. J. R. Macleod, M.B., assisted by R. G. Pearce, A. C. Redfield, N. B. Taylor, and others. Fourth edition. London: H. Kimpton. 1922. (Roy. 8vo, pp. xxxii + 992; 243 figures, 9 plates. 42s. net.)

This new edition, although the paging is unaltered from the previous edition, has undergone many minor alterations, and several chapters, such as those on the output of the heart, the acid-base equilibrium of the blood, and movements of the stomach, have been more or less rewritten. In the chapter dealing with pancreatic diabetes there is a short section on the important research work on "insulin" which is now in progress in Professor Macleod's laboratory at Toronto, as described by him in our issue of November 4th (p. 833). In this volume we have an excellent, readable, and most useful book.

NOTES ON BOOKS.

INVESTIGATORS and administrators who are concerned in the problem of ankylostomiasis will welcome the exhaustive *Bibliography of Hookworm Disease*,⁸ published by the International Health Board of the Rockefeller Foundation. When the Board first undertook the task of co-ordinating measures for the control of hookworm infection one of its earliest steps was the preparation of a bibliography which should be at the service of hygienists and administrators. In the compilation of the elaborate register now issued, which contains 5,680 entries, emphasis has been laid on the social and economic aspects of the disease and the efforts to control it rather than on the biology of the parasite. A short introduction gives an historical summary of the prevalence of the disease and the measures taken to treat it and bring it under control. The bibliography proper consists of 366 pages. This is followed by a key to the abbreviations of the titles of periodicals, an author index, and a subject and place index. The volume is well printed, and all workers in this subject will be grateful to its compilers.

George Joseph Smith was a vulgar scoundrel whose only claim to notoriety is the fact that he appears to have discovered a new method of wife murder. We say "wife murder," but in fact not one of his deluded victims was lawfully married to him, seeing that his first wife was alive and undivorced when he went through the forms of marriage with the murdered women. Unlike some other cases dealt with in former volumes of the Notable British Trials series, this one⁹ presents no novelty except that of the method employed. To the medical jurist the chief interest lies in the establishment of the fact that it is easy to drown a healthy woman in a bath without any alarm being raised and without any marks of violence being visible on the body. In each of the three cases Smith followed the same system. Having persuaded his victim to marry with him he got possession of her savings, insured her life, or got her to make a will in his favour if she had disposable property. Having removed her from the neighbourhood where her friends lived he took her to consult a doctor with a story of headache and "fits." His success in persuading his "wives," who were previously in good health, that they were ill is remarkable. No evidence was called of his having given them drugs in order to produce symptoms. Soon after this the patient would be found dead in a bath. The doctor would give evidence of having been consulted shortly before death and of finding nothing *post mortem* inconsistent with epilepsy. The inquest and funeral were hurried over before the friends of the deceased could arrive on the scene. The "widower" pocketed the money and departed to perpetrate more seductions, extortions, and murders. But the pitcher went to the well once too often. A relative of one of his victims saw a newspaper report of a subsequent murder and the game was up. Smith, who was so callous to his confiding victims, displayed abject terror after his sentence, and had to be carried to the drop. To the practitioner the case with which the murderer succeeded in imposing his story of epilepsy and death owing to a fit, upon three different medical men and upon three coroners, should be a warning against too facile an acceptance of a suggested cause of death, when there is really no good evidence to support such a hypothesis.

Of the small number of Lecch's sketches which have to do with medical men one shows the interior of a brougham in which a country doctor is changing into hunting kit on his way to a meet. There are, no doubt, still many country doctors, and town doctors too, who hunt, and to them we may commend the new edition of *Records of the Chase*¹⁰ by "Cecil"; we may commend it also to that most respectable

⁸ *Bibliography of Hookworm Disease*. Publication No. II. New York City: The Rockefeller Foundation International Health Board. 1922. (Demy 8vo, pp. xxvi + 417.)

⁹ *Trial of George Joseph Smith*. Edited by Eric R. Watson, LL.B. Edinburgh and London: William Hodges and Co., Ltd. 1922. (Demy 8vo, pp. viii + 323; 12 illustrations. 10s. 6d. net.)

¹⁰ *Records of the Chase*. By Cecil. Third edition. London: P. Allan and Co. 1922. (Demy 8vo, pp. xi + 23; illustrated. 12s. 6d. net.)

person, as Cecil would have said, the desultory reader, if he knows how to skip, an art the editor of this third edition has wisely practised in eliminating most of the detail about particular bunts the original author introduced into his second edition. The book was first published in 1854, and in the slightly pompous diction sporting writers affected gives a picture of the countryside in that day of great nobles and great commoners, men of broad acres, who did things in the grand style; incidentally it describes some "originals" both among them and their poorer fellow sportsmen who followed the hounds on foot.

The edition of the *Medical Directory* for 1923¹¹ has been published. It has not been allowed to increase in bulk; in fact, it contains fewer pages than the issue for 1922, but it does not appear to be in any respect less complete. We doubt, indeed, whether any profession is supplied with so comprehensive a directory to its members and to its principal institutions. The number of names in the volume has grown from 45,586 last year to 46,311 this year—an increase of 725. In the two previous years the increases were 660 and 666 respectively, but in the issue for 1920 there were 1,160 names more than in that for 1919. The numbers recorded are larger in each of the parts into which the *Directory* is divided, except under "Services," where the number has declined from 3,475 to 3,458; this is still rather larger than in 1913. Of the total increase of 725 names England, outside London, accounts for 260. In conclusion, we can only once more commend the publication to the profession as a most reliable work of reference.

In the preface to the fourth edition of his work on tropical diseases¹² Surgeon General STITT states that he has adhered to the original plan of the manual, as he believes the arrangement gives the student or tropical practitioner a concise and readily accessible presentation of the subject. He accepts the spirochaetal etiology of yellow fever, and has transferred the chapter on this disease to the section on protozoal diseases. But we may ask why the transfer is to this section. The leading protozoologists of the day do not accept the spirochaetes as protozoa, but regard them as more akin to the bacteria group. Six new chapters have been added in this edition. They deal with epidemic jaundice, rat-bite fever, tularaemia, tables of helminthic and arthropodan diseases, trench fever, and a chapter on the diagnostics of tropical joint, muscle, and bone lesions. Accounts of the treatment of ankylostomiasis by carbon tetrachloride and of methods of administering aspiroclonamine and anthony have been introduced. It was certainly very necessary to make these additions, which bring the book up to date. Many new illustrations have been added. Every effort has rightly been made to retain the feature of a pocket manual, but even so it has been necessary to increase the number of pages from 524 to 610 and the illustrations from 119 to 159. This deservedly popular little work should, in its new guise, retain its high place amongst works on tropical medicine.

¹¹ London: J. and A. Churchill. Seventy-ninth annual issue. 1923. 36s. net.)

¹² *The Diagnostics and Treatment of Tropical Diseases*. By E. R. STITT. Ph.D., M.D., Sc.D., LL.D., etc. Fourth edition, revised. London: Lewis and Co., Ltd. 1922. (Post 8vo, pp. xiii + 622; 159 figures. 18s. net.)

MEDICINAL AND DIETETIC PREPARATIONS.

Hemostyl.

HEMOSTYL is the trade name given to a preparation of sterilized horse serum, obtained from horses in a state of active blood regeneration, induced by repeated bleedings. The claims made for it are based on the results of Professor Carnot of Paris, who maintained (1906) that such serum was of particular value in anaemia. Preparations are made for oral, rectal, or hypodermic administration. Horse serum from horses in a state of active to be of value in anaemia by their claims cannot be considered acceptance. It is, of course, difficult to account for such an action, and it is surprising that horse serum, given by the mouth, should have any general action, particularly in persons living on a diet containing meat. It is scarcely necessary to remark that the estimation of the value of any agent as a cure for anaemia is a matter of very great difficulty whether in clinical practice or by laboratory experiments. The agents for hemostyl in this country are Bengue and Co., 52, Charlotte Street, Oxford Street, W.1.

Idozan.

Idozan is stated to be a neutral preparation, containing 5 per cent. of iron in a non-irritant form, which is readily dissociated to liberate ionized iron. Our examination showed that idoan had a sweetish taste and did not produce any

astringent effect in the mouth, even when tasted undiluted. It was found to contain 5 per cent. of iron in a non-ionized form, and ultra-filtration tests showed that at least 97 per cent. of the iron was present in colloidal form. Free iron is slowly released on warming with dilute acids, and therefore the iron should leave the stomach in a form in which it can be assimilated. Idozan is therefore a concentrated non-irritant preparation of iron very suitable for therapeutic administration, particularly when it is desired to give large doses of iron. In the literature supplied interesting quotations are given from Professor Ponisen and Dr. Lichtenstein, urging the importance of intensive iron administration in cases of anaemia. The purveyors are Messrs. Chas. Zimmermann and Co., 9 and 10, St. Mary-at-Hill, London, E.C.3.

Opioidine.

An interesting new preparation of opium, called opioidine, has been placed on the market by Messrs. Macfarlan and Co. (11, Moor Lane, Fore Street, London, E.C.2). It is a preparation of the total alkaloids of opium in soluble form; one part of opioidine is equivalent to five parts of opium. Opioidine contains about 50 per cent. of morphine, the remaining 50 per cent. consisting of the other opium alkaloids—narcotine, codeine, etc. Straub and others have drawn attention to the remarkable action of narcotine in "potentiating" morphine. The minimal lethal dose for mice of morphine is 0.6 mg. per gram of body weight, and of narcotine more than 0.5 mg. per gram; but a mixture of morphine and narcotine may be fatal in a dose of 0.2 mg. per gram. In the case of opioidine, for example, the minimal lethal dose for the mouse is 0.3 mg. of total alkaloids per gram (hypodermic). The exact differences between the mode of action of morphine and of the total alkaloids of opium are not fully understood, but there is considerable evidence that the latter are of particular value when it is desired to act upon the gut or upon plain muscle. Certain preparations of the total alkaloids of opium of Continental origin are upon the market and have proved of value, and we welcome the enterprise of Messrs. Macfarlan in providing a British preparation of this nature.

ROYAL MEDICAL BENEVOLENT FUND.

At the meeting of the Committee held at 11, Chandos Street, W., on October 10th, 1922, 51 cases were considered and £627 ls. voted to 39 applicants. The following is a summary of some of the cases relieved:

... a staff surgeon in the Royal Navy who ...
... naval pension of £14 a year until she is 21, ...
... the Royal Naval College. She asked the ...
Fund to help her with fees for King's College. Her brother-in-law has ...
... Voted £10.
... 1915. Owing to ill health ...
... her capital, which is now ...
... very little—last year £20.
...
... as a ship's surgeon. ...
... daughters. School fees ...
...
... owing amount to £24 15s. ...
Widow, aged 57, of M.R.C.S. and L.R.C.P. who died recently. When ...
the estate is settled it is expected that income will only amount to 45s ...
per annum; she asked for assistance towards the school expenses of her ...
son, aged 14. Voted £18 in twelve instalments.
M.R., Ch.B., Aberd., aged 37, with pulmonary tuberculosis and unable ...
to work. He has been in a sanatorium fourteen months. Disability ...
pension £10 a month, and after deducting 12s. a week he is able to pay ...
his wife £7 10s. a month allowance £6 6s. a month fees at sanatorium

Subscriptions may be sent to the Honorary Treasurer, Sir Charles Symonds, K.B.E., C.B., F.R.C.S., at 11, Chandos Street, Cavendish Square, London, W.1.

The Royal Medical Benevolent Fund Guild is overwhelmed, in these days of exorbitant prices for clothing and household necessities, with applications for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. The Guild appeals for secondhand clothes and household articles for the benefit of the widows and children who in happier times would not have needed assistance. The gifts should be sent to the Secretary of the Guild, 43, Bolsover Street, W.1.

An institute for the study of the influence of mountain climates on tuberculosis has been opened at Davos, under the direction of Professor Adolf Loewy of Berlin.

In Japan suicides caused by persons taking rat poison are rapidly increasing; in 1921, according to the *Japan Medical World*, there were 1,017 cases. During 1920 there were 640 deaths from this cause, and in 1919 there were 95. The attention of the Japanese Home Department was first called to this painful mode of suicide in 1914, when 6 deaths from it were reported.

Nota et Vetera.

MASTER JOHN ARDERNE.

For the general reader the imposing figure of Guy de Chauliac dominates mediæval surgery. The reader has also perhaps heard the names of Henry of Mondrevillo and of the Fleming Jehan, while Haeser's notice of John Arderne excites without satisfying curiosity. Mr. H. S. Wellecome has increased the already heavy debt of gratitude owed him by historical students by causing to be published a translation of the old Newark practitioner's *de Arte Physicali et de Chirurgia*. The editor and translator is Sir D'Arcy Power, which is a concise way of saying that text, notes, and introduction leave nothing to be desired. The translation is of an illuminated manuscript, from an early fifteenth century hand, preserved in the Royal Library of Stockholm. The editor says that it "omits much, adds something, and takes out entirely the personal element and quaint touches which make the original manuscripts such excellent reading. It is in fact Arderne, spoilt by his editor—a catastrophe which still happens to some medical writers of repute." Sir D'Arcy Power is much too modest in the appraisal of his literary wares; indeed any one of the thirteen beautiful plates with which the volume is embellished establishes a better claim to be called picturesque than most historical monographs.

Master John Arderne was born in 1307 and lived to the end of the fourteenth century. He was probably (says Haeser) educated at Montpellier and certainly in the service of Henry Plantagenet, first Duke of Lancaster. The Duke died of plague in 1361 and Arderne perhaps then attached himself to John of Gaunt. He practised at Newark from 1349 to 1370 and then in London. He was essentially, says his present editor, an operating surgeon in good practice, a man of good education meeting his clients on terms of equality.

Sir D'Arcy Power propounds the fascinating hypothesis that the Stockholm manuscript may have been sent to John of Gaunt's granddaughter, Queen Philippa of united Norway and Sweden, by "some one who had known and loved the wise old surgeon who had been so long in the service of her grandfather."

John Arderne was a bold, practical surgeon; he had sufficient originality "to invent the operation for the cure of fistula which, after falling into disuse for nearly five hundred years, is now universally employed." The writer of the Stockholm manuscript has not, we submit, altogether dissipated the aroma of the original case notes in the following account.

"I enred a man from Northampton of the aforesaid Fistula in ano who had three openings in the left buttock and three in the cleft of the scrotum as is here depicted, and all in turn communicated the one with the other and had perforated through the middle of the scrotum. I enred him by incision of all the holes, both in the rectum and elsewhere. Blood welled out strongly from the incision in the rectum because the fistula was very deep. I, therefore, dipped a sponge in cold water and swabbed up the blood; afterwards I put on the wound a blood styptic of powdered madder, and

a good sponge having been placed under the patient he was made to sit in a chair and immediately the bleeding ceased. When he had taken food the invalid was put to bed and slept well all that night without any bleeding forsooth, and in the morning he said he was 'fine.' Afterwards, however, viz., on the second day after the operation, I filled all the wound with powder 'sine pare' and with oil and eggs and sal. populi and with diaphosm, and in less than twelve weeks I cured him completely. And he said, indeed, that twenty doctors had treated him and he had been operated upon by ten. Nevertheless he rode on horse-back about the fortieth day after I made the incision."

The name of the "man from Northampton" has come down to us in another manuscript. He was one John le Colier, mayor of the town in 1326-27, and again 1339-40. We should think it was thanks to John Arderne's skill rather than to the twenty doctors he was able to be so regular an attendant at the Town Council that his name appears as a witness to thirty-three documents between 1315 and 1340.

John Arderne tackled a squelch in the leg of a nobleman in this way:

"I first removed the flesh down to the bone with an ointment of roses, and I scraped it every day. And one day when I was scraping the bare bone with an instrument it moved upwards and downwards. I watched this remarkable node: but for the rest I gave up any further operation and put nothing over the wound except lieum mingled with new honey and the yolk of a raw egg applied on carded linen stupes, and I did this from day to day until the aforesaid bone, with the flesh receding from it, appeared at the end of the wound and became more and more moveable. And when I saw this I put the point of a scalpel under the edge of the bone: and raised it little by little. But that piece of bone was four thumbs in length and two thumbs in breadth, and in thickness it extended nearly to the marrow of the bone, and it was the front of the tibial bone, i.e., Schynboue. After the separation of the bone I finally closed the wound with a lieum dressing of honey, etc., and the yolk of raw eggs."

His medical treatment was less spirited and dealt largely in "nasty or innocuous substances." "Against epilepsy," says John, "write these three names with blood taken from the annular finger of the patient—Jasper, Melchior, Balbazar; and put gold, frankincense and myrrh into a box. Let the patient say three paternosters and 3 Ave marias daily for the souls of the fathers and mothers of these three kings for a month and let the patient drink for a month of the juice of peony with beer or wine." We may not agree that "without doubt this remedy never fails," but it is quite as effective as and much less nasty than draughts of the warm blood of gladiators which have classical authority. We may laugh at the three kings from the East; we shall not laugh at another prescription, the recital of which shall conclude our brief notice of the wise old surgeon. "A good prayer to be said. O God, Who hath wonderfully created mankind and hast more wonderfully reformed him, Who hath given medicines to govern the health of men's bodies, of Thy great goodness look down from Heaven and give Thy blessing to this antidote; or electuary, or potion, that the bodies of those whom it shall enter may be worthy to receive health of mind and body through Christ our Lord. Amen."

nosters and 3 Ave marias daily for the souls of the fathers and mothers of these three kings for a month and let the patient drink for a month of the juice of peony with beer or wine." We may not agree that "without doubt this remedy never fails," but it is quite as effective as and much less nasty than draughts of the warm blood of gladiators which have classical authority. We may laugh at the three kings from the East; we shall not laugh at another prescription, the recital of which shall conclude our brief notice of the wise old surgeon. "A good prayer to be said. Amen."

"Quidam jugulati gladiatoris calido liberantur, apud quos miserrimum fecit" (Celsus, de Med., III, 22).

* *De Arte Physicali et de Chirurgia*, of Master John Arderne, Surgeon of Newark. Dated 1412. Translated by Sir D'Arcy Power, K.B.E., M.B. Oxon., F.R.C.S., from a transcript made by Eric Miller, M.A. Oxon. London: John Bale, Sons, and Danielsson, Ltd. 1922. (Dobles cr. 8vo, pp 62; with coloured frontispiece and 13 plates.)

JOHN ARDERNE.

British Medical Journal.

SATURDAY, DECEMBER 9TH, 1922.

CANCER AND SPECIFIC IRRITANTS.

For none of the many theories relating to the causation of cancer has such concrete evidence been obtained as for the theory of irritation, expounded, if not indeed originated, by Virchow; but this evidence, striking though it be, is forthcoming only in a comparatively small number of cases of cancer, and is as conspicuously absent in the great majority. Whether future research will succeed in identifying any large number of cancer-producing agents in addition to those now implicated cannot of course be anticipated, but since Virchow's time many more specific irritants have been brought into prominence in this connexion. The Section of Pathology at the Annual Meeting of the British Medical Association was fortunate in bringing together such important contributions to the discussion on this subject. Even if irritation cancers should be found to represent only a small percentage of malignant tumours, the investigations, clinical and experimental, which are now being conducted may be expected to throw light on numerous problems in tumour pathology. Here, indeed, the clinician and the experimenter can work together. The observations of such cases occurring in man constitute experimental inquiries no less than those performed in the laboratory. Apparently the pathological processes take longer to develop in human beings than in laboratory animals, a fact which seems to permit of more detailed examination of the pre-cancerous states in man, and of the adoption of measures to combat the onset of the malignant stage; on the other hand, laboratory experiment enables the investigator to exclude many, if not all, of the adventitious circumstances that prevent a clear view of the real etiological factors.

The mere fact that so very few of the subjects exposed to the action of any particular suspected irritant do develop malignant disease, and then only after what seems an inordinate length of time, gives colour to the prevalent conception that the part played by the irritant is, even in these instances, quite secondary, and that we must still search for some single recondite cause that operates only on suitably prepared soil. According to this view the pre-cancerous alteration of tissues may result from the action of very diverse pathogenic agents, but the actual malignant tumour formation, which may or may not supervene, is an independent process, and not merely a further progressive development of the original tissue reaction. It thus comes about that, speaking broadly, two schools have arisen: the one regards cancer as a single pathological entity resulting in every case from some single identical cause, while the other considers cancer to be a broad classification of similar tissue reactions which may result from numerous different causal agents. Between these two contending schools no one can judge at present.

For a hundred years chimney-sweeps' cancer stood as the solitary example of the close association between a definite irritant and a peculiarly located disease. Within the last forty years others have been added—as, for example, tar and pitch cancer, kangri cancer, paraffin cancer, aniline cancer, and, perhaps most striking of all, x-ray cancer. The personal experience of any one man in most of these has been confined to the observation of very few cases, and has lacked the broad outlook over a large number that would be necessary to warrant the drawing of sure conclusions. Even more disconcerting

was the fact that all attempts at experimental reproduction of cancer by any of these agents were, until quite recently, perfectly fruitless. The communications which we publish in this issue supply this deficiency: the clinical observers have had experience of a sufficiently large number of cases from which to draw conclusions, and the laboratory workers have been eminently successful in their experimental essays.

Epitheliomatous ulcerations occurring in industries dealing with tar, pitch, and paraffin are now compulsorily notifiable by order of the Home Office. The recognition of the peculiar liability of workmen in these trades to skin cancers as a result of their occupation allows not only of the recognition of the earliest signs of tumour growth, and consequently the prompt use of remedial means, but also of the institution of preventive measures against their occurrence. The general adoption of the precautions urged by Dr. Legge must do much to diminish the incidence of such occupational diseases. He points out that there are grounds for supposing that blast-furnace tar is devoid of the dangerous properties associated with ordinary gasworks tar, and we understand that this has been experimentally corroborated by Dr. Leitch. It is of interest to note that though chrome workers are liable to ulcerations from contact with chemical substances yet no case of cancer developing on these ulcerations has been reported to Dr. Legge. If it were merely a question of a pre-disposing cause it would be natural to expect that epithelioma would supervene just as frequently in them as it does in pitch and paraffin workers.

Dr. Alexander Scott during his twenty years of practice in a paraffin refining neighbourhood has had unique opportunities of investigating the occupation dermatoses of paraffin workers. More cases have come under his personal care than have previously been reported in the literature of the subject, and he has traced the development of the cancerous conditions to their earliest beginnings. The very long latent period before the onset of cancer in those exposed to the action of the irritating oils is a point that merits careful consideration in attempting to found causal relationships between a suspected primary agent and the pathological effect.

X-ray cancer may be considered as an instance of the experimental production of cancer in man. Mr. Rowntree, who has investigated and followed for several years practically all the cases that have occurred in this country, points out that a preliminary burn and frequently repeated small exposures to the softer rays seem to be essential to the production of epithelioma, and he is of opinion, in view of the recognized dangers and the precautions now adopted against them, that no more cases are now likely to develop.

During the last few years experimental cancer research has entered on a new phase, in that it has begun to concern itself with the direct investigation of possible causal agents. This development had its starting point in the patiently pursued and brilliant researches of Fibiger of Copenhagen, who was the first to produce indubitable cancer by experimental means. It will be fresh in the memory of all who read the full accounts published in our columns that, having found some cases of gastric cancer in a single batch of rats, he discovered in these tumours a hitherto unknown species of nematode, the *Spiroptera neoplastica*, and set himself to trace the origin of this worm, which passed its larval stage in the muscles of imported cockroaches; he succeeded in cultivating the parasite, and by transmitting it to other rats produced gastric carcinomata in them. Inspired by the success of his work, Yamagiwa and Ichikawa resumed again the attempts to induce cancer of the skin by long repeated applications of tar to rabbits. Their experiments, performed during the late war, might not have

gained general credence, even when they were more convincingly demonstrated on mice by Tsutsui, had they not been verified and extended by Fibiger and Bang, who were the first European investigators to realize their great value. In this country the observations have been continued by Murray and Woglom, Leitch, Crnickshank, Russell, and others, and many important facts have been elicited. The variations in individual susceptibility, the different rates of tumour development, the relation of tumour reaction to the duration of the irritant rather than to the age of the animal, the histological examination of the precursory conditions, and the endeavours to discover the particular noxious substance contained in the complex mixture of coal-tar, are some of the points that have been, and are being, dealt with. Dr. Murray finds in the ether-soluble fractions of tar a very potent tumour-producing agent, and Dr. Passey has succeeded in isolating from soot what are probably very similar substances—a research which throws some light on the etiology of chimney-sweeps' cancer.

Dr. Leitch, using experimental methods to supplement or explain clinical observations, shows that even though the operation of the causal agent be removed when only simple papillomata have been produced, yet the reaction of the tissues continues in many cases to the full development of carcinoma; indeed, he finds that if the irritant has been in action for a sufficient length of time and is arrested before any neoplastic change whatever is discoverable, epithelioma not infrequently declares itself at a later date. This convincing experimental demonstration appears to indicate that cancer is the result of cell damage done a long time before the response by new formation is in evidence. The same observer has also succeeded in inducing carcinoma by means of the paraffins of shale oils, and, strangely enough, he has been able to produce sarcoma by the same substances—a thing which has not yet been reported amongst the cases of paraffin cancer in man. Finally, he and Dr. Kennaway have produced cancer in mice by external applications of arsenic.

Thus cancer has now been produced by various agents—by the *Spiroptera neoplastica* (Fibiger), by tar (Yamagiwa and Ichikawa), by the *Cysticercus fasciolaris* (Curtis and Bullock), by paraffin oils (Leitch), by arsenic (Leitch and Kennaway), and by soot extract (Passey). Probably the number of substances that are capable of producing cancer will be largely increased in the near future, and the theory of irritation will in consequence become more impressive.

THE ASSOCIATION IN 1922.

THE year 1922 has been a fortunate one for the British Medical Association; its membership has increased, its political work for the profession has been carried on with success, and it had in Glasgow an ideal place for its Annual Meeting. That great city is not only a centre of huge industrial population for the benefit of which important hospitals exist, but it possesses also an ancient university whose renown has been in no way diminished, but, on the contrary, much increased, by the great staff of teachers which it now possesses. For its President the Association had one of the greatest of these teachers—Sir William Macewen, Regius Professor of Surgery in the university, whose renown as a clinical and scientific surgeon is world-wide. He had the cordial co-operation of his colleagues in making the Annual Meeting the scientific and social success it was. Reports of the work of the scientific Sections have been published in our columns during the past four months, and are now nearly complete. On many occasions during 1922 we have had opportunities of bringing to notice the clinical and scientific work accomplished by members of the Associa-

tion in the Divisions and Branches, and have published a number of lectures given for the Association by many distinguished clinical and scientific workers—lectures which in themselves are important contributions to post-graduate study.

It would be impossible to attempt even to mention all the political and social work the Association has done during the year, but we may point to a few of the more outstanding events, turning first to its hospital policy, which has undergone great developments. Recent years have brought new problems in hospital administration. There has been a steady growth and elaboration of modern methods of treatment, and the expenditure thereon has necessarily become greater. That the popularity of the voluntary hospitals has grown is shown by the ever-increasing demands upon their resources. These conditions, together with the sudden alteration in money values following the war, brought the voluntary hospitals face to face with bankruptcy if newer methods of support could not be found. Temporary help was given by the Government upon lines that had been advocated by the Association—that is to say, through an independent intermediary body. Further support came from the patients themselves; for it was evident that the higher level of economic condition attained by the bulk of the patients now seen at hospital removed very many of them from the category of the indigent, for whom alone the free treatment of a charity could properly be provided. Payments by patients during treatment, and the expectation that there would be developments in contributory schemes through which fit and proper persons could provide against the possible necessity for hospital benefit during serious sickness, made much of the existing policy of the Association as regards hospitals out of date and valueless as a standard of medical policy.

The Council of the Association therefore undertook, through its Hospitals Committee, the preparation of a complete report on hospital policy. This was submitted to the Annual Representative Meeting at Glasgow in July, 1922. A document of such magnitude, dealing with so variable a problem as hospital practice, might well have been expected to provoke much criticism and possibly lively opposition. Thanks to the methods the Council had followed in the preparation of the report, especially the summoning of conferences of hospital staffs, the report was accepted with remarkably little opposition. The only point on which serious opposition developed was on the recommendation for assessment for the purposes of a staff fund of the smaller payments made by individual patients. On this there is now before the Divisions a recommendation from the Council, which it is believed will prove acceptable to all parties as a suitable line of policy in this regard.

The whole scheme of hospital policy, as approved by the Annual Representative Meeting, was published so recently in the JOURNAL (SUPPLEMENT, October 7th, 1922) that extended reference to it is scarcely necessary. The main provisions include, first, the recognition of a dual policy for voluntary hospitals in the continuance of the charitable side of the hospitals for indigent patients, who should receive maintenance and treatment free; and in making provision for others who cannot secure or pay for adequate treatment elsewhere, but from whom payment should be received by the hospital, and on account of whose treatment some method of remuneration of the honorary medical staff should be arranged. Secondly, the requirement that services rendered by the hospitals to the State (either central or local departments) should not fall upon the funds of the charity, but be met by the State or local authority, both as regards the costs to the hospital and the services of the medical staffs. Thirdly, the recognition of the principle of contributory schemes for hospital benefit, and the indication of standards by

which such schemes could be tested—for example, the protection of the hospital from insurance risks which properly fall upon the scheme or the contributors thereto; the preservation to the hospital of the right of determining the suitability of a patient for admission; the need for improvement of out-patient departments with the object of making them primarily places for consultation, and in this connexion securing that members of contributory schemes should not be collected into these departments but receive consultations and specialist treatment outside through independent practitioners. Already these standards are proving of value to medical staffs in enabling them to check the details of contributory schemes now being promoted—for example, that of the Hospital Saving Association for London.

The policy of the Association has been further developed with regard to Poor Law infirmaries and municipal hospitals. The Association desires that these should be no longer isolated institutions but brought into the main stream of medical practice; and to this end it aims to secure that private practitioners shall have opportunity for entry into these hospitals, so that they may treat therein their own patients who so desire. Further, the relations of the several forms of hospital provision—voluntary, Poor Law, and municipal—are under review, and it is probable that the Council will make recommendations for the unification or correlation of hospital policy throughout the country, with a view to preventing overlapping of provision and wasteful competition.

Two other issues of major importance were dealt with by the Representative Body at Glasgow; they were the conditions under which it is proposed to extend the support of the Association to members acting in vindication of the accepted principles of professional secrecy, and the expression of a considered verdict upon the merits of the experiment in the provision of medical benefit under the Insurance Acts. Both are matters of vital interest, not to the profession alone but to the community, and the fact that the machinery of the British Medical Association provides the only available method of concentrating the collective experience of the profession upon the solution of these and kindred problems of public policy is in itself most striking evidence of the place taken by the Association in national as well as in professional life.

In the field of public health the minimum salaries adopted as a temporary basis of remuneration during the latter part of the war have been successfully maintained in almost every area, and it has been possible to secure more suitable remuneration in certain important cases, notably that of the medical officer of health for Manchester. This, it is true, is but the beginning of the work for the public health services that lies before the Association, but it affords a sound basis. Several conferences have taken place between representatives of the Association and of the Society of Medical Officers of Health, and it is hoped to present an agreed programme in respect of public health salaries and conditions of service for the consideration of the Council at an early date. Meanwhile the general policy of the Association with regard to the development of municipal health services has been under review.

The past year has not been marked by legislative activity. As an earnest of the future it is worthy of note that the replies of members of the present Parliament to a series of questions submitted by the Association, based on the accepted policy of the Association, show a very considerable body of parliamentary opinion in support of the constructive measures of reform included in the Association programme.

Overseas, as at home, the year has brought develop-

ments of no small significance to the profession. In Australia final effect has been given to the provision for autonomy within the Association, and, whilst the future of professional organization in South Africa is for the moment in suspense, it is clear that the decision of the South African Branches of the Association will be a determining factor in the solution of the present difficulties. It is satisfactory to recall that by common consent the Association has succeeded in providing means for the unfettered exercise of self-determination. In the Colonial Medical Services the problem of the moment is not to secure local freedom of action, but rather to exercise a stronger protective influence centrally. No Association and no Government can secure for the Colonial Services immunity from the devastating economic consequences of the war, but certain abuse call for remedy, in the interests not only of equity but of a sound economy. This is the case more particularly with the West Indian Medical Services, and whilst the year has necessarily been a period of waiting it is at least satisfactory that with the receipt in London of the local comments upon the Wood report, the Dominion Committee will at last be in a position to make a definite and final claim for reform in the interests both of the medical officers and of the public health.

At the beginning of the year the chief outstanding professional difficulty connected with medical benefit under the Insurance Acts was that arising from the Regulations concerned with the transfer of insured persons on the death or retirement of a practitioner. The great majority of insurance practitioners have held that these arrangements were inequitable to the doctor and were disadvantageous to insured persons, and the would, when fully operative, involve the distribution of insured persons who had been the patients of one doctor among other doctors at the will of a composite, but largely lay, committee. Such a procedure may be unavoidable with regard to a small number of persons in exceptional circumstances, but to establish it as a routine whenever a practice changes hands would seem to be highly objectionable. This difficult controversy has at last been settled. The Insurance Acts Committee has secured that, where the Panel Committee take the necessary steps, the credits which would have been due to the retiring or deceased practitioner shall be continued to his successor, and that not till eighteen months later will those insured persons concerned who have not the chosen any doctor be assigned to practitioners. It may now be said that all the important matters of the regulation of insurance practice have been settled, and that there remain only those minor adjustments which must be required where any attempt is made to control in any degree the relationship between fourteen thousand doctors and fourteen million patients, actual or potential.

Two other insurance matters, however, of great importance to the whole profession have emerged in the course of the year. They have reference not to the present conduct of the service, but to its development and extension. One is the question of the exercise of a control over medical benefit by the approved societies; the other is the provision and administration of specialist services for insured persons under the aegis of approved societies. With regard to the former it must be said at once that it is impossible for the profession to recognize such control in any form. It is believed, however, that this claim is not, in fact, advanced by the great bulk of responsible members and officers of societies, though it has undoubtedly been made by a few of the less thoughtful and restrained of the officials. The societies are, of course, interested in the proper working of the insurance service, and therefore, like others, have the right to be heard by the Government department concerned; but the term

of the contract under which the profession agrees to give its services to the State must be arranged without the intervention of any third party. The Insurance Acts Committee is calling a conference early in 1923 to which representatives of all classes of approved societies, of Insurance Committees and their clerks, and of the pharmacists are being invited, and it is hoped that at this conference it will become evident that while all those represented sincerely desire to contribute to the efficiency of the service and its harmonious working, there is no wish on the part of any section to usurp functions which do not properly belong to it.

A beginning in the provision for the services of specialists for insured persons has been made during the year in two directions. If when a regional medical officer is consulted he wishes to have further help of a special kind this is to be available at the provision of the Ministry of Health. It is believed that this arrangement has not as yet matured, but it is obviously of great importance that the profession should watch carefully the method by which and the terms on which the services of such consultants are obtained. The funds of a number of approved societies, after valuation, have enabled them to provide certain "additional benefits"—such as ophthalmic benefit—for their members, and these remain under the administration of the societies so long as they take the form of a contribution to the cost of obtaining the particular service in question and not the direct provision of that service. It is unsatisfactory that additional services, whether those of nurses, dentists, or surgeons, should be available for a portion only of the insured population, and should be administered piecemeal by societies and not by public bodies. Serious difficulties are already arising, and here too the profession must watch carefully the narrow line which divides "contribution to cost" from "provision of treatment"; and those members of the profession who are approached to give such treatment should assure themselves as to the propriety of acceptance. The profession, no less sincerely than the societies, desires to extend the range of the medical benefit secured to insured persons, but the conditions under which this is brought about are of vital consequence, and every one, whatever his class of practice, should be prepared for united action.

INDIRECT ADVERTISEMENT.

BEFORE the General Medical Council brought its winter session to an end an interesting discussion took place on what has, for convenience, been called indirect advertising. The subject was raised by Dr. Bolam, who spoke from a sheaf of cuttings from lay newspapers collected during the last few months. Dr. Bolam's lucid and well documented statement convinced the Council, which unanimously resolved to instruct its Executive Committee to report on the expediency of amending its Warning Notice (No. 5) issued seventeen years ago.

The discussion is reported in the SUPPLEMENT, and it will be seen that Dr. Bolam, in his review of the situation, dealt with things old and new. Among the latter he instanced the insertion of announcement in the column of "Fashionable Intelligence," which in many newspapers follows the Court Circular. Sandwiched between announcements that a financial magnate has sailed for Mexico, and that a duchess has taken a new house in London where her new telephone number will be Westend 6000, we learn that Dr. C. has returned to 210, X Street, and that his telephone number is unaltered (Westend 4000). The announcement may be less crudely phrased, but, however ingeniously worded, it is an advertisement and is paid for—usually at a special rate. This sort of thing

is not new, but we seem to be suffering from a recrudescence just now. Then there is the habit of writing letters to the lay press on some disease or epidemic in which the public happens to be interested at the moment. This also is not new, and such letters may be quite useful, but they come under suspicion when the writer appends to his name a string of diplomas and his address. There is more novelty in the publication of interviews and the like, sometimes illustrated by a portrait of the interviewee, and in the appearance in a series of lay journals of articles by the same hand on some specific medical subject about which the writer implies or asserts that he has had an extensive experience. These things are no doubt to be associated with the curious revival of "personal journalism" we are witnessing. In this the newspapers of to-day are coming to resemble those of a century ago, with this difference—that the personal articles then were often scathing criticisms, whereas now they are usually laudatory and only injure the person mentioned when the latter is clumsily spread or is laid on too thick. The discovery by the reporter of the Harley Street specialist dates back some ten or twelve years at least, and the average reader was at first mildly curious to know how it happened that the eminent one always lived in Tennyson's "long unlovely street" and never in the square at the bottom, or in one of the adjacent thoroughfares. After a time the more intelligent or the more cynical began to say with Mrs. Betsy Prig, "I don't believe there's no such a person," or to suspect that he had been gathered to his fathers, leaving behind him a textbook convenient for reference; this theory seemed to find support in the somewhat antique character of some of the oracles. But the reporters had a ready retort, declaring, in the words of Mrs. Gamp, that such a doubter was a "bago creetur," and that it was simpler to use the telephone than to search a medical work of reference containing many terms with which they were unfamiliar. There was a simplicity, as of Brother Juniper, about all parties which rendered the plan almost innocuous, and the average man might even find that the thunders of his morning paper gave to the dishes he consumed at dinner the added zest of the forbidden.

But after a time His Eminence of Harley Street began to pay on the public; like Launcelot Gobbo's father, he "did something smack, something grow to—he had a kind of taste," and the reporter, being a man of resource, set out to search for a substitute; he found it quite easily in the interview. He may have remembered how Mrs. Gamp, who was a famous practitioner, though she did not live in Harley Street, when she repelled Mrs. Prig's bragging words, appealed to Mrs. Harris's "own sweet picture hanging up afore you all the time." So we may suppose arose the illustrated interview.

There is no reason why the editor of a lay paper should not get good articles written for him by authorities who really know what they are writing about. It is one of the advantages of anonymous journalism, upon which the press has flourished in this country and indeed in most countries (the signatures in French newspapers, except in the case of politicians, are mostly pseudonyms), that the anonymity makes the editor and his assistants more fully conscious of their responsibility towards their readers.

The task before the Council is not quite easy, and it is annoying that the tactless self-seeking of a few should have compelled it to be undertaken. The Council will be anxious to do nothing to hamper the discharge of the obligation under which the profession lies to inform the public of the progress of knowledge with regard to the prevention of disease and the preservation of health. Dr. Bolam touched on this aspect of the matter when he said that it was a man's right and duty (and

a woman's also) to take part in public work; he went on to point out that the degree of publicity necessarily attending such work need not, and with the high-minded did not, lead to the advertisement of the individual in his professional capacity.

THE FIRST FOULERTON PROFESSOR.

It may be remembered that last July the Council of the Royal Society announced that it had created a Foulerton Research Professorship, and that the duty of the professor would be to conduct such original researches in medicine or the contributory sciences as were calculated to promote the discovery of the causes of disease and the relief of human suffering. At the anniversary meeting of the Royal Society on November 30th the President, Sir Charles Sherrington, announced that Dr. E. H. Starling had been appointed the first Foulerton professor. The election, the President said, was "of happy augury for the success of the professorship. The fine work he has done is well known, not only to us of this Society, but to physiology and medicine throughout the world. As first Foulerton professor he is the distinguished forerunner of what we may hope will be a long line of distinguished successors in the Foulerton chair." In administering the emoluments the Royal Society would take advantage of the facilities of existing research institutions and endow selected workers wherever in those institutions they might happen to be, presupposing always the existence there of due facilities for their researches. The Society's research emoluments, therefore, did not compete with or tend to deplete existing research institutions, but to co-operate with and reinforce them. They did not withdraw the researcher from the university or other research institute to which he already belonged. "This dovetailing," the President continued, "with existing research appears especially important in its regard to the universities, because it affords help needed by the universities for the execution of research; and it seems a happy feature of the scheme that it assists research where that can be prosecuted in contact, so to say, with students, thus tending to promote research schools." Professor Starling will, we understand, continue to work at the Physiological Institute, University College, but by an arrangement between the College and the Foulerton Committee he will, after next summer, be relieved of administrative work and of the duty of teaching undergraduates, so as to give all his time to research and the training of men in research. The new laboratories at University College, with the extension to the physiological department, will be completed at the end of next term. May we humbly add our congratulations to the Royal Society on its choice. Professor Starling is one of the small band of men who have placed British physiology in the commanding position it holds throughout the world. Intellectually he is in the direct succession to the founder of British physiology, Sharpey, who in his teaching never failed to impress on his students that physiology is one of the institutes of medicine, and that though its fascination as a science might seem sufficient to justify its pursuit, it must ever have regard to the great part it can take in the advancement of medicine and in the promotion of the welfare of mankind. To few men can it have been given better to justify the position of physiology in this respect than to Starling; to him, for example, and his colleague Bayliss we owe the conception of hormones, which has had so profound an influence on medical thought and medical practice, an influence as yet by no means exhausted. We look on Professor Starling's work with that kind of gratitude which has been defined as the expectation of favours to come.

SUBCUTANEOUS VACCINATION.

The possibility of adopting, as an alternative to vaccination by scarification or incision, the subcutaneous injection of lymph by a hollow needle has received attention from time to time in recent years. In 1908 it was reported on in Germany,¹ to the general effect that immunity follows a

sufficient injection both in man and animals, but that unless a considerable reaction is produced immunity is uncertain. In India,² owing to a native practice of wiping off vaccine lymph from the skin, Fearnside and Poi injected hypodermically in four places. There was reaction, but no vesiculation unless the needle used had scratched the surface. In twelve cases the result was tested by application of lymph by surface scarification in the ordinary way, in every case with a negative result. The interval between the original operation and the testing is not stated. Subcutaneous vaccination on a very considerable scale has been practised by Dr. J. R. Goodall, Assistant Professor of Gynecology, McGill University, Montreal.³ In the army he used the method for about 6,000 troops, and for a number of children of officers. The skin of the arm was sterilized with iodine, and for each case about a half to three-fourths of a tube of lymph was used, with enough sterile water to make one cubic centimetre. A fine hypodermic needle was used, and the injection was made diagonally into the subcutaneous tissue. In a few cases it was unintentionally applied intracutaneously. In about 8 per cent. of the cases there was no reaction, and in these the operation was regarded as ineffective. In the others the reaction usually began on the second to the fourth day but was occasionally delayed until the twelfth or even the fifteenth. The reaction resembled that after antityphoid inoculation—local swelling, heat, tenderness, pain, and redness. In a few cases there was swelling and oedema of the elbow, and, in a very few, of the hand and arm. After the symptoms had subsided a hard nodule was left in the subcutaneous tissue for about a month. It is claimed in effect that subcutaneous injection (1) is a clean surgical operation; (2) involves no open wound nor dressing; (3) is attended by practically no risk of secondary infection (there was no case of infection in the 6,000); (4) has a high percentage of positive results (8 per cent. negative); (5) results in a very small percentage of complete temporary incapacity; (6) is comparatively painless; and (7) causes no difficulty with children, the operation being so quickly performed. Dr. Goodall does not mention whether he in any case applied the test of subsequent vaccination in the ordinary way. Perhaps he had no facilities for doing so, and may have relied on the twelve negative tests (after an unstated interval) reported by Fearnside and Poi in India. We hear that the subcutaneous operation has been adopted under the name of inoculation to some considerable extent in London in the case of ladies during the recent prevalence of small-pox. The news brings some misgiving. The production of a vesicle or pustule, resembling more or less that of variola, has commonly been regarded as essential to successful vaccination, and the extent of vesiculation—a total of half a square inch amongst four insertions—has been demonstrated statistically to be of value in respect of the duration of immunity. But the evidence of the worth of the subcutaneous method is as yet insufficient. As to immediate immunity, far more tests by subsequent scarification or incision are required. In the early days of vaccination the small-pox inoculation test and Bryce's test were applied on a very extensive scale in various parts of the world before testing was abandoned as needless. Also, as to the duration of immunity, it would be important to know whether many of the 6,000 troops and the children have subsequently chanced to be exposed to infection, and, if so, whether and how far they have succumbed. Possibly Dr. Goodall might give us the benefit of any experience he has had since the operations were performed. Science must always be prepared to accept new light, but the protection of humanity against small-pox is so tremendously important that the efficacy of subcutaneous injection of vaccine lymph should be proved very abundantly before being accepted as an alternative to a method the value of which has been demonstrated by the experience of a hundred and twenty years.

CALCUTTA SCHOOL OF TROPICAL MEDICINE.

The long-term session 1922-23 of the Calcutta School of Tropical Medicine opened on October 16th. There was keen competition for admission. Only fifty places could be provided and eighty candidates applied; they came from all parts of India. Of the fifty seventeen were sent by the Imperial and Provincial Governments, and thirty-three were independent practitioners. The course will last for six months, and at the examination with which it will conclude a candidate must obtain 50 per cent. of marks both in the written and in the practical examinations. The equipment of the school, which is of the most modern type, includes a large laboratory for experimental pharmacology, where work is being done on the investigation of Indian indigenous drugs reputed to possess therapeutic value. The Hospital for Tropical Diseases is continually full, the demands upon it being in fact in excess of the accommodation provided. The out-patient department, which was opened in 1921, is also full to overflowing and already needs enlargement. The facilities for research work at the school are limited only by the funds at disposal; although the public has given generous financial support it is insufficient to meet all the demands of a promising programme of research work.

THE CAUSATION OF INDUSTRIAL ACCIDENTS.

A REPORT (No. 19)¹ issued recently by the Industrial Fatigue Research Board contains two contributions to the study of accident causation. A preface by the Board itself affords an interesting introduction to the very difficult and involved problem discussed by Mrs. E. E. Osborne and Dr. H. M. Vernon, who describe observations they made on accidents in relation to temperature and other conditions at two large shell factories. The temperature was registered continuously for periods of nine to twelve months by means of thermographs, and at the same time the accidents treated at the surgeries were tabulated. Immunity from accidents was greatest at 67° F.; at lower temperatures their frequency gradually increased till at 52° they were 35 per cent. more numerous than at 67°. At a still lower temperature (47°) they fell off slightly, perhaps because the workers were too cold to work with their usual speed, so that there was a consequent diminution of accident risk. At temperatures above 67° the accidents showed a small rise in the women, but the men suffered 39 per cent. more accidents at 77° than at 67°, their greater liability being due, in all probability, to the heavier and more trying nature of their work. Considerable doubt exists as to the causation of the gradual rise in accident frequency which commonly shows itself in the course of the morning and afternoon spells of industrial work. It is usually attributed to fatigue, but Mrs. Osborne and Dr. Vernon bring forward evidence which indicates that under ordinary working conditions fatigue plays but a very small part. It is true that when the women at a shell factory changed over from a 61-hour week of work to a 39½-hour week their accident frequency, compared with that of the men, who continued on the 61-hour week, fell off some 25 per cent., but since the war no women are called upon to work 61 hours, and indeed very seldom more than 48 hours. The chief controlling factors in accident causation are speed of production and the psychical state of the workers. This latter factor is suggested by the accident incidence of the night-shift workers at the munition factories, for they showed a maximum liability to accidents when they first came on to work. They were then for the most part in a lively and excited state, but as they calmed down in the course of the night accidents gradually fell to half the original number. The unimportance of moderate fatigue as a factor in accident causation is suggested by the laboratory experiments described by Professor B. Muscio in the second part of the Report. When a test involving moderate muscular activity (the pendulum test) was carried out continuously for a period of three and a half hours the accuracy attained

improved throughout, though much more slowly in the latter half of the experiment than in the first half. There was no indication of loss of manual skill, such as might under industrial conditions have led to increased accident liability. Still, it is possible that if the test were continued for a longer time, and were repeated by other subjects, it might not always yield the result described. Another test (the aiming test) was tried at half-hour intervals during the course of the day; it showed a gradual increase in accuracy of performance during the morning, a relapse to minimum accuracy during the midday break, followed by another increase of accuracy during the course of the afternoon; but as the intervals between the tests were occupied with mental work it is doubtful whether the results obtained can be applied to continuous manual work.

HOSPITAL FINANCE.

A CONFERENCE arranged by the Federation of Medical and Allied Societies was held in London last week, to discuss the future financial stability of the voluntary hospitals. Lord Islington, in taking the chair, suggested that the hospitals should be relieved from certain public charges, such as local rates and legacy duties, and that contributions and donations should be allowed as a reduction for income tax purposes. Dr. Gordon Dill (Brighton), who opened the discussion, expressed the opinion that no reduction in the cost of voluntary hospitals could be expected, but rather an increase with the advance of knowledge. Though the voluntary hospitals were established for the benefit of the poor and necessitous, such persons now constituted only 25 per cent. of the patients. As they could not obtain them elsewhere the services of the hospitals were equally important and necessary to the remaining 75 per cent., who were not necessitous. The contributions from patients admitted to hospitals produced a large sum in the aggregate, but the average contribution did not amount to more than 12s. a week. The difference between what patients paid and what they cost was the largest item of hospital expenditure. The only way in which non-necessitous persons could pay for hospital treatment when it became necessary for them was by way of annual subscriptions during health. Beyond annual subscriptions, the ordinary income of a hospital consisted mainly of the proceeds from endowments and capital account, to which items of extraordinary income should be added. Dealing with the multiplicity and irregular distribution of the smaller hospitals, Dr. Dill, while admitting that hospitals for certain special diseases were necessary, raised the question whether the treatment of one particular organ of the body could not be as well and much more economically done at special departments of large general hospitals. A check should be placed upon the establishment of new hospitals without regard to the needs of the area. Much economy might be effected if hospitals would agree to make their out-patient departments consultative, except for the necessitous poor. All hospitals should strive for a closer agreement both on policy and in action. Viscount Hambleden (Chairman of King's College Hospital) agreed with Dr. Dill that there could be no finality in the expenditure of the larger hospitals, for the increase in size and number of special departments must go on. He thought that steps should be taken to encourage local practitioners to send patients to the out-patient departments; co-operation between practitioners and the hospitals would ensure a certain saving. United action was necessary, and the arrangement of the approved societies for the payments of contributions in respect of their members while in hospital was a step in advance. Payments by patients did not represent 50 per cent. of the increase in the present maintenance costs. The Hospital Saving Association was prepared to launch a scheme for the regular collection of small subscriptions, either weekly or annually, from persons who used the hospitals; he believed that the future of the voluntary hospitals depended upon the success of such a scheme could achieve, and upon the amount of co-operation which could be arranged between the hospitals.

¹ Medical Research Council: Reports of the Industrial Fatigue Research Board. No. 19. *The Causation of Industrial Accidents*. By Mrs. E. E. Osborne and Dr. H. M. Vernon. London: H.M. Stationery Office. (1s. 6d.)

Sir Arthur Stanley (Chairman of the Joint Council of the St. John Ambulance Association and British Red Cross Society) argued that if once the hospitals were divested of the elements of charity it would not matter whether the voluntary system were maintained or not. He commended the plan of the Hospital Saving Association. Mr. E. W. Morris (Secretary of the London Hospital) considered that it should be possible to reduce the expenditure much below the present cost, which was at the rate of £5 a bed a week. He thought that the scheme of the Hospital Saving Association was the only way in which voluntaryism could be saved. The alternatives were either to go back to disease, or for the State to take over the institutions. "Anything but the State," he said, "but the State rather than back to disease."

SOME OLD-FASHIONED REMEDIES.

SIR DYCE DUCKWORTH has contributed to the current volume of *Saint Bartholomew's Hospital Reports*¹ some notes "on the value and employment of some remedies now much forgotten or ignored." He sets forth in measured phrase his view that the medical scientist owes much to empiricism, and expresses his sympathy with the point of view of our ancestors, who, as physicians, pondered upon the effects of their remedies, and repented their practice without undue eagerness to publish the results. He pleads that the changes in our therapeutic measures should not be too rapid either for the sick or for ourselves. Probably there are few practitioners who will regard as forgotten such drugs as arsenic and mercury, or turpentine or valerian, of which Sir Dyce Duckworth recalls some of the uses. But not many of the younger generation are likely to have prescribed musk or sarsaparilla. The art of using these drugs has, says Sir Dyce Duckworth, been lost; but he has satisfied himself that musk has great virtues in the treatment of severe cases of pneumonia, while in his opinion sarsaparilla is a restorative tonic in cachectic conditions and anaemia, though Professor Syme regarded its value as no greater than that of so much hay. Rhubarb powder has promoted healing in severe bedsores when other applications have failed; and Sir Dyce Duckworth is pleased to find that the *mistura ammoniaci* is retained in the *Pharmacopoeia* as a remedy for bronchitis in the aged. He mentions the value of poultices and of leeching; and with diffidence, as referring to a surgical matter outside his duty, a protest is entered against the *nimia diligentia* of the modern dresser and nurse, who in the cause of absolute asepsis too often disturb open wounds and ulcers. There is a pleasant old-world flavour in these notes, comparable to that afforded by reading a book by Jane Austen after a hectic course of modern psycho-analytic novels, and the reader feels that he is in the presence of a physician who has studied the art of treating the patient no less than the disease. This volume of the *Reports* contains also biographies, with portraits, of Dr. Wickham Leggc, by "A. E. G." and of Dr. F. A. Bainbridge, F.R.S., and an essay on the life and works of Sir Astley Cooper (1768-1841) by Mr. Geoffrey Keynes.

THE GENERAL MEDICAL COUNCIL.

THE winter session of the General Medical Council occupied five days. It was an unusual session in that considerably more than half the time for which the Council sat was spent in camera. In little more than one morning and one afternoon the Council dealt publicly with eight disciplinary cases, adopted the reports of six committees, and transacted other business. For about thirteen hours it was concerned with one disciplinary inquiry in which the charges were of such a nature that it was decided, quite properly, to close the doors to the public and the press. The case appeared to arouse great interest among a certain section of the population of the East End, the neighbourhood in which the practitioner concerned carried on his practice, and the corridors and staircases were crowded with people,

some of whom, by listening at any chink that offered itself, failed to respect the privacy of the Council's proceedings. Eventually, through the firm action of the Registrar, the place was cleared, and when at length the Council reached a decision and announced it publicly, the galleries were almost empty, and there was no demonstration, although this had appeared to be brewing. A full report of the discussion on Dr. Bolam's motion calling for an inquiry by the Executive Committee into any action the Council can take with regard to the prevalence of oblique or indirect advertising by medical practitioners in the lay press appears in the SUPPLEMENT, and we have commented upon it above. It was a difficult question to argue, because the advertising complained of is subtle and might even not be obvious at a first reading. Moreover, Dr. Bolam felt himself to be under the necessity of not mentioning any names, either of individuals or of journals. Yet he was able, in a masterly speech which was listened to with interest in all quarters of the Council, to put forward his points with sufficient explicitness to make every member understand what precisely it was of which he complained, and how widespread the practice had become. The Council is accustomed to hear the pleading of some of the most distinguished legal advocates, but Dr. Bolam's speech was a model even to them of logical and restrained advocacy. He was ably supported by Dr. Macdonald, Mr. Turner, and Sir Jenner Verrall, as well as by one or two others, but the discussion as a whole was ill-proportioned to the introductory speedi because the Council was working under a time limit. If it had not been for the necessity of the closure another hour of extremely interesting discussion might well have been forthcoming on a matter of some public interest. The death of Sir Norman Moore cast a shadow over the proceedings of the Council. He was one of its best-liked figures. For more than twenty-one years he was the representative of the Royal College of Physicians of London on the Council. At the date of his resignation he occupied the position of treasurer, a place that is now to be filled by Sir George Newman. The news of his death was received while the Council was actually sitting, and though no extended eulogy was attempted it was evident that it came as a personal grief to the President and members. It had been noticed in recent sessions that his health was failing, but the members of the Council hoped that he had before him many years of retirement in which, as the President expressed it, he would find "health and fruitful occupation."

THE PRINCE OF WALES, having intimated his willingness to accept the Honorary Fellowship of the Royal Society of Medicine previously held by his father, was duly nominated and has been unanimously elected.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

The Committee of Medical Members.

THE medical members of the House of Commons inaugurated their team work in the new Parliament by a dinner in the House on Monday evening last. The members surviving from the last Parliament—Lord Dawson, Sir W. Whitla, Dr. F. E. Fremantle, Dr. Molson, and Dr. Elliot—were the hosts, although Lord Dawson at the last moment was unable to be present. Six other members completed the party—Dr. Chapple, who sat in the House from 1910 to 1918, Sir George Berry, Sir Sydney Russell-Wells, Sir John Collie, Dr. Watts and Dr. Salter. The three members absent were Dr. Molloy, Mr. Harvey-Dixon, and Dr. J. H. Williams. Dr. Fremantle was in the chair, and, in proposing the health of the guests, gave an account of the work of the Medical Committee in the late Parliament, referring with regret to their loss of Sir Wm. Watson Cheyne, Dr. Nathan Raw, Dr. Farquharson, Dr. Addison, Sir Robert Woods, and Dr. Macdonald. He sketched the work open to the new Committee in the present Parliament, the lines on which the members might co-operate, and the methods of making their procedure effective and comprehensive. He was supported by his fellow hosts, Dr. Elliot ending with a moving reference to the over-

¹ *Saint Bartholomew's Hospital Reports*. Vol. IV. London: John Murray, 1922. (Cr. 4to, pp. 180; 2 portraits.)

wholming responsibility of a member to his constituents for a share in the government of the whole State. All the guests replied in turn, each adding some original contribution and foreshadowing the divergence of view from Labour, Liberal, National Liberal, Unionist, and Unionist benches. The first meeting of the Committee will be held next Monday, when a chairman and honorary secretary will be elected. One matter of urgency was, however, raised: this was the proposed new regulation of the Nurses Council, whereby nurses or nursing home staffs would be precluded from registration, except such as had had at least one year's hospital training. It was thought this would act harshly, being against the spirit of the scheme under which a first register is made. Dr. Fromantlo, Dr. Elliot (who is acting as secretary of the group), Sir John Collico, Dr. Falter, and Dr. Chaple were appointed a Committee to make representations to the Minister of Health.

The Work of the Pensions Ministry.

The cases of some 700 ex-service men whose insanity is held by the Ministry of Pensions to be in no way due to the war, and who are therefore being transferred to the charge of boards of guardians, were, on November 29th, again brought before the attention of the House of Commons by Mr. Lawson. The argument was put forward that, according to the finding of the Departmental Committee on Shell Shock, normal men were subject to neurasthenia and hysteria from the very fact that they were taken into the army, and that therefore these men should be treated liberally. Mr. Lawson submitted that medical boards were placed in a false position in being called upon to say whether the mental affliction of ex-service men was or was not due to the war.

Major Tryon (the new Minister of Pensions) welcomed the opportunity of making a fuller statement than was possible in the exchanges of question and answer across the floor. He reminded the House that he was bound by the warrant brought in by a previous Government a good way back not to grant pensions for more than a year after the termination of the war to men whose disability was in no way attributable to the war. The Government could not, without fresh legislation, give compensation longer to men whose disablement was neither caused by nor aggravated by the war. Most of the 700 men had not been overseas at all, and the cases which had been put before him by Mr. Lawson were cases of men who had not been in the army in England more than two or three weeks. Some of these recruits, it was discovered, had been in asylums once or twice before. Major Tryon added, however, that he was going through every one of the cases himself, and was considering the whole question to see if any way out could be found in view of the general feeling in the House. But without legislation it was not in his power to grant pensions to anybody when the disability was not due to the war. Major Tryon cleared up one other point. Not only was aggravation of disability already existing recognized, but when the aggravation was found the State accepted the whole liability, though only a portion, strictly speaking, appertained to it.

The Minister next came to the larger cases of the Department, referring to the 6,000 men provided for in the hospitals by the Ministry. Of all the cases that had to be attended to none, he said, caused more anxiety than those presenting mental instability and neurological disorders. The Department had obtained the services of a large number of medical men to deal with the difficult cases of ex-service men who had lost their will power. The policy of the Department was to hold on to these men to the very last possible moment; it was not for him to say that the Ministry had broken the law, but it had gone to its utmost limit in order to keep these men out of asylums. When such patients were certified under the law they could no longer be kept in the hospitals of the Ministry and had to be passed into asylums. But they were treated as private patients like those who were paid for by their friends. That was the case with about 1,000 men in the asylums; they were men whom it would not be safe for their relatives to take out. In those cases in which relatives could be allowed to take out patients the same allowance was given as for disabled men. He thanked the representative of every party in the House who had served on the Departmental Committee which dealt with this question; also the ex-service men who had been members of the Committee. The Departmental Committee recommended that the Ministry should set apart a separate wing in each asylum for ex-service men, but as gradings were needed this would, Major Tryon explained, mean practically the provision of a miniature asylum in the wing if the ordinary practice was to be followed. The Government was prepared to go into the question whether one or two special hospitals should be established for ex-service men. Such hospitals would have to serve large areas, and there was the difficulty that relatives might prefer to keep their sick within easy reach of them.

Major Tryon staid in reply to a question that the approximate number of beneficiaries under the Royal Warrants for war pensions on October 31st last, was 2,620,000 as compared with 3,135,000 twelve months previously. The total estimate of the expenditure of the department for the current financial year was £89,991,000 as compared with an approximate expenditure of £95,545,000 for the year ended March 31st, 1922.

Taking up further questions from December 4th, Major Tryon said that it was not practicable at the present date to give detailed information as to the membership of the Medical Board who examined men on enlistment. It would be remembered that in the earlier stages of the war men were examined by a single civil practitioner.

Mr. Pielou asked, on December 4th, if the Minister of Pensions would arrange that all doctors on tribunals should be independent, and not doctors transferred from the Ministry of Pensions. The Attorney-General (Sir Douglas Hogg) replied that all members of the Pension Appeal Tribunals, including medical members, were appointed by the Lord Chancellor and were quite independent of the Ministry of Pensions. To make service in the past under the Ministry of Pensions a disqualification for appointment would be to deprive the tribunals of some of the best available medical talent.

The Outbreak of Small-pox.—Major Boyd-Carpenter for the Minister of Health on November 29th stated, on inquiry by Mr. Gilbert, that cases of small-pox had occurred during the year in fifty-six districts outside London and in seven metropolitan boroughs. The number of cases discovered was 893; and the number of deaths 26. Of the cases discovered 278 had been vaccinated and 603 were either unvaccinated or showed no evidence of vaccination; in 7 cases there was no information as to vaccination. Medical officers of the Ministry had visited the districts in which cases had occurred in order to advise the medical officers of health. In reply to Mr. Frederick Roberts, on November 29th, Major Boyd-Carpenter said that the Ministry of Health had not issued any instructions or advice in favour of pressure being brought to bear upon persons to submit to vaccination. On November 30th he stated that in the London outbreak five unvaccinated children under 12 years of age had contracted the disease, and that three of them had died.

Public Health.—In answer to Sir W. de 29th, Major Boyd-Carpenter, on behalf of said that some indication of the amount of sickness of all kind amongst the employed population of this country was furnished by the returns of expenditure by approved societies on sickness benefit under the Insurance Act. The increase in the number of weeks for which benefit was paid in 1921 as compared with the previous year was 1.4 per cent. in the case of men, and 8.4 per cent. in the case of women. Many factors must be borne in mind in making a comparison between the figures for the two years and, in particular, the serious epidemic of influenza about the end of the year 1921. The material in the possession of the Ministry did not make it possible to state to what extent the increase might be attributable to unemployment and reduced wages, nor to give comparative figures for different parts of the country.

Administration of Insurance Acts.—Mr. Gould asked, on November 29th, whether the Minister of Health would set up a committee to inquire into the administration of the Insurance Acts, particularly with reference to the panel system. Mr. Gould sought "an exhaustive inquiry with the object of obtaining such recommendations as would confer the greatest benefit for those for whom the scheme had been designed." Major Boyd-Carpenter gave assurance that the Minister of Health would consider the matter.

Certifying Factory Surgeons.—Mr. Robert Young asked, on December 5th, whether to ensure confidence in a doctor acting as certifying factory surgeon steps would be taken to prevent such doctor acting also at the same time in the capacity of compensation doctor for firms in the same area. Mr. Bridgeman said it would not be possible to lay down any general rule on the subject, because in industrial districts it was often difficult to find a well-qualified man who did not hold some appointment in connexion with employers or associations of workpeople. The consideration was, however, borne in mind in making appointments, and the Department was always prepared to inquire into any case of grievances that might be brought to its notice. An appeal could be made from decisions of a certifying surgeon under the Workmen's Compensation Act to the medical referees appointed under the Act.

Voluntary Boarders in Mental Hospitals.—Mr. R. Richardson asked, on November 30th, if the Board of Control had addressed a circular to the medical superintendent of registered hospitals stating that voluntary boarders might leave after giving twenty-four hours' notice in writing; and if, seeing that according to the statute the hospital superintendent had no right to demand any notice from any voluntary boarder, the statement would be at once corrected. Major Boyd-Carpenter said that the circular was addressed to the resident licensees of licensed houses as well as to the medical superintendents of registered hospitals. Section 229(6) of the Lunacy Act, 1890, provided for twenty-four hours' notice in the case of licensed houses, and, although the Act was silent as to the notice to be given in the case of registered hospitals, it was, in the opinion of the Board of Control, reasonable to require the same notice. The circular suggested that the terms should be made clear to voluntary boarders on admission.

Defective School Children.—In reply to Mr. Groves, on December 4th, Mr. Wood said that Circular 1245, issued in January, 1922, conveyed a warning that restriction might have to be imposed during 1922-23 on expenditure on defective schools. Circular 1269, however, issued on July 5th, intimated that existing schools for blind children had been used to the full extent of their accommodation, and that no restrictions need be placed on the number of children sent to these schools by local authorities. The same arrangement applied to schools to open-air schools, and to schools for epileptic children.

THE MUNICIPAL COLLEGE, PORTSMOUTH.

NINETY-FIRST ANNUAL MEETING of the British Medical Association. PORTSMOUTH, 1923.

H.M.S. Victory at her old
moorings.

THE ninety-first Annual Meeting of the British Medical Association will be held at Portsmouth next summer under the Presidency of Mr. Charles P. Childe, F.R.C.S.; Senior Surgeon to the Royal Portsmouth Hospital, who will deliver his Address on the evening of Tuesday, July 24th. The sectional meetings for scientific and clinical work will be held, as usual, on the three following days; the mornings will be given up to discussions and the reading of papers, and it is hoped to follow again the plan found so successful in recent years of arranging afternoon demonstrations in connexion with the work of each Section. The provisional programme for the work of the Sections is being drawn up by an Arrangements Committee, consisting partly of Portsmouth and Southsea representatives and partly of members elected by the Council. The Annual Representative Meeting will begin on the previous Friday, July 20th. The last day of the meeting—Saturday, July 28th—in accordance with custom, will probably be set apart for excursions to places of interest in the neighbourhood. The preliminary note published below is the first of a series of descriptive and historical articles on Portsmouth and its surroundings which it is hoped will prove of interest to members of the Association. The Association last met in Portsmouth in 1899, under the Presidency of the late Dr. John Ward Cousins.

SOUTHSEA: PORTSMOUTH.

The last three Annual Meetings of the Association have been held in university cities, each of them having its own medical school. Portsmouth and Southsea cannot offer the learned and scientific attractions of these great *almae matres*. Southsea has not a medical school, but it is proud of its hospital, and it is proud of its municipal college. It also is proud in that it has been described as "the ideal South Coast health and holiday resort." The members of the Portsmouth Division are also proud that the Annual Meeting is to be held here and they offer a very sincere and hearty welcome to all their professional colleagues who can and will visit them in the latter part of July next. Southsea is one of the few British seaside towns that boasts of a perennial season, and it is unrivalled as a centre for land and sea excursions, and from

CLARENCE ESPLANADE, SOUTHSEA: THE JAPANESE GUN.

day to day it presents an unending variety of things to do and things to be seen. There are many fine and well-kept open spaces where outdoor games can always be had; there is golfing and fishing, swimming, yachting and boating in plenty. The climate is exceptionally even, mild, and bracing; extremes of temperature seldom occur; there is a maximum of sunshine, and the rainfall is not great, although there is a prevalence of westerly winds. There are splendid shops, good hotels and boarding houses, well equipped and up to date, well-appointed tea rooms and restaurants, theatres, music halls and cinemas innumerable.

Old Portsmouth and the dockyard have many historical and antiquarian relics to show, and relaxation after the scientific meetings can be found in many excursions to neighbouring spots of beauty and interest. The Isle of Wight with its charming hills, valleys, and villages is close at hand and easily accessible. Three cathedral cities can be visited—Winchester, Salisbury, and Chichester—as well as the grand old Abbey of Ramsey, beautiful in its perfect proportions, "harmony and music in stone." The New Forest also claims a visit to its stretching heaths of furze and heather, its grassy banks and broken glades, its fine and varied wooded parks with grand old timber trees, oaks of every size, great beeches, silver-elad birches, ashes, hollies, yews, and hosts of other smaller shrubs and trees with endless varieties of coloured flowers and mosses, countless swarms of bright and dull coloured insects, birds and beasts. From this forest came the oak that was used at Portsmouth to build the old ships of the "Royale Navie," the wooden walls of old England.

Portsmouth: Old and New.

Portsmouth town began its career at the south-west corner of Portsea Island, and has grown from a collection of a few wattle huts to a borough of a quarter of a million inhabitants. On the Isle of Portsea were at least three manors and several hamlets—namely, Portsmouth, Portsea, Landport, Southsea, Eastney, Fratton, Buckland, Copnor, Kingston, Milton, Great Salterns, and Hilsea. These have so developed and grown that they are now contiguous. Of this large and numerous family Southsea, though not the eldest, is by far the largest child.

Portsmouth was incorporated and made a borough by Henry I. The earliest charter in possession of the corporation is that granted by Richard I, and dated May 2nd, 1194. It begins "Richard, by the grace of God, King of England, Duke of Normandy and Aquitaine, Earl of Anjou, to the Archbishops, Bishops, Abbots, Earls, Barons, Sheriffs, Bailiffs, Ministers, and all faithful people of his realms,—Greeting: Know ye that we have received into our hand our Burgh of Portsmouth." The charter further gives permission to hold a fair each year lasting for fifteen days, beginning on

August 1st, to which all the King's subjects could come. Another privilege granted by this charter was the holding of a market every Thursday. For this charter the Burgesses had to pay yearly to the King's exchequer the sum of £18. King John also granted another charter, as also did King Henry III. Other privileges were granted in 1600, and again in 1627.

By the Local Government Act of 1888 Portsmouth was declared a county borough in the Isle of Portsea. On November 9th, 1904, Hilsea, formerly in the civil parish of Cosham, was added to the Portsmouth County Borough, thus bringing the whole of the Isle of Portsea under one administrative body. And by the Portsmouth Corporation Act of 1920 the whole of the civil parish of Cosham, situated on the mainland, was added to the Portsmouth County Borough. The total area of the borough is now 8,035 acres of land, and its population totals just over a quarter of a million.

Portsmouth has a court of Quarter Sessions, recorder, and coroner, and Petty Sessions are held daily at the Town Hall. The borough was represented in Parliament in 1295. Now under the Representation of the People Act, 1918, the parliamentary borough, which has the same boundaries as the county borough, is divided into three divisions, known as the North, Central, and South, each division sending one representative to Westminster.

Means of Approach.

The train service to and from Portsmouth is good—much better than it was—but there is still much that might be improved. The London Brighton and South Coast Railway and the London and South-Western Railway run frequent trains direct from their London termini to their conjoint stations in Portsmouth. There are three stations on Portsea Island. The first after leaving Cosham on the mainland is Fratton, and here most of the passengers for East Southsea alight. The second or central is Portsmouth Town Station, and is situated in Commercial Road. This is the terminus for many trains, but some pass on by the high-level line to Portsmouth Harbour Station, facing the Hard at Portsea. From here the Isle of Wight is reached by the Conjoint Railways' Boat Service.

On other lines, through carriages are run from the Midlands via Basingstoke, from Cardiff via Bristol and Salisbury, and from Plymouth via Exeter and Salisbury. Brighton and Bournemouth are also directly connected by rail.

There are also good road approaches for motorists. The old London and Portsmouth road, through Guildford by Hindhead and Petersfield, is generally in very good condition. This road was well known to Charles Dickens, who was born in Portsmouth. Nicholas Nickleby and Smike tramped the old Portsmouth road and entered Portsmouth by the old Landport Gate.

Naval Dockyard and Harbour: H.M.S. Victory.

Portsmouth possesses the largest naval dockyard in the world, and its harbour is the home of the British fleet. To write a history of Portsmouth would be to write a history of the British Navy, and to write the history of the British Navy would be practically to write the history of the British Empire. For many years the most conspicuous object to be seen in the harbour was H.M.S. *Victory*, Nelson's famous flagship at the battle of Trafalgar, October 21st, 1805. She used to ride at her moorings in mid-stream, a thing of beauty and a joy, a revered relic of the old wooden line of battleships which gained for Britain the glorious victories of the last century. Alas! owing to the decay of her keel, ribs, and timbers below water-line she has had to be docked. She has been thoroughly surveyed and overhauled and placed in dry dock by the Admiralty. Here, propped up in her iron cago, she may yet be visited and a holy pilgrimage made to "the spot where Nelson fell"; to restore her, large free-will offerings will be required from those who treasure her great traditions. The harbour and the Solent are always alive with craft. Super-dreadnoughts, torpedo boats, and submarines are constantly passing to and fro, always ready to obey the slightest call of Empire's duty.

Amenities of Southsea.

The large residential part of Portsmouth known as Southsea has a long sea front facing the silvery Solent, which separates it from the Isle of Wight, and between the terraces of houses and the Parade is a large open common, where there are plenty of sea breezes and a maximum of sunshine, which has justly earned for Southsea the title "sunny"; 2,065 hours of sunshine were registered by the Campbell-Stokes recorder for the year 1921. The greatest amount registered in one day was 15 hours 20 minutes on June 28th.

The common provides a glorious playground a mile and a half long between the two piers, and practically, except in name, there is a continuation of this open space for another three miles on past Eastney to Hayling Ferry. Between the common and the sea is a good road and a fine promenade four miles long, and along it in different sections can be found something to appeal to every phase of holiday mood.

At the west end of the promenade is the Clarence Pier, a place of call for the railway company's boats when crossing to the Isle of Wight, and a centre for steamboat traffic to Southampton and Bournemouth. On the pier is a concert hall capable of seating over 2,000 persons. The stretch of beach from here to Southsea Castle is always full of life—hundreds of visitors and children, boaters, bathers, and paddlers, Punch and Judy, concert parties, conjurers, photographers, and the old veteran with his telescope, all help to make an animated and over-moving picture. On the esplanade near the Clarence Pier will be found the old anchor of the *Victory*, and many other objects reminiscent of past wars. Well to the east, about halfway along the promenade, is the South Parade Pier, the property of the corporation. It was opened in 1909 and replaces an older structure destroyed by fire in 1904. The pier is 600 feet long, exclusive of the landing-stage. It has a large pavilion with a stage for concerts and theatrical plays, a minor hall, and an out-of-doors bandstand. Here are often heard the finest military bands. Amusement is always to be found on the pier and on the beach by its side. On the pier concert parties, theatrical parties, and other entertainment parties are always in evidence. Steamboats start from the landing-stage for Ryde, Cowes, Sandown, Shanklin, Ventnor, Sea View, and Bembridge. Beaulieu may also be visited from here, and sometimes Brighton, Bournemouth, Weymouth, and Cherbourg. Close by the pier is the canoe lake and garden, where tennis, croquet, and bowls can be enjoyed.

The View from the Castle.

Between the two piers stands Southsea Castle, originally built by Henry VIII, but strengthened and enlarged in the reign of Charles II. It is from this castle, situated to the south of Portsmouth on the sea, that Southsea is supposed to have taken its name. It is a place of considerable importance, because any vessel wishing to enter Portsmouth harbour has to approach close to the coast at this point—if friend the castle lighthouse will be its guide, if enemy the castle's heavy guns would speak with no uncertain sound.

In front of the castle is a magnificent view. Gigantic liners, battleships and cruisers, fussy torpedo boats, submarines, waterplanes, motor boats, barges, and sailing yachts are constantly passing to and fro, and four miles

away across the silvery Solent lies the Isle of Wight with its beautifully wooded shores rising from a silvery sea, running upwards and backwards towards the great down. Soldam does a town look prettier than Ryde as we see it from the sea: Sir Gilbert Scott's spire of All Saints' Church crowns the hill in the background; all the other buildings are unobtrusive, and the splendid woodlands on either side blend with and fade into the town itself, making a charming picture. Looking towards the east we see Sea View and Bembridge, with its Ledge and Lightship, and farther on out at sea one of the mystery towers. Towards the west the towers of Osborne are often visible.

From our vantage ground in front of the castle we are looking on the world-famous anchorage, Spithead, where Britain's fleets have anchored for centuries. From here they have sailed to fight the glorious battles that have helped to make the British Empire what it is. From this very beach Nelson embarked when he sailed on the *Victory* to fight at Trafalgar, and from Spithead the Grand Fleet sailed away in August, 1914, to its unknown destination.

For the loan of the two larger blocks we are indebted to the courtesy of Messrs. Charpentier, Ltd., Portsmouth.

INSULIN AND DIABETES.

ADDRESS BY SIR CHARLES SHERRINGTON, G.B.E., PRESIDENT OF THE ROYAL SOCIETY.

SIR CHARLES SHERRINGTON, in his presidential address at the anniversary meeting of the Royal Society on St. Andrew's Day (November 30th), made the following references to the action of insulin and its possible use as a therapeutic agent in diabetes mellitus:

"In the Physiological Laboratory of Toronto University has been prepared a pancreatic extract possessing striking power over the carbohydrate metabolism of the body.* Potent as it is, experience with it is still limited. Work of urgency is required with what may prove to be a desired remedy; the first programme is further investigation of the extract's full properties, with caution as to raising hopes which practice may but partly fulfil. Such are the considerations which weigh with the Canadian—and the discovery is Canadian—university to whom the discovery is due. In this country the Medical Research Council has undertaken public-spirited direction of the extract's preparation and of further determination of its properties.

"The physiological steps of the discovery may be briefly outlined thus:

"Destruction of the pancreas is well known to produce in the dog a diabetes-like condition, rapidly fatal. The liver's store of glycogen is lost, and cannot be renewed by even liberal supply of its normal source, carbohydrate food. Sugar formation from proteins ensues, with rapid wasting of the tissues; at the same time the blood is surcharged with sugar, and the tissues are unable to make use of sugar. In a normal animal, glucose put into the circulation raises the ratio of CO₂ expired to oxygen absorbed, because the tissues consume the sugar. But glucose similarly introduced into the de-pancreated diabetic animal does not raise the respiratory quotient; the tissues no longer consume the sugar.

"The inference has long been that the pancreas produces some substance enabling the body to make use of sugar—some substance that in fact should control certain forms of diabetes. At Toronto there seems to have been secured the extraction of that substance.

"The pancreas consists of two structures intimately mingled: the one, secreting cells set round ducts into which they pour the pancreatic juice, potently digestive; the other, scattered in tiny islets seemingly unrelated to the ducts though closely related to the blood channels. The want of success of pancreatic extracts in mitigating a diabetic condition might be due to digestive powers of the juice cells destroying an antidiabetic substance of the islet cells. Dr. F. G. Banting determined to avoid this possibility by preparing extracts made from the pancreas after its trypsin-yielding cells had been selectively brought to atrophy by ligation of the gland ducts.

"He and Mr. Best, a collaborator who joined him, overcoming formidable difficulties of technique, succeeded in preparing the required material, and in examining the effect of

* A paper by Professor Macleod of Toronto on Insulin and Diabetes, containing a general statement of the physiological and therapeutic effects of insulin, was published in this JOURNAL on November 4th, 1922, p. 833.

extract upon diabetic dpancreated dogs. They found the sugar fall both in the blood and urine, and that the animals, instead of dying in three weeks, remained, while treated, in excellent condition. The further prosecution of the work subsequently engaged other collaborators; to mention them in alphabetical order, Collip, Hopburn, Litchford, Macleod, and Noble; of these Professor Macleod, himself Director of the Toronto Physiological Laboratory, is well known as a skilled authority in experiments on carbohydrate metabolism, and Dr. Collip is Professor of Bio-Chemistry in the University of Alberta, though temporarily working at Toronto. With team work advance has proceeded relatively quickly, and successful extracts are now obtained from ordinary ox, sheep, and swine pancreas.

"Of much physiological interest is the fact that the active principle in the extract seems one normally controlling the blood sugar in health; its injection rapidly lessens the blood sugar in normal animals. The extract, added to a simple perfusion fluid containing a little glucose and streamed through the isolated rabbit heart, increases three- or four-fold the heart's uptake of sugar from the fluid. The extract sometimes evokes serious nervous disturbances seemingly associated with extreme fall in the amount of the blood sugar. Administered to diabetic dpancreated animals, the extract brings reappearance of the liver's glycogen store, while bringing down the sugar excess in the blood and the excretion of sugar and acetone in the urine; and it enables the diabetic organism to consume sugar. It also lessens or prevents hyperglycaemia produced in animals in several other ways. Gratifying success has already attended the use of this extract in the relief of diabetic patients; much further research is, however, yet needed for development of the methods of extraction and of the routine use of the active principle.

"The important physiological advance thus just reached comes as a fit reward to those who have achieved it. It is, of course, the striking crowning of steady work pursued by many various workers through many earlier years. Such work, we may remember, lay often open to charge by the unenlightened of being merely academic and fruitless, its reward being at the time simply the intrinsic scientific interest of the facts obtained. The Toronto investigators, we may be sure, would say with Pasteur, 'To have the fruit there must have been cultivation of the tree.' Part of the merit of the recent successful investigation has been its appreciation of possibilities indicated by previous work. But that merit is after all only a preliminary to the main achievement. The actual achievement is the deserved success of a bold attack conducted with conviction and determination, and carried through in the face of formidable experimental difficulties. High praise is due to Dr. Banting and Mr. Best and to their collaborators."

Paris.

[FROM OUR CORRESPONDENT.]

Statistics of Students in Paris.

THE University of Paris has just published the comparative statistics of students who were matriculated on July 31st, 1921, and on July 31st, 1922. In 1921 they reached a total of 21,185, of whom 17,993 were men and 3,192 women. In 1922 the total rose to 21,612, of whom 18,066 were men and 3,546 women; taking both sexes together there was an increase of 427. In the Faculty of Medicine the roll of male students has diminished by 302, but that of women has increased by 55. At present there are 4,639 medical students, of whom 738 are women. Of the total, 811 are foreigners, 113 less than in the previous year. This appreciable diminution is due to the conditions of exchange which affect Central Europe. Countries with a high exchange only exceptionally send us matriculated students who follow our regular course of study. It is unnecessary to look beyond the explanation of the fact mentioned in my last communication in this JOURNAL (November 4th, 1922, p. 891) to understand how it is so few English medical practitioners have a legal right to practise in France.

Dr. Alfred Martinet.

The death is announced of Dr. Alfred Martinet. He was a unique figure, a man so great that it can truly be said that his fame extended far beyond the frontiers of his own country. He was born in Paris in 1868, of a family in less

than modest circumstances, and was reared in the stern school of poverty. He began life as a clerk, and was afterwards a teacher. His leisure was devoted to the study first of mathematics, then of medicine, which had an irresistible attraction for him. He began his medical studies at an age when his contemporaries were finishing them, but his inflexible will surmounted all obstacles, and it was in teaching others what he himself had just learned that he gained enough to make it possible to start practice in a northern district of Paris. There for some twelve years he worked in obscurity—his only recreation to bring his observations to a definite point and to drawing conclusions from them that he could summarize in plain terms. The publications in which he placed them before his colleagues were clearly written and as full of common sense as of science; such were his books on drugs in common use, common diets, arterial pressure, and the viscosity of the blood. What characterized Martinet was, on the one hand, his system—a veritable Taylorization of medicine—and, on the other, his ambition himself to play the part of the specialist in his own consulting room, whether the question were one of chemistry, radiology, bacteriology, or the examination of the heart. His system and its results are set forth in his principal works, *Les Elements de Biométrie*; his treatises on clinical therapeutics, and above all, that on clinical diagnosis, which was translated into English (in America) and into Spanish. One day Martinet awoke to find himself famous; the Faculty of Medicine gave him the opportunity of conducting an open course of lectures, and students and practitioners struggled for places. At the same time his private practice increased enormously, and the consulting room of a suburban practitioner became as that of the leading consultant in Paris. Patients flocked to him from all over the world, until Martinet was unable to cope with their number. He remained perfectly unassuming, caring neither for honours nor for money. His whole life was in his art. He can be reproached for one thing only, that he did not apply his own system to himself and did not recognize the limit of his strength. He is dead, stricken down in the midst of his work, his death due to the greatness of his exertions. A great brain has ceased to function, and the work that he leaves us as a legacy yields place only to the example that he gave us.

The Academy of Medicine.

Why have you not an academy of medicine in London? These *compagnies* have an indelible charm; tradition finds in them a last refuge, and memories of the masters who are no more give to the discussions of the present day a sense of permanency that helps us to understand that art is long and life is short.

At its last meeting the Académie de Médecine returned to a question which has been under discussion since 1849—the relation of tuberculosis to pregnancy. Professor Bar asked whether it was justifiable to interrupt pregnancy when the woman was suffering from pulmonary tuberculosis. After a methodical examination of the problem he came to the following conclusion as a guide in practice: "If I find in a patient not far advanced in pregnancy only a slight cutaneous reaction to tuberculosis, while the state of the tuberculous lesions is such as should leave her strong enough, my inclination is towards intervention." Let it be noted that M. Bar is a professor of obstetrics, and that we are not accustomed to find the obstetric wind blowing from that quarter. Let us also listen to Pinard! There he is on the platform! A fine young old man is honorary professor Pinard, who has just carried from his professorial chair to the tribune of the Chamber of Deputies the enthusiasm which has made him the apostle of Life. "No," he says, "do not sacrifice to-morrow's seed. Take care of the tuberculosis and watch the pregnancy." And as Professor Sergent had declared, "My conscience does not allow me to sacrifice the mother to save what is still only a foetus. . . ." Pinard finds in his heart an eloquent apostrophe: "It is still only a foetus! Such language cannot be listened to without protest, for in these precincts the child, from the moment it is formed, has a right to the respect we owe to every human being. It is defenceless, small, and feeble, and on that very account ought more than any other being to be protected. It is only a foetus! How many times have I heard that horrible phrase!" And Pinard went on to point out that similar assertions will soon be found in the briefs and in the pleadings of barristers defending abortionists before a jury. "As for myself," he said, "I have never committed foeticide." Noble and beloved

master, your voice rose there to the height of your convictions! The question is serious. The public hears an echo of it in the daily press. It will go on so long as there are academies of medicine, for mixed up with the clinical problem is a question of conscience.

The Medical Society of the Hospitals.

At a few paces from the Academy is the little hall where the Société Médicale des Hôpitaux meets. The atmosphere here is quite different. Eloquence is not in fashion. To this society facts are brought, and the meeting consists solely of clinicians, the physicians and surgeons of our Paris hospitals. A curious discussion is here being thrashed out between Netter and Comby, two of the best known specialists in diseases of children. Netter defends the opinion of Bokay (1892) that chicken-pox and certain forms of herpes zoster are identical; Comby exclaims against an opinion he qualifies as *incroyable*. Netter relates instances of herpes following chicken-pox, other cases of chicken-pox following herpes, the latter observed in patients in bed and under observation, or in hospital in isolation wards; others again of nurses attacked by herpes, who transmitted chicken-pox to their nurslings, and one instance in which generalized chicken-pox developed in a patient on the fourth day of an attack of occipital herpes. Netter quoted the precise observations published by Dr. Elliott in the *Glasgow Medical Journal* in May, 1922. "Mere coincidences," replied Comby. But the eloquence of positive facts (not experimental, it is true) swept away negative arguments and recalled the epigram of a prisoner: "You bring here two witnesses who saw me; I can bring 2,000 who did not see me!"

Canada.

MCGILL UNIVERSITY, MONTREAL.

The new biological building, the erection of which was made possible by a gift of the Rockefeller Foundation, was formally opened on Thursday, October 5th, when Sir Charles Sherrington, M.D., F.R.S., Waynflete Professor of Physiology at Oxford and President of the Royal Society, was the chief speaker. Addresses were given also by Dr. Harvey Cushing, Dr. H. J. Hamburger (Groningen), and Dr. J. N. Coulter (Chicago). Representatives from other universities included Dr. Mendel and Dr. R. H. Chittenden of Yale, Professor J. J. R. Macleod of Toronto, and Dr. Simon Flexner, director of laboratories, Rockefeller Institute, New York. The degree of LL.D. was conferred upon Sir Charles Sherrington at the special Founder's Day Convocation.

War Memorial.—The memorial window given by the members of the teaching staff of the Medical Faculty in honour of three members of the staff who gave their lives in the war was dedicated on October 5th. It commemorates the life and work of John McCrae, Roland Playfair Campbell, and Henry Bridges Yates.

Medical Faculty.—Dr. George F. Armstrong, C.M.G., Professor of Surgery and Clinical Surgery, has been elected Dean of the Faculty of Medicine for 1922-23. The number of students enrolled in the Faculty for 1922-23 is 719.

Dental Faculty.—With the reorganization of the dental clinic at the Montreal General Hospital, McGill becomes one of the chief dental centres on this continent, with a clinic following in closer relation to hospital work than almost any other. The number of dental students registered for 1922-23 is 130.

Pathological Institute.—Ground has been broken for the Pathological Institute, which will be affiliated with the Departments of Bacteriology and Medical Jurisprudence. The building will be constructed of stone and will have three stories and a basement. There will be adequate laboratory equipment and facilities for all these three branches of medicine.

First Women Graduates.—The first five women to graduate in medicine from McGill received their degrees in June, 1922. Two out of the five competitive prizes offered were won by them: one, the Wood gold medal for clinical subjects, by Miss Jessie Boyd; and the other, the First Senior Prize offered by the Undergraduate Medical Society, by Miss Winifred Blampin for a paper on thrombosis. All have been given hospital posts, Miss Eleanor Percival and Miss Mary Childs going to the Montreal General Hospital, Miss Jessie Boyd and Miss Lillian Irwin to the Royal Victoria Hospital, Montreal, and Miss Winifred Blampin to the Women's Hospital, Philadelphia.

Scotland.

EDINBURGH ROYAL INFIRMARY.

THE annual general meeting of the League of Subscribers to the Edinburgh Royal Infirmary was held on November 30th. Mr. James Campbell, who was in the chair, said that it was to the credit of everyone concerned that the league had made such great progress during so difficult a period. The organizing secretary, in submitting the fourth annual report, said that £18,333 had been collected from the various groups of subscribers, comprising employees engaged in public works and business establishments, together with the staffs of schools and Government offices. Compared with last year's figures the contributions from Edinburgh and Leith showed a decrease of £116, but the country subscriptions had increased by £641. Unemployment and short-time working had had an adverse effect on voluntary contributions; nevertheless the individual membership of the league now stood at 67,000 for Greater Edinburgh and 18,000 for the country districts. It was hoped that in more prosperous times the annual offering to the Royal Infirmary might be not less than £20,000; to this would fall to be added the voluntary fund raised in a similar fashion by the miners and oil workers in the coal and shale areas of the district. Sheriff Crole said that the number of patients in the infirmary last year was 14,156, as against 13,600 in the previous year; the daily average was 876, and the highest number for any one day was 914. In the out-patient department 42,342 people had been treated—about 1,000 more than the previous year. Property had been bought in Grange Loan for the purposes of the new convalescent home, and upon one portion, of which possession had already been obtained, a department for female convalescents was being prepared. This was part of the scheme to which the money left by the late Mr. Ainslie for a convalescent home was being devoted; the interest on this estate had been accumulating for some years, and it now reached the figure of £600,000. This year the infirmary's finances would have a substantial balance to the good; it was estimated that from the workers alone £34,294 had been received in voluntary contributions. This year the expenditure amounted to £119,000; last year it was £133,000, so that there was a decrease of £13,500.

CHRISTIAN SCIENCE.

Dr. W. L. Reid presided at the meeting of the Glasgow Medical Lunch Club on November 30th, when the Rev. A. Boyd Scott, M.C., B.D., was the guest of honour. In addressing the members Mr. Scott referred at the outset to the close relationship between the minister and the medical practitioner, and said that in these days both were threatened and assailed as never before by common assailants. Several of these came under review, but in particular the lecturer dealt with the cult of M. Coué and his disciples and with the Christian Scientists. He gave a very complete and interesting exposition of the fundamentals of these two schools, which he regarded as foes alike of the minister and doctor, each of whom had enough to do in their daily round without the constant irritation occasioned by the insidious teaching and doctrine of such opponents. He pleaded for a closer bond between priest and practitioner in resisting the spread of these pernicious influences, and for a revival in the Church and the world of sane faith, and a more wholesome appreciation of the divine splendour of medical science. Dr. F. W. Martin expressed the pleasure and thanks of the members for the very able and interesting address.

GLASGOW VICTORIA INFIRMARY.

The report presented to the annual meeting of the court of contributors to the Glasgow Victoria Infirmary on December 7th pointed out that there was a deficit of £2,968 in the accounts as between ordinary income and ordinary expenditure. The ordinary income for the year was £41,754, and the ordinary expenditure £44,722, while the extraordinary income (legacies, special donations, etc.) was £41,855. The number of patients treated in the wards was 4,230, as against 4,348 in the previous year—a decrease of 118. The contributions received during the year from patients amounted to £770, as compared with £1,139 in the previous year—a decrease of £369. The Bellahouston Dispensary continued to render splendid service on the south side of the city, and at the convalescent home at Largs 556 patients were treated during the year.

Ireland.

PUBLIC HEALTH LEGISLATION NEEDED.

On the motion for adjournment of the Provisional Parliament Sir James Craig, M.D., President of the Royal College of Physicians of Ireland, received permission to raise a matter of importance dealing with public health.

Sir James Craig's Speech.

Public health conditions in Ireland, he said, were not all that they ought to be. Prevention was a great deal better than cure. Sanitation had already done wonders for the country within the last thirty years in preventing disease. There was now virtually no typhus fever in the country, and typhoid fever was also becoming extremely rare. Diphtheria had been robbed of nearly all its terrors, but no invasion of small-pox threatened. He congratulated the Local Government Board and its medical department on the efforts already made to secure vaccination at the seaports. He was not going to raise the question of the usefulness or otherwise of vaccination, but he would consider himself a criminal if he attempted to treat a small-pox patient without being himself vaccinated, or if he allowed a nurse to care for such a case without being vaccinated.

Under the Ministry of Health Act passed in England in 1919 an Irish council was formed with power to take such evidence as it wished from people interested in public health and to draft a bill. That council, which was a representative one, found that there were five or six bodies dealing with public health in Ireland, and its first recommendation was that some attempt should be made to co-ordinate these bodies. The Irish Health Council recommended that there should be centralization, and that it should take the form of a Ministry of Health. He would not press that at the moment, but would be content for the present with the centralization of the public health work under one ministry; he had no objection to the Local Government Board being in charge of all those services. The council recommended the nationalization of local systems. It suggested that the county should be the local unit, and should be made responsible for all the sanitary work in the area. The council had pressed for the appointment of a superintendent medical officer of health for the county, or group of counties, who should be absolutely independent of private practice, and for assistants who would do the minor work. Another recommendation was that the present dispensary doctors who were working under boards of guardians should be entirely detached from the workhouse system. There should be a district hospital or home in every district worked by those who represented the present dispensary doctors, and there should be district nurses who would assist in tuberculosis work, child welfare, and, perhaps to a certain extent, in school inspection work. It was felt that there should be a county hospital, with a first-class surgeon; this would necessitate the establishment of an Irish medical service, entrance to which would be gained by open competition. It would be necessary that the men in this service should be paid not only a decent salary but that there should be a chance of promotion. An effort should be made to secure proper attention for the insured, who up to the present had not been getting the attention they deserved. He hoped that in any future legislation the Local Government Board would continue to encourage the appointment of a local ladies' committee to employ and take an interest in the nurses in the district, and that they would get a subsidy from the funds of the Government to keep the work going. He hoped, also, that the Government would make use in the future of the institutions already existing for the training of nurses.

In conclusion, Sir James Craig asked whether the Irish Health Council was going to be continued or not, or whether the Minister for Local Government had in view the formation of a council on some such lines as those set out in its report. Was it, as a matter of fact, functioning at present, or had it been dissolved, or would an advisory Council be provided for in any future legislation? He had heard that a bill was being prepared, and he would like to ask whether that was so or not, and whether the bill was being formulated on the lines recommended by the council. He desired to ask the Minister whether it would not have been better to take a line from what had been done in other departments—namely, to form a committee or commission to bring this report up to date before he began to legislate. It would have been well had the Minister appointed a commission to give him advice as to the proper legislation required. Finally, if this bill was in process of preparation, he desired to ask the Minister, when it was prepared, whether he would give those interested in public health an opportunity of discussing it before it came before the Dail for consideration.

Other members having spoken of the urgent necessity for medical inspection of school children, the Minister for Local Government, in his reply, intimated that a beginning had been made to do some of the things which Sir James Craig wanted done. Something had been done in the way of centralization, as three of the four officers concerned with public health were now included in the Ministry of Local Government. The

abolition of the workhouses had separated the dispensary system from the workhouses. The question of State medical services would have to be further considered. The Public Health Council was in a state of suspended animation, but it was intended to have an advisory body of that kind. The bill which was at present being prepared would legalize formally the work of Poor Law reform carried through during the past couple of years. When it was passed the permanent legislation necessary for the reform of local administration generally, including other services as well as public health, would be considered. The question of the medical inspection of school children was under consideration. The inspection of barracks was a matter for the Minister of Defence; but if he were that Minister he would not allow the local sanitary officer to go near them. The army had its own doctors, who were just as anxious for the public health and for that of the army as any local doctor.

Correspondence.

THE TEACHING OF PSYCHOLOGY AND PSYCHOTHERAPY TO MEDICAL STUDENTS.

SIR,—In your issue of August 19th, Dr. R. Macdonald Ladell states, "I am rejoiced to read that at the recent meeting of the British Medical Association in Glasgow a resolution was passed by the Section of Neurology and Psychological Medicine advocating the addition of psychology to the student's curriculum. This marks a big advance in the right direction." There is, however, much to be said against it, and I regret that, as a university teacher of many years' standing, and one who has all his life been a close student of the nervous system, it has become my duty, in default of a blinder protest, to sound a warning note.

Before any such introduction is made into an already overburdened medical curriculum, university authorities should satisfy themselves on three points: first, what is it exactly that is going to be taught; secondly, what knowledge has the proposed lecturer of the histology, physiology, and diseases of the nervous system; and thirdly, who is going to teach it.

As regards the first point I do not think the members of my profession realize the amount of rubbish that is now disseminated as psychology. Let the following example suffice.

From the 367 pages of Varonadonck's *The Psychology of Day-Dreams* the following is selected, simply because it appears in the index as "Day-dreams, definition of." On turning this up we read:

"Day-dreaming as a process is a manifestation of the universal energy. If we now examine the day-dream as a product of affective thinking on the fore-conscious level we cannot deny it a teleological character. Like nocturnal dreams, day-dreams betray preoccupations with unsolved problems, harassing cares, or overwhelming impressions which require accommodation, only their language is not symbolic as that of their unconscious correspondents. Moreover, their end-representation is often of a more immediate and topical character. But they all strive toward the future: they all seem to prepare some accommodation, to obtain of the ego; in fine, they are attempts at biological meaning."

It is a relief to know that there is a meaning. Personally I had not suspected it.

On page 173 of Lny's *Man's Unconscious Conflict* we read:

"Not satisfied with the materialistic interpretations put upon dreams by Freud, Jung thinks that they have not merely a retrospective meaning, but have a meaning for the present and a value for the future. Freud is criticized by Jung for tracing too much of the dream back to the period of infancy, and to exclusively sexual causes. . . . Jung therefore sees in the dream not only a psychic product absolutely determined by preceding causes in the strictly scientific sense of to-day, but regards the dream as an aspiration toward a higher form of intellectual and spiritual life."

It seems almost too brutal to point out that many dreams are aroused in a brain from which sleep has removed the control of the outer cell lining, as the result of enteroceptive impulses coming in from a distended stomach or seminal vesicle, or proprioceptive impulses from the pressure of the bedclothes.

Aural Kolnai gives the case away on page 45 of his *Psychanalysis and Sociology*, when he says quite bluntly that psychoanalysts refuse to commit themselves to any physiological interpretation of the phenomena they investigate. He is also, apparently, an upholder of the ridiculous and indecent Oedipus complex, which he defines as "the usually

unconscious) desire of a son to kill his father and possess his mother."

As regards psycho-analysis the following extract will make it clear that the days of its utility to the medical profession are numbered. Baudouin says on page 187 of his *Suggestion and Auto-suggestion*:

"Everyone can verify the efficacy of the method" [that is, auto-suggestion] "for himself by applying it in minor troubles, thus ascertaining if he has grasped the correct procedure. You wish to stop a haemorrhage, nose-bleeding for instance? If this nose-bleeding ordinarily lasts a quarter of an hour, with intermissions, you should readily be able to secure the formation of a good clot and the arrest of the haemorrhage within two or three minutes. Attain collectedness, and make use of some form of special suggestion. You can place a watch in front of you and keep your eyes on the second-hand, having fixed a line in your mind when the bleeding is to stop. You ought to be successful; and if you fail, it will be because your method is still faulty, because you have overlooked some detail. In like manner, if you are subject to colds in the head which usually last a week, suggest to yourself that the trouble will pass over in four days. At a later stage you can forbid the catarrh to develop at all. You can dictate to an abscess the moment when it is to burst. Without any other treatment than auto-suggestion, you can cure pimples, warts, varicose ulcers, eczema."

And yet in the Middle Ages men were burnt at the stake for telling the truth.

It may be objected that the examples cited are from the writings—perhaps "wanderings"—would be a better word—of lay people. This is readily admitted, but it shows the extraordinary fantasies to which psychology may lead, and, what is worse, there are signs that this "sloppy thinking" is permeating the medical profession, and the time has come to ask the reasonable members of that profession to get back to nature. Get back to the natural facts of the nervous system. Let medical men who psycho-analyse dreams read their physiology first, and remember that dreams are more or less afferent impulses from enteroceptive, proprioceptive, and exteroceptive sources running riot amongst the cells of a brain where control has been removed by sleep, and that beyond the fact that a dream is a jumbled-up and disorderly manifestation of previously acquired afferent impulses, stored up in granular and short association cortical cells, it has no psychological significance whatsoever.

To the scientific study of the phenomena of mind there can be no possible objection, always provided it is based on a thoroughly sound knowledge of the nervous system, not only of man, but of vertebrate animals also, and this knowledge, this modern knowledge, the lay psychologist has not, nor does it appear that some of his colleagues in the medical profession are much better off in this respect.

From the luxuriant mass of verbiage in which the psychologist delights there occasionally emerge a few facts worthy of investigation. My experience has been that neurology can explain these facts better than can psychological speculation, and, as a university teacher, it is my duty to insist that those who are to teach psychology to medical students shall at least have an adequate knowledge of the functions and diseases of the nervous system, and that their theories shall accord with known facts.—I am, etc.,

RICHARD J. A. BERRY, M.D.

University of Melbourne, Sept. 29th.

PSYCHO-ANALYSIS.

SIR,—Dr. Steen's letter in your issue of November 18th (p. 998), in regard to cases of morbid fear, etc., is of great interest to me as I have treated many successfully by convincing their reason that their fear was unfounded and teaching them how to overcome it. This, of course, necessitates the consideration of the plan to be adopted in each case. For example, a young girl was brought to me at the outpatient department of St. Thomas's Hospital who had been unable to leave the house alone for some months. She was directed to go down the steps of the house into the street and return; she would, of course, see that nothing had happened; then to go five steps along the street and return, then ten, and so on. She came alone from Stoke Newington in a fortnight.

A patient, having a fear of contagion from contact with people in buses, etc., which was causing much depression and danger of losing occupation, after one interview remained quite well, riding in public conveyances quite freely.

I could, if space permitted, give many examples of very many forms of fear thus overcome, as well as examples of blasphemous thoughts, of illusions of hearing, etc., and should

be very pleased to try what I could do for the cases mentioned by Dr. Steen, if he would send them to me or allow me to see them.

It is of course necessary to keep at the case until you are quite sure that the patient is convinced, and it is necessary to know when this has been done; this requires much time at the first sitting. Cases of long standing, or of associated disease, or which are the prodromata of serious mental disorder, are in a different category. Simple uncomplicated forms of fear should not require so complicated and protracted a method of treatment as psycho-analysis or so questionable a procedure as the inducing of stupor.—I am, etc.,

Hamstead, Nov. 21st.

HENRY RAYNER.

SIR,—It is evident that so long as the protagonists of the "New Psychology" decline to discuss it in terms of physiology and logic they cannot be compelled to do so. At most the weakness of their position can be demonstrated and emphasized.

I have no desire to be discourteous, but must confess that it is rather difficult for me to accept Dr. Steen's explanation in your issue of November 25th. It seems extraordinary to attempt to discuss a biological problem with the proviso that we are not to use physiological terms. Dr. Hart's "little book" is merely an epitome of psycho-analysis, and when reading it the passage which Dr. Steen quotes struck me as giving the whole position away, if indeed the author aims at anything approaching a scientific position. Dr. Steen and I evidently differ as to interpretation of language and accuracy of statement, and in order to show my reasons for this assertion I quote in parallel columns from his two letters to you:

Letter from Dr. Steen, BRITISH MEDICAL JOURNAL, Nov. 14th.

"Asks how the intelligent student is to reconcile the fact of the consciousness with the fact of the unconscious. Dr. McBride, visualizes ideas as nerve cells and so on. No one will object to the vision if it does him or anyone else any good, but as he has no facts to support this signment of his imagination, he is theorizing in a demoralizing manner."

Letter from Dr. Steen, BRITISH MEDICAL JOURNAL, Nov. 25th.

"I am bound to reply, as I have to enter the protest that I have been misrepresented. The offending passage is: 'Ho [Dr. Steen] apparently believes that thought can occur without physiological nerve and brain activity.' I can assure your readers that I believe nothing of the sort, and furthermore I did not say so. I do not accuse Dr. McBride of willfully misquoting me, and I fancy I understand how he made the mistake."

Courtesy prevents my doing more than propounding to your readers the following questions: (1) What does your correspondent seem to believe and to have said? (2) Where is my mistake?

I hardly think that Dr. Steen's championship of psycho-analysis will have gone far towards establishing its claim to be scientific, and in this correspondence no one else has even attempted to do so. Perhaps your readers will draw their own conclusions. *Verbum sat sapienti.*—I am, etc.,

Harrogate, Nov. 25th.

P. McBRIDE.

INSULIN AND DIABETES.

SIR,—In his letter (November 18th, p. 997) Dr. Cammidge states that, since his experience has suggested that insufficiency of the internal secretion of the pancreas is the dominant factor in less than half the cases of glycosuria met with in England, one would expect that "insulin" would be useful in some such proportion of diabetics; it appears as if by this he would also incidentally mean that one would not expect that insulin may be useful in the rest of the cases. Even granting that Dr. Cammidge might be right in his opinion that pancreatic insufficiency is not the dominant factor in more than half the cases of glycosuria met with in England, I think that there is no strong reason why one may not expect that insulin, when properly administered, will be useful in any case of what is generally understood by "diabetes mellitus."

The published results of experiments by the Toronto team of workers on insulin show that the injection of a certain amount of this product to normal animals is capable of lowering their normal blood sugar content, and even of preventing the hyperglycaemia that, without the previous injection of insulin, would be elicited by different experimental agencies, such as Bernard's puncture of the floor of the fourth ventricle, injection of adrenalins, inhalation of

other, etc.—that is, those experiments show that insulin is capable of causing a certain amount of sugar to disappear from the blood, or of preventing an increase of the existing blood sugar in cases in which neither the presence in the blood of the sugar that will be caused to disappear by insulin, nor the increase of blood sugar that would take place without the action of that product, have anything to do with an insufficiency of the pancreas.

Following the principles described by Collip to the extent allowed by the degree of correctness of my interpretation of them, and by the efficiency of the technical means at our disposal, small amounts of pancreatic extracts containing insulin were obtained at the Institut de Fisiologia de la Mancomunitat de Catalunya and its action was studied in one extremely severe case of human diabetes, in one experimentally diabetic dog, and in some normal dogs and rabbits. So far as the result of our experiments go, and in the light of some of the Toronto experiments suggesting that the sugar disposed of by the action of insulin is either stored as glycogen or katabolized by the tissues, producing an increase of the respiratory quotient, or both, one would say that it seems as if in all circumstances a given dose of insulin causes, within a certain period of time after its injection, a certain amount of blood sugar to be metabolized in some way or ways closely resembling, if not identical with, those of normal carbohydrate metabolism.

If we look at insulin as a pharmacological agent, possessing such a pharmacological action, and not as an extract of an organ that may have or may not have a causal relationship with a given pathological disturbance, it will be clear that we are justified in at least expecting as a possible thing that insulin may be useful in every case in which it may be desirable to lower the blood sugar content at a given moment, or to prevent its increase which would be produced by the ingestion of a given amount of certain foods, or to make a certain amount of carbohydrate, that would otherwise be wasted, follow the normal way of metabolism—that is, that insulin may be useful in every case of diabetes mellitus. It is clear enough that to *expect* is not the same thing as to *foretell* with assurance, and that to say that a remedy may be *useful* is not the same thing as saying that it will be *almighty*, nor even that its action is of a *cumtiro* nature.

The fact that, as Dr. Macleod has said and is recalled by Dr. Cammidge, insulin will be chiefly of value in tiding patients over those crises which are frequently uncontrollable by other means, does not mean that, if sufficient amounts of the product are available, it cannot be also of great use in other cases, as an agent to be used in combination with a proper dietary regulation. I would point, as very important, to the possible employment of insulin for the preparation of previously untreated or insufficiently treated diabetic patients for peremptory surgical interventions; and, as very interesting, to the possibilities opened in the dietetic treatment of diabetes by the fact that we may have at hand a remedy the occasional employment of which may enable us safely to administer in a given moment a certain amount of carbohydrate in addition to that which would be spontaneously tolerated by the patient at that particular moment.

On the other hand it must be recognized that, whereas it can be expected that insulin will make the dietetic treatment of diabetes a lighter burden to the patient and a more pleasant task to the physician, it will not eliminate the necessity of dietary regulation, and, very likely, will not even make it an easier task.

Dr. Cammidge is no doubt right in claiming against excessive optimism, such as that of those who speak of a curative action of insulin; but I think that it is not quite out of place to claim also against excessive pessimism, and to insist upon what reasonably can be expected of this new discovery, which, as many of the epoch-making points in the history of diabetes, is due to the genius and the labour of English-speaking practitioners and men of science.—I am, etc.,

R. CARRASCO FORMIGUERA,
Assistant at the "Institut de Fisiologia de la
Mancomunitat de Catalunya."

Barcelona, Catalonia, Nov. 27th.

SOME ARMCHAIR REFLECTIONS UPON INSULIN.

SIR,—The successful treatment of diabetes mellitus opens up new avenues for exploration. Some people are in the unfortunate position of being able to explore only one, but may gaze down others and say what they see. Some of the visions may be mirage.

The cost of insulin as prepared at present will prove prohibitive if made in London, unless wealthy diabetics are prepared to pay for the needy. How can insulin be reduced in cost? At present a dose needs half a pancreas of an ox and about three quarts of alcohol. It is true that much of the alcohol can be regained.

1. Insulin must be prepared in places where alcohol is very cheap and the pancreases of oxen do not demand high prices. I am told that in Durham alcohol is ninepence a gallon, whilst the pancreas of an ox can be bought for less than a shilling.

2. Improvement in the methods of extraction: (a) to extract more insulin from the raw material; (b) to reduce the cost of the extracting substances.

Before attempting to extract more insulin from the pancreases of oxen it would be wise to be certain that the yield by the patented method of extraction is not more than 80 per cent. of that present.

Some idea might be formed of the quantity of insulin made by the pancreas of an ox by estimating its blood sugar and then injecting intravenously a solution of dextrose in sufficient quantity to raise its blood sugar to half as much again and noting the rate of fall of the percentage of sugar in its blood. It is true that this method might lead to a conclusion that there was more available than it was possible to extract, because it seems likely that dextrose is the activator of the cells of the islands of Langerhans. No doubt experiments are being conducted to determine whether a better yield of insulin is obtainable from the pancreas of fasting or recently fed animals. Deducing from observations upon diabetes one would expect the best yield from an animal which had been fasted at least twenty-four hours, then fed with carbohydrate, and slain one hour later. If a recently fed animal proves to give a greater yield it will be necessary to attempt to estimate the increase, and determine whether that increase would compensate for the cost of the food.

One would not anticipate a large production by the pancreas of an ox, because oxen feed on grass, and therefore must obtain a very large percentage of their energy from cellulose. Cellulose is converted into an absorbable carbohydrate comparatively slowly, and therefore absorption is very prolonged. For this reason no large quantity of insulin is required at any moment. The pig which eats roots and nuts is more likely to possess a pancreas rich in insulin.

The fact that insulin prepared from an ox will act in man and dog makes it unlikely that it is essential for the action of the cells of the animal, but that it is a ferment which has as its function an action upon dextrose: it changes dextrose so that it can be stored or burnt. This leads one to hope that some other ferment much more easily prepared may be found to possess a similar property. Preparations are being made to test the zymase group in the laboratories of the London Hospital Medical College.—I am, etc.,

Portland Place, W.1, Nov. 27th.

O. LEYTON.

PERSISTENT EOSINOPHILIA WITH SPLENOMEGALY.

SIR,—I have been very much interested in the case published under the above title by Drs. Stuart McDonald and A. F. Bernard Shaw (November 18th, p. 966). With many other haematologists, I hope they will accept my compliments and thanks. They discuss certain comparable cases in the literature, but not all, and that is my reason for advertising to the subject. May I direct the attention of those interested to the case recorded in the *Lancet* of September 15th, 1894 (p. 627)?

The patient was a woman, aged 30. On December 25th, 1893, she was suddenly seized with acute abdominal pain. On January 2nd, 1894, an enlarged rotated spleen was removed. Her blood was examined two days later and the leucocytes found to be 10,000 per c.mm. From this date on until May 23rd, when she left hospital, the white cells continually increased. On the latter date they were 50,000 per c.mm. In a private communication the late Sir Edward Malins, who published the case, informed me that he last heard of her seven years after the operation and that she was then in good health.

In those days blood examinations were less detailed than they now are, but it is stated that there was nothing special to be noted about the white cells, other than their number, except on one occasion. On this occasion (more than three months after operation) "the most remarkable point was the presence in the blood of fairly considerable numbers of large white nucleated corpuscles, varying in diameter from 30 to 50 μ , in which were contained several red cells, in some twenty or more."

It was the remarkable avidity of the eosinophiles in the recently reported case which recalled the case of Malins to my mind. Although it may be more nearly related to that of Tsuchy, it is at least a case of splenomegaly with leucocytosis.

which presents analogies to those already mentioned, and to the cases of Stillman, Giffen, and Aubertin and Gironx. Moreover the case of Malins leads naturally to the mention of two other remarkable cases of splenomegaly and leucocytosis.

The first of these is that of van Nuyss. The patient was an adult suffering from aortic regurgitation and massive splenomegaly. The leucocytes reached 100,000, but during an attack of erysipelas fell almost to normal. In this case the peculiar cells noted by Malins were a constant finding, but they did not usually suggest red cells, apparently preferring leucocytes.

The second case is that of Bartlett, later reported very fully by Rowley. It was again the case of an adult male with heart failure and splenomegaly. The white cells reached 700,000, and not only were the cells described by Malins present, but all the white cells became at a later stage phagocytic for red cells and for each other. Moreover the diluted blood injected subcutaneously into a guinea-pig caused its white cells to go mad and eat each other, but the effect was not lasting and the animal recovered.

I have always regarded this as one of the most remarkable cases ever recorded, almost too strange for belief, but the authority of Malins and Mary Rowley is undoubted, nor can one question that of van Nuyss or Bartlett. Those who will be so good as to refer to the *Proceedings of the Royal Society of Medicine*, 1919 (Medical Section), xiii, pp. 1-21, will see that the analogies may be further expanded until one meets with the cases of Herriek, Washburn, Cooke, and Meyer, in which the spleen is not enlarged, and there are other interesting and characteristic features, but there is a constant leucocytosis with 5 to 7 per cent. eosinophiles.

It may perhaps appear that we have travelled far from the case of McDonald and Shaw, but yet there is undeniably a series of connecting links which suggest that an explanation of the pathology of these cases is to be found in the direction of the aebolic jaundice group rather than in that of leukaemia. It would be extremely interesting to know whether the plasma of McDonald and Shaw's case would produce any effect when injected into the blood of a guinea-pig. One feels that the eosinophiles in that case are doing their best to meet some demand. The fact that they are, *inter alia*, devouring red cells (a most improper activity for the eosinophile) suggests that their potentialities are increased rather than diminished as is usual in the indifferently finished cells of leukaemia. The further fact that in Herriek's case the red cells were (1) abnormal owing to a plasma defect which rendered even the cells of other persons similarly abnormal, (2) occasionally undergoing phagocytosis in the peripheral circulation, and (3) associated with a leucocytosis in which eosinophiles had a prominent part, would possibly suggest that further investigation of the serum in McDonald and Shaw's case might be well worth undertaking.

On the other hand, we must admit that if these cases are regarded as leukaemic in nature the literature again provides certain intermediate cases, or cases which might be considered intermediate. There is, for instance, the case of Simon, in which a fractured tibia that had become septic was associated with splenomegaly, 50,000 leucocytes, and 17 per cent. of mast cells. There is also a suggestive case reported by Coles in which eosinophiles very largely dominated the blood picture in a case which progressed to a typical myeloid leukaemia. But, generally speaking, the cases which might connect those of Giffen, Tuohy, etc., with leukaemia are of an acute transient character and are characterized by their symptomatic nature, while those which connect (at the end of the line) with haemolytic jaundice have far more the appearance of clinical entities. It is a peculiar fact that so many of them have been complicated with heart failure when first seen.

Should Drs. McDonald and Shaw care to follow out the train of thought I have suggested, I shall be glad to lend them (under bond and heavy penalties if not returned) copies of most of the papers herein mentioned. This will save them much wearisome search of the literature.—I am, etc.,

GORDON WARD.

Sevenoaks, Nov. 28th.

P.S.—References will be found in the paper in the *Proceedings of the Royal Society of Medicine* referred to above.

NON-MALIGNANT AFFECTIONS OF THE COLON (INTESTINAL STASIS).

SIR,—Is it not surprising that in the year of grace 1922 the colon should still be considered as maintained in position much in the same way as a pair of "shorts" pegged to a clothes-line, and that it should be supposed that its contents have to be

pushed up one limb against gravity, presumably falling down the other by their weight? Such is the impression I get from the report on the discussion on the above subject in your issue of November 25th. Thus, Sir Henry Gray states that the right and left borders of the omentum "tack" the hepatic and splenic flexures "to the abdominal wall or adjacent viscera." And Mr. Waugh says: "The exposure of the alimentary tract to the influence of gravity as the result of man's upright position has imposed upon it a strain unique in the animal world."

But is this tenable? I wonder how often the distinguished surgeons who participated in the above discussion have incised the abdominal wall outside the rectus in well-developed individuals, and how often they have noticed the thickness of the flank muscles in such individuals. I venture to ask them, What interpretation is to be put on the presence of these massive muscular sheets? Are the transversales abdominis—which collectively would be better called the *constrictor transversus abdominis*—with the individual in the erect posture, doing nothing? And is the thoracic diaphragm, a veritable *epigastric depressor* simply of respiratory significance?

Transverso section through the trunk in the frozen dead reveal the abdominal cavity all packed closely with viscera and visceral parts. In the living healthy individual, in virtue of the tonic and other contractions of the constrictor transversus abdominis and other muscles, these viscera are maintained closely pressed against each other even in the erect posture, in which, indeed (for circulatory reasons), the compression is greater than in the dorsal decubitus. The ascending colon is thus supported by the pressure of surrounding parts, and the hepatic and splenic flexures squeezed high into the lateral epigastric recesses. The compression resulting from the muscular walls of the container, in which is located the visceral mass, puts gravity out of court. During evolution, with the production of an equilibrium, the strain resulting from the erect posture is thus not on the gut, but on the walls of the container (the abdomino-pelvic cavity). Comparative anatomy shows how these musculatures have developed step by step with the increasing activity of the vertebrate, the most pronounced changes being found with the transition from the pronograde to the orthograde form. So also we see that when the well-developed adult stands up the lower abdomen does not pouch.

Intestinal stasis seems to me so buttressed up with un-anatomical, unphysiological, and unpathological reasonings that it is not easy to discuss. What will happen to it when these props are removed I do not know. That the whole structure of man is not considered I have shown. That unphysiological reasoning abounds seems to me indicated by the picture of the greatly elongated pelvic colon "puddling" in the pelvis, with many angles, offering "a great obstacle to the passage of solid material through it, since the more the individual strains to expel the bowel contents the farther is the flaccid gut driven into the lower limit of the pelvis" (Lane). Has the distinguished author forgotten that defaecation depends on peristalsis (which can smooth out angles even in the abnormal), and that in the absence of peristalsis, in health, faecal masses can only be expelled if located in the ampulla of the rectum, and even then only with the greatest difficulty?

That an unpathological element is present seems to me evident from the suggestion that morbid processes occurring in the colon arise irrespective of vital processes elsewhere. The relation of the visceral activity (which includes that of the excretory organs) to the tonic and other contractions of the musculatures enclosing the visceral mass and the rise of abnormal intestinal processes and the effect they have (directly or indirectly) on the enclosing musculatures are all unconsidered. But these perhaps are extremely important.

In the absence of definite intestinal obstruction, caused by organic kinks (due to adhesions), narrowing of the lumen (strictures), foreign bodies (intestinal gall stones), and of ulcers, etc., the yielding of the abdominal wall, as evidenced by its flaccidity palpable in the dorsal decubitus, and by a marked bulging of the lower abdomen when the individual stands, dominates, in my opinion, the pathological process. How such can be remedied by partial colectomy, colonic exclusion, or the other numerous procedures mentioned, seems to me inexplicable. I have seen only one patient who suffered a partial colectomy; and her opinion was that she wished she were dead.—I am, etc.,

R. H. PARAMORE, F.R.C.S.F.

London, W., Nov.

RED FATIGUE.

SIR,—Recently I read your editorial (of September 10th, 1921, p. 413) concerning Dr. Edridge-Green's important experiment on the white equation or the amount of pure spectral red, green, and violet required to match simple white. He finds that after red fatigue of 5 seconds only about half as much green is then required. If a myoid or muscular nature is assigned to the rods and cones his results are explained as due to residual tetanus or tone, an after-image effect of slight fatigue. The tone for red is prolonged and co-operates with the green to balance the violet and give the tone for white. To my mind it is ridiculous to regard the rods and cones as nerve elements; for their constant lengthening and shortening—or contracting and relaxing—would be grotesque and unheard-of behaviour on the part of nerve cells, though quite proper for muscle cells. With longer red fatigue the after-image would be complementary and this explains his other results. These solutions depend upon the myoid theory of vision formulated by me in 1919 in *Mental Biology*, Part IV (and published by F. W. Talbot, Cambridge). Dr. Edridge-Green rightly taxes the theories of Young, Hering, etc., for failing to explain his results.—I am, etc.,

Kandavu, Fiji, Aug. 30th.

WALTER M. COLEMAN.

CANCER OF THE SCROTUM.

SIR,—I read with interest the observations of Dr. Archibald Leitch (November 25th, p. 1047), with regard to the production of malignant disease in mice, by means of crude mineral oil products. I noted clinically the association of the disease with mule-spinners as far back as 1906-7, whilst house-surgeon for the late Mr. G. A. Wright. It may interest Dr. Leitch to know that some of our sections showed very little chronic inflammatory change, but marked proliferative changes in the deeper layers of the epithelium, suggestive of the action of some auxetic substance.

As regards the frequency of the disease, it would appear to be relatively common in South Lancashire, for since publication I have had communications from surgeons in other South Lancashire towns confirming the observations. It appears, however, to be a very rare disease in chimney-sweeps in this district.—I am, etc.,

Manchester, Nov. 27th.

S. R. WILSON.

LILLIPUTIAN HALLUCINATIONS.

SIR,—I was interested in Dr. F. M. Rowland's letter (November 18th, p. 999) on Lilliputian hallucinations, for quite recently this rarely described syndrome came under my notice during the early stages of a severe case of scarlet fever.

The patient was a young adult. On the second day of the fever he became delirious and continued so for four days. Prominent amongst the mental symptoms were hallucinations of the type described by your correspondent. The patient pictured vivid scenes, in which hosts of small people—men, women, and children in gaily coloured clothing—were the chief actors. Their many and varied activities appeared to be vastly entertaining. The most up-to-date mechanical appliances (all proportionally small in size) were used in their multiple undertakings. They worked noiselessly and were never heard to speak. Animals did not figure in the pictures. These hallucinations did not excite fear in the patient. For the most part he seemed interested and amused, always preserving a normal conception of persons and surrounding objects.

Occasionally giant types were described.

The patient made a good recovery and still retains pleasant memories of his sojourn amongst the Little People.—I am, etc.,

Caxton, near Cambridge, Nov. 20th.

J. C. HALL.

* Dr. J. W. Duncan (Hockley, Birmingham) sends us a note in which he mentions the case of a lady over 70 years of age, who recently complained to him of feeling giddy and of seeing little stars, like fire, all moving about.

DYSTOCIA DUE TO GIGANTIC FOETUS.

SIR,—The case of gigantic foetus reported by Dr. E. L. Moss on October 7th, 1922 (p. 643), is interesting, not only because of its rarity and the difficulty of diagnosis and treatment, but as a case helpful in throwing some light on the etiology of this condition generally, and also on the causation of "progressive enlargement of foetus."

As general physiological growth of the body is stimulated by a hormone from the pituitary, and pathological overgrowth, such as gigantism and acromegaly, is due to an excess of this endocrine, it seems reasonable to assume that in the foetus also both conditions—growth and overgrowth—are likewise brought about by analogous causes—namely, in the former by normal, and in the latter by an excessive, amount of pituitary hormone in the mother.

In support of this view let me quote from among others the case of Mrs. L., reported by me in the *South Africa Medical Record* (April 8th, 1922). I have attended her with babies weighing 12, 14, and 16½ lb. respectively; in her last pregnancy she developed the typical appearance of acromegaly, with glycosuria; the latter condition persisted.

In Dr. Moss's case we have also similar evidence of hypopituitarism: (1) in the marked overgrowth of the foetus; (2) in the greater degree of ossification of the bones (due to pituitary Ca retention); (3) in the manifestations of pre-eclampsia symptoms; of high blood pressure (160 mm. Hg), renal disturbance, and in the finding of traces of acetone and diacetic acid, all of which can be traced to hyperpituitarism (Karl, "Eclampsia: Evolution as a causative factor," *BRITISH MEDICAL JOURNAL*, June 10th, 1922).—I am, etc.,

Cape Town.

S. E. KARR, M.B., Ch.B.

THE SMALL-POX OUTBREAK AT POPLAR.

SIR,—My letter in your issue of November 25th was an invitation to Dr. Killick Millard to come out into the open; His attitude, however, is still not quite explicit. His letter in your issue of December 2nd (p. 1097) is an ingenious attempt to run with the hare of vaccination and to hunt with the hounds of Leicester and the Anti-Vaccination League. While admitting that small-pox can be effectually prevented by vaccination, he implicitly condemns the latter because it "masks" small-pox by modifying it. He appears to regard with complacency the possible epidemic prevalence of mild small-pox (among the unvaccinated) because it "tends to" breed true and does not give rise to a virulent form of the disease. It may be admitted that there have been outbreaks of small-pox in which most of the cases were mild (as in the United States a few years ago), but it by no means follows that naturally mild cases are not dangerous. The idea that mild small-pox can be relied on to breed true is opposed to analogy in other diseases and contrary to experience in small-pox. I have only a small experience of the disease—limited to two outbreaks in Reading during the last thirty years, in both of which I saw nearly every case, but, though there were few deaths, there was every gradation of type from the mildest to the most severe form, and neither the mild nor the severe cases were all in vaccinated persons.

Another point of Dr. Millard's is the old antivaccinist wheeze that "most of the deaths are in vaccinated persons." I fear this fact, when it is a fact, may be, at least partly, the fault of certain black sheep in the profession who, for a consideration, have vaccinated inefficiently. I once knew a medical man who built up a large practice (of a kind) by vaccinating in one small spot only and then signing a certificate of "successful vaccination." (This was, of course, before "conscientious" objection provided such an easy and convenient means of escape.) Another medical man once told me that he vaccinated just as much or as little as people asked for, apparently regarding the question as simply a matter of supply and demand like the sale of potatoes.

I agree with Dr. Millard that saturation of the population with vaccination is probably unattainable in this country. If the people prefer small-pox to vaccination they must have it, but we of the medical profession need not back them up in their preference. On the contrary, I would proclaim constantly that no individual need have small-pox at all unless he or she wishes it, however much the epidemic may rage in others, and that every death from small-pox is a case of either suicide or murder, and should be stigmatized as such.—I am, etc.,

Reading, Dec. 4th.

F. W. STANSFIELD.

OUTBREAK OF SMALL-POX IN POPLAR WORKHOUSE.

A Correction.

SIR,—In the concluding paragraph of my letter appearing in your issue for December 2nd I stated, "It is interesting to learn that all of the 22 fatal cases in the present outbreak had been vaccinated, presumably in infancy." I mentioned this on the strength of a statement appearing in the daily press. I now learn that the statement is incorrect. I understand

C. KILLICK MILLARD.

Major Arthur Cameron Duffey, R.A.M.C., died of pneumonia in London on November 12th, aged 47. He was educated at Trinity College, Dublin, where he graduated B.A. in 1894, M.B., B.Ch., and B.A.O. in 1896, and M.D. in 1897, in which year he took the L.R.C.P. also. After filling the post of medical officer of the City of Dublin Hospital for two years, he went out to the South African war as a civil surgeon, subsequently entering the R.A.M.C. a lieutenant from November 29th, 1900. He became major on August 29th, 1912, and was placed on half-pay on November 10th 1920. He served in the South African war, in operations in Cap Colony and in the Transvaal, receiving the Queen's medal with four clasps. In 1899 he went to the United States as special commissioner of the Cancer Society, and was the author of a work *Conditions and Treatment of Cancer in the United States*.

Obituary.

SIR NORMAN MOORE, Bt., M.D., LL.D.,

Late President of the Royal College of Physicians of London;
Consulting Physician to St. Bartholomew's Hospital.

[With Portrait on Special Plate.]

By the death of Sir Norman Moore, which occurred on November 30th at his house, Haucex, near Battle, the medical profession has lost a distinguished physician and one of its brightest ornaments. Born in 1847 at Higher Broughton, in Lancashire, he was the only son of Robert Ross Rowan Moore, a graduate of Trinity College, Dublin, and a barrister by profession. Robert Moore was descended from an Ulster family, and he contributed in no small degree to the success of the anti-Corn Law agitation by his ability as a public speaker, and his earnestness in the cause he was advocating. He toured the country in co-operation with Bright, Cobden, and Fox, and a share of the success of that movement was certainly due to his power of lucid exposition.

Norman Moore began his education by entering Owens College in 1863, and while there he showed considerable aptitude in the subjects of history and biography. From Owens College he proceeded to St. Catherine's College, Cambridge, and in 1868 obtained the second place in the second class of the Natural Science Tripos. The following year he took the degree of B.A., in 1872 the degrees of M.A. and M.B., and four years later he graduated M.D. While at Cambridge, although engaged in the study of medicine and science, his interest lay chiefly in the direction of literature, and much of his spare time was spent in association with men engaged in the study of the arts rather than with those engaged in acquiring a knowledge of science. Indeed, apart from a keen interest in natural history and comparative anatomy, it cannot be said that he evinced any deep regard for natural science. It was at Cambridge that he laid the foundation of that wide acquaintance with literature on which his lasting fame will rest. Among others he was brought into contact at Cambridge with Henry Bradshaw the famous University Librarian, and this acquaintance was largely responsible for the deep knowledge shown by Moore in medieval history. Through the influence of Bradshaw he became interested in the study of palaeography, a subject in which he acquired great skill.

On leaving Cambridge Norman Moore proceeded to St. Bartholomew's Hospital in order to finish his medical curriculum, and with this hospital his name was closely identified for the remainder of his life. After taking the M.B. in 1872 he filled successively the posts of house-physician from 1872 to 1874; casualty physician from 1875 to 1877; assistant-physician from 1883 to 1902, and physician from 1902 to 1911. For a period of eleven years, from 1874 to 1885, he was a lecturer on comparative anatomy to the hospital, and he occupied the post of warden for no less than seventeen years. Throughout the whole of the period, extending over thirty-seven years, that Norman Moore was connected with St. Bartholomew's Hospital, he was devoted to its welfare. His activities were incessant, and whether he was teaching in the wards, or engaged in committee work connected with the school, he was always alert and ready with suggestions, conveyed often with humour, and always with clearness and precision. He had great moral courage, and was fearless of the opinions of others. For many years he was responsible for teaching pathology at the hospital, and in this subject he took a great interest. Later in his career he was appointed Lecturer on Medicine, a post he held from 1893 to 1911. Here his ability as a ready and fluent speaker made his lectures popular. His method of teaching was based upon the principle of insisting on cardinal facts, and these were illustrated with many apt references drawn from his vast store of knowledge obtained from books. The result of his medical work in connexion with his long association with St. Bartholomew's Hospital found expression in many published works, of which the following may be regarded as representative. His first medical work was *Observations on the Shape of the Chest in Cases of Hypertrophy of the Heart*, published in 1873. This was followed by *Observations on the Morbid Anatomy of Gout* in 1887; *The Distribution and Duration of the Visceral New Growths*, which formed the subject of the Bradshaw lecture delivered in 1889; *Pathological Anatomy of Diseases*, 1889; *Principles and Practice of Medicine*, 1893; *Pleurisy: Its Pathology and Treatment*, 1905; and as the

subject of the Lumsden lecture in 1909 he chose Rheumatic Fever and Valvular Disease. Besides these works he contributed many papers to the St. Bartholomew's Hospital Journal and other medical journals. Clear and easy exposition was the main feature of his medical writings, and they all bore the stamp of great literary skill. He was also an active member of the various medical societies, and took especial interest in the work of the Pathological Society.

It might be supposed that the narration given above of the medical activities of Norman Moore would account for the whole of his busy professional life, but that is far from being the case. Throughout his life he was devoted to the interests of St. Bartholomew's Hospital, but that devotion was in equal measure shared by the College of Physicians, for which he had a deep and abiding love; in its service were spent his happiest hours. Here he was in an atmosphere congenial to his spirit, surrounded by the books and manuscripts he loved and knew so well, gazing on the portraits of the great physicians whose biographies he had written with such skill, and taking his seat at the Comitia where Freund, Mead, and Steno—his ideals of the cultured physician—had sat; here he was truly in his element. The work he accomplished for the College must ever remain as the brightest memorial of his active and valuable service. He saw in the College an ancient institution containing so much of value in its composition that it had been able to survive the wreck of time. With his veneration for antiquity he applied himself wholeheartedly to the task of preserving and perpetuating the sound principles on which the College is founded, and he watched with unremitting care lest innovations, introduced in conformity with modern requirements, should weaken the main structures of the foundation. But he was no reactionary; he was merely conservative, and when once he was persuaded that a change was for the good of the College he adopted it without reserve or qualification.

He was admitted a Member of the College in 1873, and four years later was elected a Fellow. From that time he was a constant attendant at all the meetings, and held at various times all the offices connected with the College with the exceptions of Treasurer and Registrar. He was a member of the Council from 1896 to 1898; censor in 1904 and 1905, and senior censor in 1908. In 1910 he was elected Harveian librarian in the place of Dr. Payne, and this post he held until 1918. From 1901 to November of the present year he was the representative of the College on the General Medical Council, and in that capacity supported with great energy the claims of the College. He gave the Bradshaw lecture in 1889, the Harveian oration in 1901, the FitzPatrick lectures in 1905 and 1906, and the Lumsden lectures in 1909. In 1918 he was elected President, a fitting honour to one who had served the College so well, and this office he held until the present year with great ability and distinction. When the annual meeting of the British Medical Association was held at Cambridge in 1920 the portrait painted by Sir William Orson was presented to Sir Clifford Allbutt by Sir Norman Moore on behalf of the subscribers. At that time he received from the University of Cambridge the honorary degree of LL.D.

Hitherto we have dealt with the career of Norman Moore as a physician engaged in the active practice of his profession. We have now to give an account of him as a man of letters. It is true that he occupied a distinguished position as a physician, but it is probable that his fame will rest on the literary work he accomplished. From his youngest days he was gifted with a love of books and a keen literary sense. His heart was always in his study, and the amount of knowledge he absorbed from reading was truly marvellous. He had a most retentive memory and the capacity for detecting with clarity the salient parts of a book. Some members of our profession may have possessed a more profound knowledge of certain special branches of the learning contained in books; few have been so widely read as the subject of this memoir. But Norman Moore was no mere bookworm steeped in book learning with no power to apply it to his environment. His vast knowledge was made subservient to the daily work, and whether he was attending a committee, instructing his clinical clerks in the wards, addressing a meeting, or engaged in familiar intercourse, he drew freely upon these rich stores to enforce an argument, "to point a moral, or adorn a tale." In his travels over all branches of literature, for some he evinced a special affection; history and biography had for him a great attraction, and in this field he passed the greater part of his literary career. For the *Dictionary of National*

SIR NORMAN MOORE, BT., M.D.

(After the portrait by R. G. Eves.)

Biography he wrote no less than 459 biographies, chiefly of medical men, and a perusal of those lives will show that he possessed a literary skill equal to Aikin, and an accuracy on a level with Muir. He once stated that he had never written a biography without first reading everything that the subject had written, and the condensed knowledge contained in these biographies readily attests the accuracy of the statement.

For years, when the subject was scarcely thought worthy of attention, Norman Moore was urging the importance of a study of the history of medicine, and he is entitled to be regarded as one of the founders of that branch of study in this country. Through his influence the FitzPatrick lectures in the History of Medicine were established at the College of Physicians, and in 1905 and 1906 he delivered the lectures, taking for his subjects "John Mirfield and Edward Browne in connexion with the education of physicians" and "The history of the study of clinical medicine in the British Isles." As Linacre lecturer in 1913 at Cambridge he chose as his subject "The physician in English history," and when called upon to deliver the Redo lecture in 1915 his subject was "St. Bartholomew's Hospital in peace and war." He was chosen President of the Section for the History of Medicine at the International Congress of Medicine in 1913, and at the Congress this year in London devoted to the history of medicine he was unanimously elected President of Honour. His pen was constantly employed in writing papers connected with the history of medicine, and among these may be mentioned *The History of Medicine in Ireland*, in 1910, and in conjunction with Mr. Stephen Paget, a history of the Royal Medico-Chirurgical Society in 1905. He was also a trustee of the British Museum, and had conferred upon him the distinction of being elected an Honorary Fellow of St. Catherine's College, Cambridge.

Norman Moore's type of mind naturally attracted him to mediæval history, and in the centuries belonging to that epoch he was thoroughly at home. Perhaps his interest flagged when the seventeenth century was passed, but his knowledge even of modern literature would excite admiration in any circle. As evidence of his ability as a writer of archaeological and mediæval history, towards the end of his life (in 1919) his *History of St. Bartholomew's Hospital* appeared. This book, containing a complete and exhaustive history of the hospital to which he was devoted, had occupied his leisure for more than thirty years, and is a fitting monument to his learning, research, and literary skill. Indeed, it is doubtful if the history of any institution has ever been written with such a wealth of detail. It was his last great effort, and worthily closes a brilliant literary career.

Quite early in his life (1871) he contributed an excellent memoir of Waterton as a preface to the collected Essays of that naturalist. He also translated the concise Irish grammar of Windish in 1882, and the following year he published a translation of the Irish text of the "Loss of the Crown of Loegaire Luc."

Norman Moore was twice married, first in 1880 to Amy Leigh Smith, daughter of William Leigh Smith of Crowham, Sussex, and secondly in 1903 to Millicent, daughter of Major-General John Ludlow. By his first wife he had two sons and a daughter. A son was killed in the war, and he is succeeded in the title by his son Alan Hilary.

His personal characteristics are almost too well known to require description. A man of intense convictions and great moral courage, regardless of the opinions of others in pursuing the course he believed to be right. Quick to see the central pivot in debate, he did not "suffer fools gladly," but was always ready to listen to opinions formed on serious grounds. As President of the College he ruled with prudence and dignity, and in all his actions in that capacity he adopted the position of a strictly constitutional ruler. He was the highest expression of that fast diminishing class of physicians who counted wide intellectual attainments the most important asset of the doctor, and the profession is infinitely poorer by his loss. Other men deeply versed in various branches of learning will arise in our profession, but it is doubtful if we shall see again a man endowed so bountifully with varied learning as Sir Norman Moore. It is not the purpose of this memoir to enter into personal and intimate details, but we may perhaps be permitted to say how much we have in mind to-day his unflinching kindness during a period of thirty-five years, and how valuable to us his high example has been. In the annals of the College he will take his place beside Freund, Mead, Sloane, and Askew. He himself would not have desired a higher honour.

ARNOLD CHAPLIN.

Sir HUMPHRY ROLLESTON, President of the Royal College of Physicians of London, writes:

Numerous recollections and memories of kindnesses from Sir Norman Moore since 1881, when as warden of the college he admitted me as a medical student at St. Bartholomew's Hospital, are recalled by the death of this striking personality. He was a clear and emphatic teacher successively of comparative anatomy, pathology, and medicine, and often emphasized his remarks by historical instances. His literary and historical distinction has thrown into the shade the large amount of work he did in his earlier days in morbid anatomy; on this subject he wrote a textbook, gave the Bradshaw lecture (1889) at the College of Physicians, and was very active at the old Pathological Society of London, serving for eleven years on the Morbid Growths Committee. An outstanding characteristic was his affection for the old, whether men, manners, institutions, or books. While at Cambridge he was the disciple of Charles Waterton (1782-1865), the naturalist, whose life he wrote in 1871, and of Sir George Pagot, the regius professor of physic; his acquaintance with men of learning is also shown by a letter of Professor John Richard Green (1837-83) referring in 1877 to "Norman Moore, one of the surgeons at St. Bartholomew's, but a man of marvellous knowledge in all Irish matters old and new. . . . Indeed, he is the only Irish person from whom I ever learned anything about Ireland." His devotion to the ancient foundation of Rahere is perpetuated in his splendid *History of St. Bartholomew's Hospital*, on which he was engaged for thirty years. This labour of love illustrates his gift for conveying in an attractive form the results of wide research, which in less able hands might easily have appeared dry-as-dust and uninspiring. As a medical biographer he was in the first flight, and was among the seven who contributed to all the original sixty-three volumes of the *Dictionary of National Biography*, and it is known that in constructing these 459 lives he followed the admirable rule of first reading all the published works of the man whose notice he was engaged on. Not only was his reading remarkably extensive and his memory wonderfully alert, but he had the power of aptly applying his stores of quaint knowledge and anecdote with a humour and manner particularly his own; he was thus for years pre-eminent as an after-dinner speaker in the medical world of London, and delighted his audience, especially when proposing the toast of the guests, by unexpected analogies and contrasts. Together with his pupil, Stephen Paget, he compiled the centenary volume (1805-1905) of the Royal Medico-Chirurgical Society, and thus performed for the premier medical society the same service, though infinitely less exacting, that he did for the oldest hospital of this city. At this society and its continuation the Royal Society of Medicine he was almost constantly in office, and from 1899 to 1918 was honorary librarian, only resigning when elected president of the Royal College of Physicians of London. This indeed would appear to have long been his ambition, and it may well be doubted if this high honour has ever been more deservedly won by long and unremitting devotion. From the onset he was a member of the important committee of management of the two colleges and thus was much concerned with the Conjoint Board examinations; for twenty-one years he was the representative of the College on the General Medical Council, and for seven years Harveian Librarian; further, he was instrumental in obtaining for the College the endowment of the FitzPatrick Lectures in the History of Medicine—a subject for which he did so much in this country, his position being clearly recognized by his selection as President of Honour of the recent International Congress of the History of Medicine in London. Though intensely interested in the traditions of the past, he had his finger on the pulse of present movements, and was an influential and efficient member of committees. For the honour and position of the College he was ever on the watch and never spared himself; in fact, it is not improbable that his self-sacrifice was instrumental in the rapid failure of his health that became apparent during his last year of office. The College loses a loyal friend, the like of whom it will not see again, and British medicine mourns a scholarly representative recalling the learned physicians of Linacre's ideal.

One of Sir Norman Moore's house-physicians writes:

The Editor has allowed me to see the admirable memoir written by Sir Norman Moore's successor in the office of Harveian Librarian, and the discerning tribute by his successor in Harvey's chair. It is most fitting that his life and work should be recorded in the *BRITISH MEDICAL JOURNAL* by

distinguished physicians who followed in his path, from Cambridge, through St. Bartholomew's, to high office in the Royal College of Physicians. As a younger son of these three great and ancient foundations, which were always in his thoughts, may I add a word from a rather different aspect? Dr. Norman Moore (to use the familiar name) was a good friend to young men, and showed his interest in practical ways. No pupil was ever forgotten. Those who earned his friendship kept it, and it went on from father to son. Little escaped that observant and critical eye; one quick look would sum up a new student's possibilities, or the fulfilment of early promise in an old student now shaping a career in practice. Dr. Norman Moore's clinical teaching was individual and personal, it had no direct relation to the passing of examinations; but his sayings stuck in the mind, and the drilling in accurate observation was of life-long value. The three chief things he taught at the bedside were consideration for the patient, careful study of the signs of disease, and precise statement of the facts observed. He praised a clear case-note, but paid no attention to the clinical clerk who tried to impress him with textbook knowledge; indeed, no learned man ever seemed to care less for pedantry. He was quick to note ability, but one of the most charming sides of his remarkable nature was his liking and respect for the unbookish man of action—the kind of student who after many disappointments at the examination hall wins success in the rough-and-tumble of practice. His afternoon visits to the wards had a civilizing effect on the rawest student, and his informal teaching communicated a point of view in clinical medicine which might colour a whole career. His ready allusion to old books and authors seldom fell on stony ground, because he would often add: "I do not want you to read those books because they are old but because they are good." Many such sayings stand out in the memory of his pupils. We remember, too, the unfailing loyalty and kindness to his house-physicians.

The funeral took place on the afternoon of Tuesday, December 5th, at Sedlescombe Churchyard, Sussex. Among those present at the graveside, with Lady Moore, Sir Alan Moore, Mrs. Marlborough Pryor, and other members of the family, were Sir Humphry Rolleston, President, and Dr. J. A. Ormerod, Registrar, of the Royal College of Physicians; Sir William Lawrence, Bt., Senior Almoner, and Dr. H. Morley Fletcher, Senior Physician, representing St. Bartholomew's Hospital; Mr. F. M. Rushmore, President and Tutor of St. Catherine's College, Cambridge; and Dr. N. G. Horner (BRITISH MEDICAL JOURNAL). A solemn Requiem Mass will be sung at St. James's, Spanish Place, to-day, December 9th, at 11 a.m.

SIR ISAAC BAYLEY BALFOUR, K.B.E., M.D., D.Sc.,
LL.D., F.R.S.,

Emeritus Professor of Botany in the University of Edinburgh.

ALTHOUGH Sir Isaac Bayley Balfour never practised medicine his was for many years (from 1838 to 1922) the first professor's voice heard by every Edinburgh medical student commencing his curriculum in the University; so he took his place in the great system of the teaching of the healing art, if not in the active prosecution of it. Although he was not appointed to the professorship (in succession to Professor Alexander Dickson) till 1838, he had already taught the class in 1876 and 1878; in the summer session of the latter year Sir Isaac's father, Professor John Hutton Balfour (affectionately known to that generation of students as "Woody Fibre"), began the lectures, but being immediately laid aside by illness his work was taken up and carried on till the end of the session by his son, then a brilliant young botanist of 25. The writer, who was a member of the class that summer well remembers the changed outlook upon botany which was revealed to the undergraduates when Dr. Isaac took his place at his father's lecturing desk. John Hutton Balfour was the author of a memorable textbook in two volumes; his teaching flowed smoothly along in the wake of that work, and there was no great danger (from the examination point of view) if a lecture or two were missed; Dr. Isaac Bayley Balfour put before the class the newer botany from Germany with its emphasis on histology, on embryology, and on the lowest and simplest forms of plant (or was it animal?) life; at once interest was aroused and enthusiasm excited, and the benches in the classroom in the Royal Botanic Garden were packed even before 8 a.m., the hour of lecture. The Saturday excursions, too,

with an active young teacher eager to impart knowledge, leading the way over hill and dale, gained in popularity.

Dr. Bayley Balfour was born in Edinburgh in 1853, and received his education at the Edinburgh Academy and the University, graduating (with honours) M.B., C.M. in 1877, and gaining a gold medal for his M.D. thesis (botany of Socotra) in 1883. He had already taken part in the transit of Venus expedition to Rodriguez in 1874, and he published three years later his *Botany of Rodriguez*. Had a botanist accompanied the *Challenger* in its scientific voyage, it is more than likely that Dr. Balfour would have been the man. At this time he was an M.A. and B.Sc., and was taking out medical classes, acting also as assistant to Huxley, who was doing professorial duty in Edinburgh in 1875-6, and as dresser to Lister in 1876. In the year of his graduation as M.B. and C.M. he acted as assistant to Sir Wyville Thomson, the Professor of Zoology fresh home from the *Challenger* expedition. Later he worked with De Bary at Strasburg and also at Würzburg. As has already been stated, he lectured for his father in 1878, and in the following year he was appointed to the chair of botany in the University of Glasgow in place of Dickson, who had succeeded to the Edinburgh chair. In 1879 also, after the close of the classes, he explored the island of Socotra, making researches which he afterwards (1883) embodied in his gold medal thesis. In 1884 he was appointed Sherardian Professor of Botany in the University of Oxford and was elected a Fellow of the Royal Society. Three years later Balfour published his work of the *Botany of Socotra*, and then in 1889 he returned to his native city and his Alma Mater, having been appointed Regius Professor in the University of Edinburgh and Regius Keeper of the Botanic Garden there.

John Hutton Balfour held the chair of botany for thirty-four years (1845-1879), and so did his son, Isaac Bayley Balfour (1883-1922). The son gave his time and energy pretty evenly between the teaching work of his chair and the care and improvement of the great Botanic Garden of which he was keeper. His work in both spheres was of the highest order. His lectures were always clear and intensely interesting, and his personal touch with his pupils was close and helpful to them. His reputation as a botanist was shown in various ways, more particularly perhaps by the fact that he was one of the first sixty botanists to receive from the Royal Horticultural Society the Victoria Medal of Honour. In time many other honours came to him, a knighthood in 1920, and the honorary LL.D. from Edinburgh University as recently as last July. He retired from the active work of his chair in April last. He has not been long spared to enjoy the rest and freedom from teaching responsibilities which his retirement promised, for he died on St. Andrew's Day (November 30th) at Courts Hill, Ha-lewens, the residence to which he had removed in the south. He married a daughter of the late Mr. Robert Balloch of Glasgow, by whom he had one daughter. Sir Isaac worthily maintained the high reputation which had become attached to the chair of botany in the university, and he and his father between them held the professorship for the long period of sixty-eight years. The newly equipped and extended Botanic Garden remains as a memorial in large part of the Balfour occupancy of the Regius professorship.

Dr. GRATTAN ROBERT CROLYN, who died on November 23rd, was the son of the late Dr. John Crolyn of Dublin. He was born at Kingstown, near Dublin, in 1854, and was educated at Foyls College, Londonderry. He served with the King's Liverpool Regiment for seven years in India, and on his return finished his medical training in Dublin at the Meath Hospital and the Rotunda. He took the diplomas of L.R.C.S.I., L.R.C.P.I., L.M. in 1896. For three years he acted as assistant to Dr. Pim of Barrowford, Lancashire, and then served as Civil Surgeon during the Boer war, in the Military Hospital, Dublin. For three years he examined recruits for the army at Liverpool, and then returned to Barrowford and assisted Dr. Pim for another two years. He went to Maidenhead in 1907 to take over the appointment of medical officer to the Union Infirmary and district. He held this appointment to the time of his death, and also worked up a large private practice. For ten years he had been on the honorary staff of the Maidenhead Hospital.

The celebrated comparative anatomist and biologist, OSCAR HERTWIG, has recently died in Berlin at the age of 73.

Medical News.

A TROPICAL Diseases Committee has been appointed in connexion with the British Empire Exhibition to be held at Wembley in 1924. The chairman of the committee is Sir Humphry Rolleston, K.C.B., M.D., and the deputy chairman Major-General Sir W. B. Leishman, K.C.M.G., F.R.S. (War Office). The committee includes representatives of the Tropical Schools, the Natural History Museum, the Royal Navy, the Royal Colleges of Physicians and Surgeons in London, veterinary medicine, and also the India Office and the Colonial Office. The joint secretaries are Lieut.-Colonel W. W. Clemesha, C.I.E., M.D. (70, Victoria Street, London, S.W.1), and Dr. S. H. Dawkes, O.B.E. (Wellcome Bureau of Scientific Research, 25-27, Endsleigh Gardens, London, N.W.1). The chairman of the executive subcommittee is Dr. Andrew Balfour, C.B., C.M.G.

At the social evening of the Royal Society of Medicine, to be held at 1, Wimpole Street, W.1, on Wednesday next, December 13th, Messrs. Marconi have arranged to install one of their newest models and a Magnavox loud speaker, which will enable the audience in the Robert Barnes Hall to enjoy a wireless concert without the necessity of using individual earpieces. It will begin at 8.20 p.m.; after the concert news too late for the evening papers, latest weather reports, and so on, will be delivered.

At a general meeting of the members of the Royal Institution held on December 4th, when Sir James Crichton-Browne was in the chair, Sir Arthur Keith was elected secretary in succession to the late Colonel E. H. Grove-Hills. Professors Urbain (Paris), Ehrenfest (Leyden), Kundsén (Copenhagen), Bjerknæs (Christiania), and Dr. Irving Langmuir were elected honorary members.

THE annual dinner of the London School of Medicine for Women (Royal Free Hospital) was held on Friday, December 1st, at the Holborn Restaurant, with Dr. Ethel Vaughan-Sawyer in the chair; 282 graduates, students, and their friends were present. The chairman, in proposing the toast of the school and hospital, referred to the loss sustained by the resignations of Dr. J. Walter Carr, senior physician, and of Miss Cox-Davies, the matron. The greatest need of the school at the moment was a suitable recreation ground for the students; there were 480 students with only one tennis court amongst them all. Mr. J. Gay French proposed the health of the guests in a felicitous speech, and Lord Riddell made a witty response. Several songs delightfully rendered by Madame Teresa del Riego added greatly to the pleasure of the evening.

At the meeting of the Manchester Surgical Society, to be held in the library and reading room of the Manchester Medical Society, Medical School, Comland Street, on Tuesday next, December 12th, at 8 p.m., papers will be read by Mr. M. Mamourian on massive excision of diseased bone followed by immediate or early bone-grafting, and by Mr. Garnett Wright on after-results of gastrectomy for ulcer. The discussions on the papers will be opened by Mr. Harry Platt and Mr. H. H. Rayner respectively.

A THREE months' course of lectures and demonstrations in hospital administration will be given at the North-Western Hospital, Hampstead, by Dr. E. W. Goodall, medical superintendent, on Mondays and Thursdays, at 5.15 p.m., beginning Monday, January 8th, 1923. The fee for the course is £3 3s.

AN extension of the nurses' home of the London Fever Hospital was recently opened by Lord Muir-Mackenzie. The building is four stories high, and the ground floor contains class and sitting rooms for 100 nurses. The other stories each provide seven bedrooms, and each has a sanitary wing.

THE *Times* correspondent in Berlin reports that malaria is prevalent in the centre of Russia and in the city of Moscow. Until the beginning of this year the area affected was restricted to the south-eastern regions—the marshy district of the Dnieper, the Don, Kuban, the Black Sea border of the Caucasus, and Transcaucasia. But from January to September, 1922, the number of cases registered in the government of Moscow alone was 25,280, and of these 2,223 occurred in the city. Similar or worse conditions prevail in the governments of Tver, Vladimir, Riazan, and in the Volga regions. It is reported that of the total number of persons affected 25 per cent. have died. It is added that adequate medical organization and supplies are wanting.

THE State Medical Officer of Texas recently announced that 500,000 cases of dengue had been reported in the State within a few weeks, but that the disease is not of a serious character. It was expected that the coming of cold weather, causing the death of the mosquitos, would end the epidemic.

THE forty-fourth autumn meeting of the Irish Medical Schools' and Graduates' Association was held at Pagan's Rostaurant on November 30th, with the president, Dr. J. A. Macdonald, in the chair. There was a large attendance, including several members resident in Dublin. A letter of condolence was sent to the widow of Sir Charles Ryall. The members and their friends, to the number of 101, subsequently dined together, the guest of the evening being Professor Andrew S. Dixon. After the loyal toasts had been honoured, Dr. William Douglas proposed "Our Defenders," and Colonel George A. Moore replied. In proposing the health of the guests Dr. Gubbins Fitzgerald said that Trinity College, Dublin, of which Professor Dixon was such an ornament, had the reputation of welcoming to its halls men and women of every creed and every shade of politics; nothing contentious was allowed to interfere with the prosecution of studies. "Prosperity to the Association" was proposed by Sir Jenner Verral, who congratulated the members on their good fortune in having as their president Dr. Macdonald, a man in whom were combined much wisdom, quick perception of points requiring proper consideration, and the courage to state his convictions without giving offence to those differing from him. The president, in reply, briefly narrated the origin of the association. The idea occurred to an old Portora boy, who had had long service abroad as an army surgeon, and he broached this in 1878 to a schoolfellow who had been serving abroad as a naval surgeon. The association now numbered nearly 700 members, whose homes were in every part of the world. Its success was due to the camaraderie it fostered and the exclusion from its meetings of everything connected, even remotely, with politics or polemics.

A MEETING of the Royal Benevolent Fund Guild was held at the house of the Medical Society of London on November 26th, when Lady Bradford, the president, introduced Mrs. Kendal, who took the chair. Mrs. Scharlieb, M.D., described the work of the Guild. Lady Frigg said that it was proposed to hold a dinner after Christmas, and many members present agreed to act as stewards, undertaking to collect £10 before January 30th or to bring eight or ten guests. Tickets can be obtained from Miss Swinford Edwards (68, Grosvenor Street, W.1) or Miss Fletcher (98, Harley Street, W.1). Under the auspices of the Ladies' Medical Golfing Society a bogey competition, open to all lady golfers, is to be held between January 1st and September 30th, 1923, for the benefit of the Guild. Play may be on any course, but the card must bear the special stamp (price 6d.) issued by the Guild, and be certified by a member of a recognized golf club. The lady who returns the best aggregate of five scores will win a silver cup. Further particulars and sheets of twenty stamps may be obtained from Lady Rigby (24, Queen Anne Street, W.1).

IN 1919 an Act was passed by Parliament providing for the registration of nurses for the sick. Under that Act a General Nursing Council was established, one of whose duties was the formation of the Register of Nurses. Work on its preparation has been going on steadily since that time, and the Minister of Health has given notice, as required by Statute, that the Register has now been compiled. The effect of this notice will be that after three months from December 5th (the date of the notice) the unauthorized use of the title "registered nurse" will render a person liable to a fine not exceeding £10 for a first offence and £50 for any subsequent offence. The first Register is now being printed, and will be published by the General Nursing Council, 12, York Gate, Regent's Park, N.W.1.

DR. WILLIAM BROWN, Wildo Reader in Mental Philosophy in the University of Oxford, has been added to the consulting staff of Bethlem Royal Hospital as honorary consulting psychologist.

A NATIONAL congress of medical practitioners was held at Rio de Janeiro in October, with Dr. C. Sunpaio as president. Professor F. Mahalhas delivered the opening address, on the thesis that "democracies succeed only when the authorities take as their guide the principles of social medicine." The meetings were organized by the Medical and Surgical Society of Rio, and lasted for a week; it was decided to form a Brazil Medical Association.

A CONVENTION of the Federation of the Experimental Biological Sciences will be held in the Faculty of Medicine of the University of Toronto on December 27th, 28th, and 29th.

A CANCER instituto has just been opened at Madrid. Professor Goyanes, the director, supervised the building and equipment after visiting similar institutions in other European countries.

A NUMBER of cases of tropical malaria have recently been reported, according to the *Münchener medizinische Wochenschrift*, among persons who have never lived away from Berlin; none of them had any suspicion of the disease until it flared up under a course of salvarsan treatment.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

Authors desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

The postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, Allottery, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, Mediscera, Westrand, London; telephone, 2633, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Baellius, Dublin*; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

QUERIES AND ANSWERS.

QUALIFICATION FOR M.O.H.

"K."—The Sanitary Officers Order, 1922, made by the Minister of Health, requires that a person who is appointed medical officer of health of a district shall be registered in the *Medical Register* as the holder of a diploma in sanitary science, public health, or state medicine, or shall have had not less than three years' previous experience of the duties of a medical officer of health. These requirements may be dispensed with by the Minister of Health if it appears to him desirable to do so. As our correspondent lives so near to a town in which there is a medical school he should have no difficulty in attending the necessary courses of training for the D.P.H. He will be able to obtain full information from the authorities of the school.

SANWAYS'S ANCHOR TOURNIQUET.

Dr. D. W. SANWAYS (Mentone) writes: I found during the war that many of the anchors, on the anchor tourniquet which I designed many years ago, were not correctly made. The flukes of the anchor were too near the ring for the rubber tube to pass easily, the makers evidently thinking that some jamming action between the ring and flukes was necessary. None is necessary. The rubber tube jams itself by passing under the flukes and over the shank, and the pull of the rubber on the shank presses the flukes on the tube passing beneath them. The twists in the tube, and the compressions on it, hold it firmly. The shank of the anchor should always be made long enough for the rubber tube to pass on easily; otherwise skill or trouble, neither of which should be necessary, will be required to fix the tourniquet.

INCOME TAX.

"A" inquires as to what adjustment should be made between partners in the following circumstance: "A" and "B" were in partnership until "B" bought up "A's" two-thirds share and the "practice house" as from June 30th, 1922.

. The first and second instalment of income tax 1921-22 relate, of course, to the year ended April 5th, 1922, and should be paid and borne by "A" and "B" as if the subsequent change had not taken place. The income tax assessment Schedule D for 1922-23—for which the first instalment is payable in January, 1923—should be made or adjusted on the basis that "A" has one-fourth of two-thirds—that is, one-sixth of the profits and he should bear his share of the tax accordingly. The rates and income tax Schedule A payable on the house should be apportioned—for example, on the basis of half and half as regards the half-year to October, 1922, and the first income tax instalment 1922-23—between "A" and "B" unless there was some specific arrangement or allowance made in that connexion on the contract for sale.

LETTERS, NOTES, ETC.

INTRAUTERINE DECAPITATION.

Dr. H. W. OGLE-SKAN (Hendon) writes: Dr. Pole's letter on this subject (November 25th, p. 1054) reminds me of the following incidents, which may be of interest. Mrs. "A." sent for me on a Friday afternoon a few weeks ago as she was three months pregnant and was having slight pains and some haemorrhage. Abortion appeared not inevitable, so I gave opium and told her to stop in bed. I was called urgently late on the Saturday evening to find that, not regarding the situation as serious, she had invited her friend, Mrs. "B.," round for the afternoon and evening while their husbands went to watch a cup tie. About 9 p.m. they thought they would go out to the nearest public-house and get some beer for their husbands on their return. While in the public-house Mrs. "A." felt very queer and had a glass of brandy and proceeded to walk home. While going along a dark lane Mrs. "A." was violently sick and felt some-

thing come from her. Mrs. "B." groped around in the dark and felt the "something," which she picked up and put in the basket of eggs she was carrying; on arriving home she found the "something" was a foetus without a head. She sent for a nurse and telephoned me. On arrival I was shown the foetus minus a head, and on examination found the head in the vagina. I anaesthetized and removed the head and extracted the placenta from the uterus. On the Monday I was called to Mrs. "B." (who opened the door to me), and she showed me a pall in which was a foetus she had expelled early that morning. This one had a head all right! As no placenta was forthcoming next day I anaesthetized and removed a very adherent placenta piecemeal through an or which would not dilate more than enough to admit one finger. Mrs. "B.'s" foetus was also about three months. The coincidence was rather remarkable. Both women made an uneventful recovery.

THE SMALL-POX OUTBREAK AT POPLAR WORKHOUSE.

Dr. H. LAIRD PEARSON (Birkenhead) writes: Dr. C. Killick Millard, writing on this subject, says: "It is interesting to learn that all of the 22 fatal cases in the present outbreak had been vaccinated." Now to substantiate his argument one needs to know if these fatal cases had been efficiently vaccinated. In last week's issue of the *Medical Officer* I have recorded a case (a contact) of a child aged 2 years with one "mark," who upon revaccination produced four perfect vesicles.

STRECHNINE AND THE HEART.

Dr. CHARLES J. HILL AITKEN (Kilnburst, Dr. Rotherham) writes: In the BRITISH MEDICAL JOURNAL of November 11th, 1922, Dr. John Hay, in his interesting article on cardiac failure, states that "strychnine has a wide and unwarranted reputation as a cardiac stimulant in Great Britain." Yet in the *Practitioner* for June, 1905, the late Sir Thomas Lauder Brunton wrote the following words: "In the *Medical Record* of 1874, p. 293, I abstracted a paper on the action of strychnine on the respiratory centres, and in a conjoint paper with Professor Cash (*St. Bartholomew's Hospital Report*, vol. xvi, p. 229) I showed its powerful action as a cardiac stimulant. In my lectures on therapeutics for thirty years I have insisted upon the facts." Rather different statements which are an interesting contrast.

A DISCLAIMER.

Dr. MACKENZIE STEEDMAN (Hounslow) writes: It has been brought to my notice that a paragraph appeared in the *Middlesex Chronicle* of December 2nd, giving prominence to my name and that of my assistant as being responsible for a blood transfusion. As this paragraph has, naturally, caused me some annoyance, and may lay me open to criticism from members of the medical profession, I shall be glad if you will give me this opportunity of disclaiming any knowledge whatever of the paragraph in question until my attention was called to it subsequent to publication.

FIRST AID IN COAL MINES.

In reply to an inquiry published last week the Chief Secretary of the St. John Ambulance Association writes to call attention to the pamphlet *First Aid in Coal Mines*, which can be obtained (price 6d., by post 7d.) from the St. John Ambulance Association, St. John's Gate, Clerkenwell, E.C.1. We understand also that a useful book is *First Aid in Mining* by Louis G. Irvine (price 8s. 6d., net) published by the Book Department of the *Mining Magazine*, 724, Salisbury House, London, E.C.2. Messrs. John Bale, Sons, and Danielsson publish a card *First Aid in Fire Works* by Dr. J. M. Carvell which we are informed is in use by many factories, collieries, and railways.

MESSRS. GRAFTON AND CO., publishers (Coptic House, Coptic Street, London, W.C.1), write: Will you allow us space in your columns to say that we have no connexion whatever with the firm calling themselves the Grafton Publishing Company and circulating a publication entitled "London Doctors and Dentists"? Their circulars do not appear to bear sufficient address, and correspondence has been sent to this address.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 55, 58, 59, and 60 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 56 and 57.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 213.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£s.	d.
Six lines and under	...	0 9 0
Each additional line	...	0 1 6
Whole single column (three columns to page)	...	7 10 0
Half single column	...	3 15 0
Half page	...	10 0 0
Whole page	...	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a cheque or postal order payable to the order of the Post Office to receive postage or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

433. Is Tuberculous Meningitis Curable?

A. CRAMER and G. BICKEL (*Ann. de Méd.*, September, 1922, p. 226) observe that the unanimous opinion of several generations of physicians has been that tuberculous meningitis is incurable, prognosis fatal, and death inevitable. Everyday experience has confirmed this view. The authors then discuss the extreme gravity of this disease compared with other forms of tuberculosis. Ninety per cent. of cases present other tuberculous lesions, often of the generalized military type; very frequently meningitis is a terminal development. The mechanical effects on such delicate structures are far more serious and rapid in action than in other organs. The toxin has an elective affinity for the central nervous system. In spite of all these facts cases of recovery have been recorded, though in the majority sufficient scientific proof is wanting. The authors record the case of a youth of 19, having a history of winter cough, etc., for several years, who developed typical tuberculous meningitis, the diagnosis being fully confirmed by bacteriological and experimental findings. Full details of the case are given. In all four lumbar punctures were performed during a period of twenty-nine days; the cerebro-spinal fluid at the last puncture was normal and the patient was discharged, apparently completely cured, two and a half months after his admission to hospital. Eighteen months afterwards he was in excellent health, played games, and neither physically nor intellectually showed any sign of disease. The writers have collected from various sources about 250 cases of cured tuberculous meningitis. Rejecting all cases in which the diagnosis was not confirmed by discovery of tubercle bacilli in the cerebro-spinal fluid and the infection of guinea-pigs which had been inoculated with the fluid, they have found 45 cases which fulfil these conditions, of which particulars are given. The authors append a table of results in 40 of these cases whose ages have been given by the writers. This shows that whereas the percentage of recoveries below 2½ years is only 2.5 per cent., that of patients above 20 years is as high as 30 per cent. The majority of authors who have published these cases think that recovery was due to treatment. That most generally employed is cerebral decompression, usually by repeated lumbar punctures; others have achieved this by trephining. Bier's treatment was employed in 6 cases, of which 2 are stated to have recovered. Tuberculin is recommended by several authors. "Auto-serotherapy"—that is, subcutaneous injection of a few cubic centimetres of the patient's cerebro-spinal fluid—has been employed with good results, but continuous drainage of the vertebral canal and puncture and irrigation of the cerebral ventricles have not produced any cures. Much depends on the patient's power of resistance and on the relative mildness of the infection.

434. Cardiac Complications of Gonorrhoea.

W. S. THAYER (*Johns Hopkins Hosp. Bulletin*, October, 1922, p. 361) reviews the cardiac complications of gonorrhoea occurring at the Johns Hopkins Hospital over a period of thirty-three years, together with 60 cases collected from the literature. Of 176 cases of acute endocarditis 20 were gonococcal, the organism being cultivated *intra vitam* and *post mortem* and demonstrated bacterioscopically in six instances culturally negative. Arthritis occurred in 41.1 per cent., as compared with 68.5 per cent. of cases from other sources, and the relation of the time of onset of cardiac involvement to the appearance of the disease was indefinite. Cardiac complications usually appear as acute or subacute vegetative and ulcerative endocarditis, arising at varying periods in the course of the infection, and frequently without any other apparent complications. The onset is usually acute, but may develop gradually with chills and remittent or intermittent fever, and a rapidly developing anaemia and leucocytosis. Constitutional symptoms are usually severe, and there may be petechial eruptions, embolic phenomena, and signs of grave nephritis. The duration is usually from four to nine weeks, but may be longer in the subacute variety. The aortic valves are those most commonly involved, but the right side appears to be affected more often than in chronic rheumatic valvular disease, and the involvement is not restricted to the endocardium, endoarteritis, pericarditis, and suppurative myocarditis being not unusual. The course of the disease is generally progressive and fatal, its virulence occupying a position between the more subacute *S. viridans*

and *B. influenzae* infections and those produced by the more virulent *Staphylococcus albus* and *aureus*, pneumococcus, or *Streptococcus haemolyticus*. Recovery may occur, but is rare.

435. Angina Abdominalis.

W. FREY (*Klinische Wochenschrift*, September 30th, 1922, p. 1984) describes an abdominal affection similar in nature to angina pectoris and intermittent limping (claudication). It is characterized by the occurrence of attacks of severe pain in the abdomen, associated with increased blood pressure and meteorism. In a case recorded the autopsy revealed marked arterio-sclerosis of the intima of the aorta, extending as far as the iliac arteries. The renal, splenic, and superior and inferior mesenteric arteries showed also arterio-sclerotic changes in the intima. In the etiology of the affection the sclerosis of the mesenteric arteries is the most important factor and gives the diagnosis a certain basis. The symptoms are produced by a more or less acute disturbance of the arterial blood circulation in the intestine. It has been shown that inhibition of the supply of oxygen to the isolated intestine of the rabbit produces first a condition of stimulation, followed by paralysis. Probably paroxysmal arterial contraction occurs in the attacks of angina abdominalis, and the author offers suggestions as to the exact cause thereof. In well-marked cases of angina abdominalis, with severe pain in the abdomen, sudden increase in the blood pressure, and meteorism developing acutely, the diagnosis is easy. In the less severe cases the diagnosis is often indefinite. The proneness to abdominal pain in every arterio-sclerotic patient should suggest the possibility of changes in the intestinal arteries.

436. Preserved Food.

T. J. UNDERHILL (*Journ. Roy. Naval Med. Service*, October, 1922, p. 241) discusses some points of interest regarding preserved food, particularly as supplied to the Royal Navy, consisting of corned beef, unsweetened condensed milk, jams, beef-tea, Bovril, gravy, and ox-tail soup, chicken and mutton broth, bottled fruits, sausages, sardines, bacon, beans, peas, meat and vegetable rations, salmon, refried suet, and salt pork. With the exception of the last, which is contained in casks, and of the bottled fruits and jams, all are packed in tins and the contents sterilized by heat. Jam and marmalade rely for their preservation upon a percentage of water and sugar and the exclusion of air, the tin being filled and closed while the contents are very hot. Refined suet is not sterilized, but decomposition is slow when it has been freed from nitrogenous matter and protected from light, air, and moisture in tins. Sterilization and desiccation are the most satisfactory methods for preventing decomposition for long periods. Freedom from metallic contamination by tin, lead, copper, and zinc is essential, 2 grains of tin per pound being the maximum permitted, and it is the unsweetened milk which gives the greatest trouble. Carrots, tomatoes, onions, and black currants exert a very pronounced action upon tin surfaces, but treatment of the surface with a specially prepared lacquer has overcome the difficulty, and no importation of fruits should be permitted unless in tins so treated. No coating, however, has yet been obtained which will resist sterilization at high temperature of meat products, broths, etc. The continuous use of saltpetre in the preservation of corned beef and other articles has more disturbing effects upon digestion than is generally appreciated, and its only effect is to redden the meat and render it more palatable and appetizing. Experience shows that large firms of repute, guided by skilled chemists, with clean factories and well-paid and well-cared-for employees, are thoroughly reliable.

437. Vaccine Treatment of Asthma.

S. BONNAMOUR and DUQUAIRE (*Lyon méd.*, July 25th, 1922, p. 609) treated a large number of cases of asthma and emphysema of different kinds by antituberculosis vaccines derived from various sources (Maragliano, Mérienx, Lumière), which were applied by scarification. A general reaction, shown by fever, prostration, and somnolence, was rare. Locally the reaction might be feebly positive in the form of erythema with branny desquamation, or strongly positive, as shown by the formation of a large scab on an erythematous base. In cases of cardiac and bronchial asthma the skin reaction was negative and the therapeutic result was nil. In other cases in which a previous history of bronchitis suggested tuberculosis the vaccine treatment was also without result, showing that the disease was due to another cause. Lastly, every case of asthma in a tuberculous subject was not.

necessarily due to tuberculosis, so that an asthmatic patient with a positive skin reaction might show little or no improvement from vaccine treatment. The authors report 16 cases in which the local reaction was very definite and the success of vaccine treatment very rapid. Most of the patients were aged from 50 to 80 with a history of tuberculosis or bronchitis, and had suffered from emphysema for several years, with attacks of asthma which first occurred at long intervals, and subsequently became more frequent, proving refractory to ordinary treatment. In some cases the cure lasted for several years, and seemed permanent. As a general rule, however, it lasted about six months, and a fresh vaccination was needed. Several cases were cured in thirty-six hours, after an illness of fifty years in one instance and of forty-three years in another.

438. Milk Intolerance.

CANNATA (*La Pediatia*, June 15th, 1922, p. 529) says that intolerance of the nursing infant to milk may be termed either complete, when this intolerance is present for any woman's milk, or incomplete, when it is concerned with only one woman. The symptoms are mainly those of dyspepsia, or may resemble anaphylactic shock. The class of case considered has no relation to chemical changes in the milk, but applies only to cases where as far as can be ascertained the milk presents no chemical or microscopic departures from the normal. Not infrequently milk which disagrees with one child may be quite satisfactory for another. The author quotes a case illustrating this. In the case of cow's milk some cases may be explained on anaphylactic grounds—for instance, when milk feeding has been suspended for a time owing to gastric disturbances and on resumption acute symptoms arise. Peshkin and Rost showed that in 10 per cent. of normal children a condition of sensitiveness to heterogeneous albumin is present—in other words, a state of potential anaphylaxis. Some of these cases have been improved by anti-anaphylactic injections of milk. On the other hand, some children show intolerance to mother's milk from birth, which is rather against the anaphylactic theory. The author thinks one should exclude every other possible cause before taking repose in anaphylaxis.

439. Erythema Nodosum and Tuberculosis.

W. HOLLAND (*Norsk Mag. f. Lægervidenskaben*, August, 1922, p. 626) is sceptical as to the teaching that erythema nodosum is a reaction to the tubercle bacillus, and he notes that hitherto the relationship between the two has not been proved by histological examinations, inoculations of animals, or tuberculin tests. Between November, 1916, and December, 1921, thirteen cases of erythema nodosum were treated at the skin department of the Rikshospital in Christiania, and the inoculation of thirteen guinea-pigs with fresh nodes from nine of these patients invariably gave negative results. Early in 1922 inoculation of two guinea-pigs with the fresh nodes from a patient, aged 19, failed to provoke any disease, but cultures from the nodes yielded an anaerobic, short, Gram-positive streptococcus. The author adds that the frequency of the association of erythema nodosum with acute rheumatic conditions cannot be ignored, and the causal relationship of these two diseases must be disproved before the relation of erythema nodosum to the tubercle bacillus can be regarded as probable.

SURGERY.

440. The Surgical Treatment of Epilepsy.

L. PUSSER (*Klinische Wochenschrift*, October 21st, 1922, p. 2142) records the results of his operations on 318 cases of epilepsy during the last twenty years. In 13 cases only (4 per cent.) was a definite cure obtained (that is, no fits had occurred after five years). In 29 cases (14 per cent.) an interval of three years elapsed before the fits recurred. In 71 cases (28 per cent.) an interval of one year elapsed before the fits recurred. Thus 113 cases (one-third) had no fits in the first year after the operation. The best results were obtained in cases of circumscribed or localized cortical epilepsy—4 cases cured in 23 (17 per cent.). The portion of the brain surface presenting definite pathological changes was always removed. In traumatic localized cortical epilepsy the results were less favourable—3 cases cured in 43 (7 per cent.). In general traumatic epilepsy (showing scars or bone deformities) only 2 cases in 46 (4.3 per cent.) were cured. In non-traumatic cortical epilepsy, with general convulsions, only 4 in 97 cases were cured (4 per cent.). In 37 of these cases small serous cysts were found at the operation. No cures were obtained in 28 cases of general traumatic epilepsy without signs of skull injury, and also in 40 cases of essential (idiopathic) epilepsy, and in 19 cases of epilepsy with idiocy.

The author concludes: (1) That operative treatment is indicated in localized cortical epilepsy (limited cerebral cortex epilepsy) when the affection is not of long duration. (2) In traumatic epilepsy, both cortical and general, operation is only indicated when brain cortex symptoms are detected. In all other cases operation is not indicated. The author considers it best to remove all areas of the brain cortex and meninges presenting pathological changes. In cases where definite objective changes in the cortex are not detected the brain cortex should be stimulated by the electric current, and centres of increased excitability should be removed to a depth of about half a centimetre. It must be allowed that the surgical treatment of epilepsy is unsatisfactory. Cases in which the disease presents a definite localized character form an exception.

441. Radiography of the Appendix.

J. G. EDWARDS (*Med. Journ. of Australia*, August 26th, 1922, p. 238) points out that the value of radiographic examination in the diagnosis of appendix disease is little known to the general practitioner; the appendix shadow can be demonstrated in 80 per cent. of examinations. The patient is given a meal of barium sulphate suspended in mucilage of acacia. The stomach and duodenum are examined, and the patient is seen after six hours, and again after twenty-four hours. The caecum and appendix, when examined on the screen, may vary in level as much as four inches. The size of the lumen of the normal appendix is small and its outline regular; it should not contain barium after the caecum has emptied. The pathological appendix may have a lumen of large size and show segmentation. By palpation under the screen it can be shown whether the appendix is fixed by adhesions or kinked. The organ may be found in many unusual situations—it may be to the left of the mid-line or adherent to the pylorus or liver. When the appendix is adherent at its tip it drags on the loaded caecum and causes appendicular colic. Any marked delay in emptying points to a pathological condition. When the appendix cannot be seen adhesions of the ileum and caecum may be shown, with tenderness over the site of the appendix. This points to antecedent inflammatory lesions in the right iliac fossa. A loop of terminal ileum may be mistaken for the appendix, and is a possible source of error.

442. Gall-Bladder Problems.

W. BOYD (*Canadian Med. Assoc. Journ.*, October, 1922, p. 689) points out that the blood cholesterol is derived from a dual source, the first coming from the food by absorption through the intestine, the second being the cholesterol in the bile which is reabsorbed through the gall bladder, and that it is this circulating cholesterol which becomes deposited in the mucosa of the "strawberry gall bladder." It seems also that in some cases gall stones originate in the gall-bladder mucosa, eventually becoming detached and increasing in size from additional deposits of cholesterol and bile pigment. Under a low-power dissecting microscope the mucosa of the normal gall bladder, when immersed in water, shows tall, delicate, fine membranes covered by a tracery of blood vessels, and dividing the mucosa into a series of tiny, well-like spaces sunk between the surrounding walls. In the strawberry gall bladder these delicate folds become thickened and opaque, with yellow lipid material in discrete deposits along the ridges. Investigation shows that this lipid stains with ordinary fat stains, is soluble in ordinary fat solvents, is doubly refractive, and answers the chemical tests for the ester of cholesterol. Further examination showed that there was a real increase of cholesterol content in the strawberry cases, being sometimes 120 times more than normal. That the cholesterol content may vary in different parts of the same gall bladder was shown by one case in which two-thirds of the gall bladder showed advanced inflammatory changes without there being any lipid visible to the naked eye, while the remaining third showed a marked strawberry appearance though the inflammatory change was comparatively slight. Recent research and the anatomical arrangement of the mucosa point to the function of the gall bladder being one of absorption, and this receives further proof from investigations as to the effect of cholesterol feeding and cholecystectomy on the blood cholesterol in rabbits, it being found that the cholesterol in the bile is reabsorbed into the blood by means of this gall-bladder function.

443. Indications for Splenectomy.

M. CHIRAY (*Journ. de Méd. et de Chir. Prat.*, October 10th, 1922, p. 635), after an exhaustive study of the physiology, anatomy, and histology of the spleen, applies the ascertained facts to the question of splenectomy. With reference to experimental splenectomy, it is pointed out that the patients' power of resistance is not so great as that of laboratory animals, and that an unfortunate splenectomy may prove quickly fatal

OBSTETRICS AND GYNAECOLOGY.

446. Dublin Methods in Treatment of Eclampsia.

G. FITZGIBBON (*Brit. Journ. of Obstet. and Gynaecol.*, Autumn, 1922, p. 402), in a paper of which one of the objects is to emphasize the grouping of pregnancy albuminuria, hyperemesis, neuritis, accidental haemorrhage, and eclampsia as conditions of one and the same disease (toxæmia of pregnancy, with differing clinical pictures, of which albuminuria is the only universal symptom), describes the treatment carried out for toxæmia and eclampsia at the Rotunda Hospital in Dublin. The patient is kept in bed and given continued purgatives (3 oz. doses, two or three times daily, of *Enemata* are given at the beginning of the treatment if the bowels have not acted for some time. No food, but at least 6 pints of water are given daily; when the symptoms have abated and the urinary secretion is at least normal in amount, milk is added gradually to the diet. If the patient does not respond, or relapses, or if the foetus is dead, labour is induced; this, however, was only necessary in 5 of 40 cases, and then not before the eighth day of treatment. In cases characterized by much vomiting, this treatment is modified by withholding fluid by the mouth for from twenty-four to forty-eight hours and by giving frequent enemata; colonic lavage if the enemata are not effective, and subcutaneous infusions of sodium bicarbonate solution if the symptoms are severe; purgatives given orally can always be retained at the end of forty-eight hours. These lines of treatment are those adopted for pregnancy toxæmias; for pre-eclamptic states, and for eclampsia when the patient is sufficiently conscious to be able to drink. In a comatose eclamptic subject the stomach is washed out with sodium bicarbonate solution, of which about 15 oz., together with 4 oz. of mist. *sennae* co., are allowed to be retained. Through a long tube introduced per rectum into the colon (a procedure which is often difficult, and may take as long as two hours) irrigation with soapy water is carried out until the bowel contents appear in and then disappear. The irrigation is continued with sodium bicarbonate solution, and 2 pints are left in, with 4 oz. of mist. *sennae* co. This is repeated at five-hourly intervals until the patient is sufficiently conscious to drink, or until the presenting part reaches the perineum; otherwise it is then interfered with, nor induced when not present. The comatose patient is kept on her side, is given large quantities of the loius sodium bicarbonate. This treatment is substantially that introduced by Hastings Tweedy in 1903, modified by reduction of the amount of morphine given, which in the latest cases has frequently been nil and has not exceeded 1/2 grain. The twenty years' 214 consecutive eclamptic cases have shown the exceptionally low mortality of 8.87 per cent. BETHEL (Ibid., p. 416) describes a similar treatment. He emphasizes the importance of careful watching in an adequately lighted room, by a skilled observer, of the comatose patient; mucus may be swabbed out from the throat from time to time, and the patient's head and shoulders made to hang over the side of the bed with the face down. He advises routine injection of sodium bicarbonate solution under the breasts in all but the mildest cases.

447. Frequency of Pulmonary Complications in Puerperal Sepsis.

J. HAGEMANN (*Dtsch. med. Woch.*, October 13th, 1922, p. 1376), in a review of the literature of puerperal sepsis, observes that most authorities touch on pulmonary complications very lightly, usually dismissing them with a casual reference to the possibilities of pulmonary thrombosis and embolism. This neglect of the pulmonary factor is the more astonishing as pulmonary disease is often the cause of death in puerperal sepsis. To obtain exact information on this subject the author has investigated the records of 209 fatal cases of puerperal sepsis occurring at the Rudolf Virchow Hospital in Berlin. Some of them were *post-partum* cases, but the majority were due to abortions. Necropsies were performed in 147 cases, and only in 35, or 23 per cent., were no morbid changes found in the lungs. Thus in 77 per cent. the lungs were involved. Of the 112 cases of pulmonary complications the first stage of a pneumonia, which was presumably there were 24 of simple hyperaemia, which was presumably perfectly healthy, although abscesses were found in the liver. As pulmonary complications occur in more than three-quarters of all cases of puerperal sepsis they deserve more attention than they have hitherto received.

448. Influence of Thyroidectomy on the Heart in Graves's Disease.

EINER (*Schweiz. med. Woch.*, August 31st, 1922, p. 872) has made a study of the heart in 80 cases one year after thyroidectomy, and he has come to the conclusion that the degree of compression of the trachea, as a rule, proportional to the which the trachea had not returned to its normal shape after the thyroidectomy, yet the respiratory disturbances completely disappeared. It seems that the pressure on the trachea causes respiratory distress independently of the degree of compression of the trachea. Tracheal stenosis had no influence on the hypertrophy of the heart, and, indeed, such hypertrophy was comparatively rare in association with marked compression of the trachea. In toxic disease of the thyroid hypertrophy of the heart was twice as common as in cases of goitre exerting a chiefly mechanical action. In about three-quarters of all the cases thyroidectomy was followed by a reduction of the heart to normal dimensions, and this process was most evident in cases of toxic goitre. The results of thyroidectomy were in other respects satisfactory, exophthalmos and tremor having invariably disappeared and nervousness having vanished or become slighter. Subjective heart symptoms and tachycardia had also disappeared or become less, and in most cases adventitious heart sounds had disappeared. The author's verdict is therefore emphatically in favour of thyroidectomy in selected cases.

449. Ulcer of the Stomach treated by Division of the Sympathetic Nerve.

R. PROUST (*Bull. et Mém. Soc. Chir. de Paris*, July 18th, 1922, p. 994) reports three cases of ulcer of the lesser curvature of the stomach treated by division of the sympathetic nerves. In two cases there was immediate relief of the pain, whilst in the third case the pain disappeared more slowly. In dividing the nerve fibres it may be found advisable to divide the coronary artery. Parman and Dorells have described a plexus of gastric nerve fibres sharply defined; this enables the nerves to be isolated and divided in a set operation. The author prefers a limited division of the nerve fibres rather than a massive resection of the vessels and nerves surrounding them. In the three recorded cases a gastro-enterostomy was also carried out; this may account for the good results. It is difficult to differentiate the effect of the two procedures. In those cases resection of the ulcer was not possible, and the section of the nerves to the stomach led to great improvement in the patients' condition. It should be possible in the future to carry out the operation by dividing the nerves and leaving, so far as possible, the vessels intact.

448. Myomata and High Blood Pressure.

J. O. POLAK, E. A. MITTELL, and A. B. MCGRATH (*Amer. Journ. of Obstet. and Gynecol.*, September, 1922, p. 227) conclude, from examination of 416 patients suffering from uterine myoma, that there is no effect on the blood pressure which can be attributed to the presence of myomata in young women; these myomatous subjects who have high blood pressure are usually over 40 years old or show signs of renal or cardio-vascular disease. Patients who have suffered from excessive haemorrhages do not appear to have lower blood pressure than other myomatous patients. Although removal of the uterus and appendages of both sides is followed during a varying period by increase of blood pressure, the pre-operative pressure is rapidly regained unless some intercurrent morbid condition is present.

449. Aneurysm of the Uterine Vessels.

E. VÖGT (*Zentralbl. f. Gynäk.*, September 9th, 1922, p. 1469) records a case in which, five years after a war injury from a bomb splinter, a pulsating, compressible swelling, somewhat larger than a hen's egg, was found occupying the left antero-lateral portion of the vaginal vault. A loud murmur, more intense during systole, was audible over the common iliac and femoral arteries as well as the lower part of the abdominal aorta. Operation was indicated by reason of the danger of compression of the ureter, bladder, and pelvic nervous and vascular trunks, and by the danger of rupture of the aneurysm during pregnancy or labour. The excised preparation showed an arterio-venous aneurysm, of which the wall in the venous portion was thickened but not "arterialized."

450. Treatment of Eclampsia.

R. MCPHERSON (*Amer. Journ. of Obstet. and Gynecol.*, July, 1922, p. 50) has treated 104 cases of eclampsia according to the following plan: On admission to hospital the patient's blood pressure is measured, a catheter specimen of the urine is taken, and she is placed in a darkened and quiet room. One-half of a grain of morphine having been given subcutaneously, the stomach is washed out, 2 ounces of castor oil are poured down the tube, and subsequently the colon is irrigated with 5 gallons of 5 per cent. glucose solution. If the systolic blood pressure is greater than 175 mm., phlebotomy is done, a sufficient amount of blood being abstracted to reduce the pressure to 150 mm. It is unwise to bleed a patient whose blood pressure is less than 175 mm., for if for any reason a good deal of blood is lost during delivery the pressure may be so reduced that the patient may die from shock; the same objection applies to *ante-partum* injections of large doses of veratrum viride. The patient subsequently receives a dose of morphine (1/4 grain) every hour until the respirations drop to 8 a minute; at this time the convulsions have usually ceased, and the patient is generally in labour. Occasionally while one is waiting for the effect of the morphine it is necessary to control the convulsions by administration of ether. In almost all cases the patient is delivered spontaneously or by an easy low forceps operation. In the writer's series the maternal mortality (moribund cases included) was 16.3 per cent. and the foetal deaths were 25.4 per cent.—figures considerably less than those obtained after accouchement forcé or Caesarean section.

PATHOLOGY.**451. Familial Immunity to Diphtheria.**

In order to gain some idea as to the distribution of immunity to diphtheria amongst members of the same family, E. RIST and M. WEISS (*Ann. de Méd.*, November, 1922, p. 356) have carried out a series of Schick reactions on the members of 33 families, and have made a very careful analysis of the results obtained. Altogether 169 persons were tested, of whom 87 were under 15 years of age and 82 above this age. The percentage of positive reactions followed a regular curve, decreasing with advancing age; thus in children from 1 to 5 years it was 68 per cent., in children of 8 years it was about 50 per cent., while in adults it was only 24 per cent. The percentage of pseudo-reactions described a curve in the opposite direction, being 6.8 per cent. for children of 5 to 10 years, and 17.5 per cent. for adults; the curve was irregular for children under 5 years. Of 28 families containing two or more children the reaction was concordant between the brothers and sisters in 12—7 positive and 5 negative—while in the remaining 16 families the results disagreed. In this latter case it was generally found that the elder children gave a negative reaction, and the younger ones a positive reaction. No definite relation between the immunity of the mother and that of her children over 1 year of age could be established. The age at which

the children ceased to give positive reactions varied considerably; in some families it became negative at the age of 5, while in others the transition had not occurred even at 29 years of age. In those families in which a child had suffered from diphtheria several years previously, the brothers and sisters who had witnessed the attack generally gave a negative reaction, while these children born subsequently were generally positive; curiously enough, the actual patient was more often positive than negative, indicating that an attack of diphtheria is not a sure method of acquiring immunity against it. It will be seen that these results are in agreement with the large amount of work which has been previously done on the subject.

452. Variations in the Coagulation Time during Pregnancy.

In normal individuals the coagulation time of the blood has a constant value of approximately three minutes, with not more than half a minute's variation each way. P. EMLE-WEIL, BOGAGE, and LECHE-WALL (*C. R. Soc. de Biologie*, October 14th, 1922, p. 925) find, however, that in pregnancy there is considerable irregularity in this time; nearly always it is increased, variable, and subject to quite arrhythmical fluctuations. This change appears at the commencement of gestation, and continues till after delivery, and sometimes longer. It appears to be more marked in the case of women who have previously displayed haemorrhagic tendencies. It is interesting to note that this delay in coagulation has apparently no relation with the number of blood platelets, which are usually present in normal quantity. All the women studied showed slight anomalies in the actual process of clotting, such as sedimentation of the red cells with coagulation of the plasma, diminution in the retractility of the clot, or disintegration of the coagulum. All these changes the authors would refer to some degree of hepatic insufficiency, and conclude that pregnancy in urban women is no longer a physiological state as it should be. Experiments on guinea-pigs show that there is no difference in the coagulation time between males and females, or, in the latter, between gravid and non-gravid animals.

453. Eosinophilia in Muscular Rheumatism.

E. BANAUDI (*R. Politecnico*, Sez. Prat., October 9th, 1922, p. 1322) records the results of his researches in eosinophilia in 7 cases of muscular rheumatism, the distribution of which was as follows: neck muscles, lower limbs, shoulders and back, thoracic muscles, lumbar region, generalized. All other causes, such as dermatoses, helminthiasis, etc., could be excluded. The eosinophilia varied from 6 to 13 per cent.—a finding which agreed fairly closely with those of Bittorf and Stackert. There was no increase in the lymphocytes, however, as found by Stackert. On the other hand, there was a slight diminution in the neutrophil polymorphonuclears, as if the increase in the eosinophiles had taken place at their expense. The eosinophilia was found to be directly dependent upon muscular rheumatism, because it disappeared entirely as soon as the disease was cured. The degree of eosinophilia was in direct proportion to the severity of the disease, the eosinophilia being slight and transient in mild forms and as high as 13 per cent. in severe attacks.

454. Changes in the Amount of Cholesterol in the Blood in Cholelithiasis.

M. v. BABARCY (*Klinische Wochenschrift*, September 9th, 1922, p. 1828) has estimated the amount of cholesterol in the blood in a number of affections, and gives the results of previous observers. (The estimations were made according to Bloor's method, but Helligo's colorimeter was used.) The conditions in cholelithiasis were chiefly studied. The percentage of cholesterol in the blood in this affection was found to be sometimes normal, sometimes diminished, sometimes increased. The author found, however, an increase in the percentage of cholesterol in the blood in all cases of cholelithiasis on the morning following an attack of gall-stone colic. This occurred both in cases with and without jaundice. In the colic and crises associated with other affections (nephrolithiasis, gastric crises, ulcer of the stomach, etc.) this increase of the percentage of cholesterol in the blood did not occur. The author thinks that the increase in the percentage of cholesterol in the blood directly after an attack of gall-stone colic is due to diminished excretion of cholesterol by the liver. From these observations Babarczy concludes: (1) that in cholelithiasis the amount of cholesterol in the blood is normal, in uncomplicated cases, between the attacks of gall-stone colic; (2) that the cholesterol in the blood increases directly after an attack of gall-stone colic—hypercholesterinaemia occurs, which continues about a week; (3) that this increase of the percentage of cholesterol in the blood is so constant that it is of value in the differential diagnosis of gall-stone colic from other affections producing somewhat similar symptoms.

NINETIETH ANNUAL MEETING

OF THE

British Medical Association.

Held at Glasgow, July, 1922.

PROCEEDINGS OF SECTIONS.

SECTION OF OPHTHALMOLOGY.

A. S. PERCIVAL, M.B., B.Ch.Camb., President.

PRESIDENT'S INTRODUCTORY REMARKS.

THE PRESIDENT of the Section, in opening the proceedings, said that he felt very deeply the high honour that had been conferred upon him in his selection for this office, especially when there were so many ophthalmic surgeons in this city of Glasgow of such outstanding merit for the office. The programme the Committee had prepared was excellent, and he looked for a free scientific discussion of the papers that would be read, so that the proceedings of this Section might not be unworthy of this great city and of the Association. Even if few conclusions could be drawn from the interchange of opinion, let them console themselves with the words of Joubert: "Il vaut mieux remuer une question sans la décider, que la décider sans la remuer."

DISCUSSION ON

THE ETIOLOGY OF OPTIC NERVE ATROPHY.

OPENING PAPERS.

I.—C. O. HAWTHORNE, M.D. GLASG., F.R.C.P. LOND.,

Consulting Physician, Central London Ophthalmic Hospital.

IN an endeavour to discharge the duty of opening this discussion I propose to present the causes of optic nerve atrophy in a series of groups. In some of these the harmful agency is open, manifest, and direct; and the interest is mainly topical and surgical. Others form part of the larger and more obscure problems of disease as this occurs in the nervous and cardio-vascular systems; and the appeal is specially to the physician. But no rigid dividing line can be drawn or ought to be drawn, for the processes of pathology do not accommodate themselves to an imposed scheme of professional titular distinctions.

Trauma.

Here the causes of optic nerve atrophy usually lie upon the surface. Wounds penetrating into the orbit, tumours of the optic nerve trunk, and intraorbital cellulitis, periostitis, and morbid growths, are conditions each one of which, obviously, may inflict damage either on the optic nerve or on its blood supply, and may thus directly or indirectly be the starting point of a process of atrophic degeneration. As exceptional experiences, lightning, electric flashes, clipso blindness, and exposure to an arc lamp have, in turn, been held responsible for optic nerve atrophy. These fashions of immediate injury I leave hopefully to my surgical colleagues. From the same source, too, I hope we may hear something of indirect violence as a cause of changes in the optic nerve and in the function of vision. Fractures of the base of the skull in the anterior fossa may, as is well known, damage the optic nerve. Here, however, the violence, relative to the nerve at all events, is direct and the loss of sight immediate, though ophthalmoscopic evidence of the nerve atrophy may be postponed. The reference I wish to make is to violence which either does not implicate the skull at all, or, if it is applied to the skull, does not cause fracture of the base in the anterior fossa. I suggest that in such cases mischief leading to optic atrophy may occur, and that, as the failure of vision is apt to be delayed, a difference of opinion relative to the responsibility of the accident may arise and an acute legal issue may be raised. I quote briefly two records.

One, that of a middle-aged woman who, two months after being thrown into a ditch from a motor car, complained of defective sight of the right eye; visual acuity was reduced to 6/18 and the optic disc was unduly white. Fortunately in this instance an ophthalmoscopic examination had been made and the presence of retinal haemorrhages noted shortly after the accident; it was therefore an easy thing to say that the accident was responsible.

In the second record such a conclusion, at least for a time, was not so obvious. The patient, a man of 43 years, was admitted to hospital as a possible case of intracranial tumour, there being exudation and haemorrhages at each optic disc. Two months previously he had fallen from a lorry, and after being examined at a hospital had become unconscious on reaching home. After three weeks in an infirmary he appeared to be quite well. Later his sight became dim and a bilateral optic neuritis with haemorrhages in all other respects, examination, skull, investigation of the nasal fossae, Wassermann test to the blood serum and the cerebro-spinal fluid, was negative. Gradually the swelling of the optic discs subsided and the patient left the hospital perfectly well and with only a slight reduction of his visual acuity; and four and a half years later the conditions were unchanged.

Are such cases examples of haemorrhage into the sheath of the optic nerve? Whatever be their pathology, they certainly have considerable medico-legal importance, and I propose them as worthy of the attention of the Section.

Poisons.

There are various poisons that are well recognized as competent to produce optic nerve atrophies. Here again I shall leave the ground mainly to my colleagues. But I will ask two or three questions. Some few years ago certain organic preparations of arsenic acquired an evil reputation as provokers of optic atrophy. Are the more modern preparations quite safe in this respect? Again, is arsenic in an inorganic form entirely free from risk? At one time it was the fashion to give Fowler's solution in large doses to children suffering from chorea, and in occasional instances the medicine, by inadvertence, was continued until it produced peripheral neuritis. But neither in such cases nor in any other have I personally seen any reason to believe that there was peril of optic nerve atrophy; and in none of the recent notorious cases of poisoning by arsenious oxide do we seem to have heard of any recognized visual defect. Yet a few cases of central scotoma following inorganic arsenates have been recorded.

A second question is, Are patients with a bilateral central scotoma always regarded as possible examples of disseminated sclerosis or of tabes dorsalis? Tobacco, no doubt, is a ready explanation and often a correct one, but such a conclusion, I suggest, is not secure until it is supported by the negative results of a complete examination of the nervous system.

Lead, quinine, sodium salicylate, methyl alcohol, and carbon bisulphide are other agents, each of which in turn has been found guilty of a toxic influence on the optic nerves. Glycosuria, I should say, does occasionally come into the same category, but the case against ordinary alcoholic beverages appears to be "not proven." The combination of excess of alcohol and excess of tobacco is regarded generally as a bad omelette, yet Sir Jonathan Hutchinson used to teach that alcohol, far from aiding the poisonous action of tobacco, afforded some protection against this disaster.

Syphilis.

Syphilis admittedly exercises a wide range of influence in the production of optic nerve atrophy. In the hereditary form of the disease the atrophy may be a part of a widespread choroido-retinal ruin; or it may be associated with an ordinary disseminated choroiditis; or, but for the atrophic discs, the fundus may appear normal, with, perhaps, choroido-retinal mischiefs or other signs of the infection in other members of the family. There is here a group of cases (far from frequent) that invite discussion—namely, cases of juvenile tabes dorsalis; and the point I wish to raise is the maximum age limit at which this form of disease may manifest itself. I have notes of cases in which optic atrophy, as part of a tabes dorsalis, was first observed at 17, 24, and 28 years respectively, and though at these ages the absolute exclusion of the acquired disease is difficult, it must be admitted that in patients under 30 years the development of tabes dorsalis apart from hereditary specific disease is most exceptional. Moreover, it will be allowed that some of the exhibitions of hereditary syphilis—interstitial keratitis, for example—may be postponed to the twenties or even to the thirties, so that there is no antecedent improbability that optic atrophy and tabes dorsalis may share in this delay. I suggest that the experience of members of the Section on this point would be valuable.

In acquired syphilis both post-neuritic optic atrophy and primary atrophy occur. The neuritis responsible for the first of these is, I should say, a very exceptional event in the early stage of the disease; I have once seen it as early as four months after infection, and I suppose it must here be regarded

as due to the direct action of the poison on the optic nerves. In the later stages, and when it is accompanied by headache, more or less severe, the presumption is in favour of intracranial gumma or syphilitic meningitis.

Primary optic atrophy due to syphilis is, of course, a familiar experience in *tuberculous* and to a less extent in general paralysis of the insane. Though there is little if anything new to say, I venture a remark or two on some of its well-known features. Its distribution is invariably bilateral, though the two eyes are at an early date often found unequally affected. It moves, invariably I think, to complete blindness. The onset is announced by peripheral contraction of the visual fields, either for white or colours or for both, yet with this, central visual acuity may remain good for a relatively considerable period; occasionally a central scotoma is observed. Personally I have never seen hemianopsia, but instances of this defect have been recorded. The discs are usually characteristic, though the apparent changes are not always equal to the visual defect. The optic atrophy may precede ataxia by many years, or spinal symptoms may follow at a comparatively early date; sometimes optic atrophy develops after ataxia has been definitely established, and in some of these last mentioned cases the loss of sight is associated with relief of the spinal symptoms.

Two questions may be presented for discussion. First, is optic atrophy, as one of the peripheral nerve degenerations of *tuberculous*, frequently accompanied by other peripheral defects such as cutaneous anaesthesia and nerve deafness? Of cutaneous anaesthesia I have collected some observations, but I have not found any reason to believe that this symptom is more frequent with optic atrophy than it is in cases from which optic atrophy is absent. Nerve deafness in *tuberculous* I can remember only in two patients, and while one of these was blind the other had normal vision.

A second question is, Do all cases of bilateral primary optic atrophy, not otherwise explained, belong to the *tuberculous* group? It is admitted that optic atrophy may by many years precede an ataxic gait, but it is said also that it never precedes loss of the knee-jerks or lightning pains in the lower limbs. If this latter statement is correct a primary optic atrophy existing as an isolated event cannot be named tabetic atrophy. For my own part I will venture to say the statement is not strictly correct, for now and again—rarely, I admit—evidences of optic atrophy are found with normal knee-jerks, and these at a later date disappear. But, again, cases of primary optic atrophy, with undisturbed tendon jerks, in patients giving a positive Wassermann reaction, are not very uncommon, and in some of these the atrophy is accompanied by a defective pupillary light response or by an ocular paralysis. No one, I take it, will say that the Argyll Robertson pupil or an ocular palsy in a syphilitic patient, even though the knee jerks are present, means anything different from what is involved in the association of one or other of these events with absence of the knee-jerks. Why, then, should an optic nerve atrophy in a syphilitic patient with evident knee-jerks be placed in a different category from optic nerve atrophy in a similar patient with absent knee-jerks? The principle here advocated has its parallel in tabetic neuralgia, which sometimes is associated with retention of the knee-jerks and sometimes with their loss; yet no one will propose the separation of the two groups. And if I dared to venture on a decidedly speculative argument I would remind members that occasional instances of return of the knee-jerks in *tuberculous* have been noted. Suppose that this happened in a case of optic atrophy: is the earlier phase to be named tabetic atrophy and the later phase to be denied this title? Hence my submission would be that optic atrophy, the Argyll Robertson pupil, and an ocular paralysis are three events any one of which may be the first announcement of parasyphilitic degeneration in the nervous system; that each may be associated sooner or later with evidences of parallel changes in the spinal cord; and that each may persist for a prolonged period, and perhaps indefinitely, without the development of spinal symptoms. In a word, I suggest that primary optic nerve atrophy, accompanied by evidences of specific infection, has one and the same clinical position and one and the same clinical prospect whether the knee-jerks be present or absent. This is not to say that optic atrophy as an isolated event, either in the post-neuritic or in the primary form, invariably means specific infection. Indeed, there are instances where such infection can be confidently excluded, and we are thus driven to admit occasional cases of optic atrophy, as of optic neuritis, for which we are unable to define any confident causation. I remember that some years

ago Dr. Leslie Buchanan of this university described a case of such cases, and the gratifying feature of the record was that under the persevering use of potassium iodide and strychnine in liberal doses the patients recovered a fair measure of vision. If we can hear further of these cases to-day it will be a welcome contribution to our discussion.

Intracranial Tumours.

The primary optic atrophy, accompanied by bitemporal hemianopsia, that may be traced to the pressure of a pituitary tumour, is a well-recognized experience. The most interesting aspect of it in recent years is the improvement that can be effected by intracranial operation. I propose to say nothing more on the subject of pituitary tumours except to remind members of Mr. Herbert Fisher's ably argued thesis that on pituitary enlargements there probably depends the so-called hereditary or family optic atrophy (Leber's disease); it offers a considerable opportunity for discussion. There are also other issues that I wish to raise. First, I ask whether intracranial tumours other than pituitary growths ever cause primary optic atrophy.

My attention was particularly directed to this point by the case of a boy who suffered from recurrent attacks of headache and vomiting relieved by repeated lumbar puncture. The optic discs were always noted as "white," but the boy appeared to see perfectly well until one morning he suddenly told the ward sister that he was blind. At no time, the observations being repeated over many months, was there any suggestion of swelling of the discs, and the case was clearly one of primary optic atrophy. Necessarily this raised the question of a pituitary growth and a possible operation. But as there was a bilateral extensor response, and as a diagram did not show any enlargement of the sella turcica, operation was not advised. The decision was a fortunate one, for the *post-mortem* examination showed the existence of several intracranial tumours, and while one of these from its relation to the floor of the third ventricle might have pressed on the optic commissure, there was no enlargement or peculiarity of the pituitary body.

Since this experience I have noted a case, described by Arnold Knapp, in which primary optic atrophy was found in a man of 36 years, proved on *post-mortem* examination to be the subject of a tumour of the frontal lobe. The tumour had led to a sacculated distension of the third ventricle, and hence, presumably, was the agency responsible for the bilateral optic atrophy. Now that the pituitary body is so readily within the reach of surgery, there is need carefully to consider how far tumours outside the sella turcica are capable of producing primary bilateral optic atrophy.

A further topic relative to brain tumours and optic nerve atrophy is provided by the following facts. Bilateral optic atrophy, plainly post-neuritic for the most part, and accompanied by blindness, is found in a group of patients, mostly young adults, who give a history in their earlier years of vomiting, headache, and other intracranial and other symptoms, with the exception of the lesion. From these symptoms, with the exception of the blindness, they have made a good recovery. What was the nature of the original illness? My suggestion is that these are cases of intracranial tumour, that the tumour has become quiescent, and that the post-neuritic atrophy is the one persisting effect of its existence.

In connexion with brain tumours and optic atrophy, Mr. Fisher's doctrine is perhaps the most inviting issue, but the relation of brain tumour to primary optic atrophy and the problem presented by the group of cases I have just defined seem to me topics well worthy of the attention of the Section. A minor and perhaps purely academic debate is whether a second attack of papillitis is possible in a disc rendered atrophic by a previous optic neuritis. Admittedly such a development is exceptional. I have notes of a case in which the second papillitis appeared three years after the original illness, the boy having been quite blind during the interval; and an occasional even longer period has been recorded.

Again, we may hope that members who are particularly interested in the relations between nasal disease and ocular disturbances may have something to say on optic atrophy due to sphenoidal sinus suppuration and on the atrophy associated with cerebro-spinal rhinorrhoea.

Meningitis.

Meningitis in its various forms is for the most part so acute and so fatal a disease that while optic neuritis may be a feature of it, optic atrophy, if it occurs at all, must be very exceptional. Now and again, however, atrophy is seen in a patient in whom there is a history of "convulsions" in

early life, but whether meningitis or encephalitis or hydrocephalus or some other agency is responsible I cannot pretend to say. Another issue which is perhaps relevant to the present discussion is, What is the cause of the temporary blindness occurring without obvious ophthalmoscopic changes in children suffering from posterior basic meningitis?

A further debate is possible on the development of optic atrophy in the primary spastic paraplegia of early life. There is here no question of specific disease, and it will be remembered that Sir William Gowers quoted these cases as examples of what he called abiotic wasting—premature tissue failure the consequence of a defective vital equipment. Can an alternative hypothesis be advanced?

Cardio-vascular Diseases.

The most obvious cases of optic atrophy resulting from vascular disease—they are not frequent—are those in which the central artery of the retina is the site of thrombosis. There may be some degree of papillitis and oedema of the retina and a few retinal haemorrhages, but the most conspicuous ophthalmoscopic fact is the fairly rapidly developed pallor of the optic disc with narrowed retinal arteries. The patients for the most part are elderly with general evidences of cardio-vascular degeneration. There is not always a high sphygmomanometer reading, but the absence of this, of course, does not exclude arterial change. The retinal thrombosis may exist as an isolated event, or it may be associated with other disturbances. In one of my records the patient—a woman of 70 years—suffered from paralysis of the left external rectus muscle for some months and then became blind in the left eye. In another—a man of 45 years—there had been two attacks of hemiplegia; the sphygmomanometer reading did not exceed 140, and neither the blood serum nor the cerebrospinal fluid gave a positive Wassermann reaction. Once—the patient a woman of 75 years—I have known thrombosis in one retinal artery repeated in the course of a few days in the artery of the opposite side.

Belonging to the same order are the occasional cases of unilateral optic atrophy with hemiplegia on the opposite side of the body. Here the presumption is that thrombosis has occurred in the cavernous portion of the internal carotid artery and that, either by extension of the thrombosis or by embolism, the ophthalmic branch of the artery or its subdivision, the central artery of the retina, is occluded.

Another fashion in which optic atrophy may result from vascular disease is when optic neuritis is associated with retinal haemorrhages and retinitis resulting from arterial degeneration; the haemorrhages and exudates may be absorbed, and the ophthalmoscopic picture may display little more than post-neuritic optic atrophy; and with this the patient is in greater or less measure blind.

Next, I must mention embolism of the retinal artery. The diagnosis appears to present no difficulty when the patient is the subject of cardiac valvular disease, but when there is no such disease the absence of any obvious source from which an embolus can take origin is a difficulty. Hence it is alleged that not a few cases named "retinal embolism" are really examples either of local arterial disease with thrombosis *in situ* or of arterial spasm. The suggestion of thrombosis *in situ* may be readily allowed in patients carrying obvious signs of degenerate arteries, and there are records that go to show that in such patients, too, spasm is at least a possibility. But in young adults free from signs of arterial disease thrombosis *in situ* can hardly be applied. Is, then, arterial spasm the inevitable explanation? It is not without weighty sponsors. The term "retinal epilepsy" was invented, I believe, by Hughlings Jackson, and under this title a number of cases were recorded by no less an authority than Jonathan Hutchinson. He believed the condition to be particularly associated with what he called "liver disturbance and sick headaches"; some of his patients were young women, and in more than one instance the affected eye became blind and the nerve atrophic. But with great respect I venture to point out that quasi-retinal embolism occurs in patients free from migrainous seizures, and, indeed, from all symptoms other than those due to anaemia; also that it occurs without any previous attacks of temporary failure of sight. On the contrary, it arrives with characteristic suddenness, and is promptly followed by optic nerve atrophy. My proposal is that these are examples of true embolism and that the obstructing clot is provided by intracardiac thrombosis—an event which, in patients with chlorosis, must be admitted as at least a possibility. It may be objected that were this true, embolism would

probably appear in other organs. Are we quite sure they do not? Embolism of the spleen and even of the kidney may be silent happenings, as is manifest in *post-mortem* examinations in cases of mitral disease; and they may therefore be equally undemonstrative in intracardiac thrombosis. Further, is it likely that in a patient structurally sound, though the subject of anaemia, a healthy retinal artery will at one swoop, as it were, be thrown into such a severe and sustained spasm as to produce complete atrophy of the optic nerve? And if spasm, why should it be unilateral? It may perhaps be said that the spasm leads to thrombosis. But this is surely improbable unless the spasm is so extreme as completely to occlude the vessel. Some narrowing of the vessel would hinder the circulation, but would not suspend it, and a sustained spasmodic and complete closure of the artery, if not a contradiction in terms, is not easy to imagine. On the whole, arterial spasm may be deemed insufficient to account for the optic atrophy that follows a sudden and final closure of the retinal artery in patients free from evidences of cardiac valvular disease and from signs of arterial degeneration. If the obstructing agent is not produced on the spot it must be carried from a distance—that is, it must be an embolus—and a possible source of such embolus may be found, I submit, in an intracardiac thrombosis.

I have notes of two cases of retinal embolism in which central vision was preserved, obviously by the agency of a cilio-retinal artery; each patient was the subject of mitral disease, and in one vision has remained unchanged over a period of three years, and in the other for more than fourteen years.

I allude, in a word only, to the optic atrophy that occasionally follows loss of blood. Personally, I have seen a few instances after gastro-intestinal and uterine haemorrhages, but some cases are recorded as following traumatic bleeding. There is obvious room for speculation both as to the fashion in which haemorrhage produces the blindness, sometimes promptly and sometimes after an interval of days; and again, how it comes about that while loss of blood is a frequent experience, optic atrophy, though it sometimes follows the loss, does so only in a very small minority of cases.

Retrolbulbar Neuritis.

Occurring as a more or less acute condition, and affecting one or both eyes, retrolbulbar neuritis may proceed to partial or complete optic atrophy; or it may, on the other hand, undergo resolution with restoration of a full standard of vision. It may appear as an isolated event, or it may be manifestly one of a series of pathological disturbances spread widely through the nervous system. The most conspicuous example of the latter possibility is seen in the rare cases named acute myelitis with optic neuritis. Here, as the patient's life is in manifest danger, the optic neuritis seems relatively an unimportant feature. But two points are worthy of notice. One, that what appears at the time nothing more than a unilateral retrolbulbar neuritis may, in the course of a few days, be followed by severe and widespread paralytic phenomena; and the other, that even in an extreme case complete recovery, including a full measure of vision, with or without obvious whitening of the optic discs, is possible.

A second disease in which retrolbulbar neuritis is plainly part of a widespread nervous disorder is disseminated sclerosis. Here again failure of sight may be one of the first evidences of the disease; and the failure may be due either to a slowly increasing optic nerve atrophy, or to a more or less acute retrolbulbar neuritis, with such chance of atrophy as this involves. Still more, either the one or the other of these ophthalmological complications may appear after the spinal symptoms of the disease are well established. I have never seen a gradual bilateral optic nerve atrophy proceed to complete blindness in disseminated sclerosis, though atrophy after a retrolbulbar neuritis may reduce, and even permanently reduce, visual acuity to a short remove from complete blindness. For the most part, however, loss of sight due to retrolbulbar neuritis, whether this occurs as an isolated event or as a member of the series we call disseminated sclerosis, begins to improve in the course of a few weeks, and vision may well reach a normal standard even though pallor of the disc remains as an obvious ophthalmoscopic fact; there is, however, some risk of recurrence either in the same or in the opposite eye. To recognize retrolbulbar neuritis as part of a disseminated sclerosis when it is associated with spinal symptoms of the disease is a simple undertaking. Apart from the immediate or close association of the one with the other

in the order of time, the suddenness of the visual loss, the subsequent rapid improvement, and the occasional recurrences, are experiences that exactly correspond to other clinical exhibitions of the pathological process. Nor is there much difficulty in the not uncommon cases where with pronounced evidences of spinal sclerosis the patient affirms that in an earlier day there had been a unilateral or a bilateral failure of sight; and some confirmation of this is found in the ophthalmoscopic appearances of one or both optic discs. It is necessary to advance another step, for, as a matter of fact, whatever be the explanation, retrobulbar neuritis unaccompanied by any other clinical evidence of disease may yet, after some years of apparently good health, be followed by quite unchallenged disseminated sclerosis. Can such an experience be dismissed as a mere coincidence? In view of all the facts this seems most unlikely. I have known the interval extend to eight, ten, and even to twelve years, and hence it seems necessary to conclude that a retrobulbar neuritis, unless otherwise explained, involves a risk of the development of disseminated sclerosis, and that this risk is not exhausted until a considerable period of years has been counted.

There therefore arises the question whether retrobulbar neuritis beginning as an isolated clinical event does ever remain permanently in isolation and free from later developments in the shape of nervous disease. To state a confident affirmative answer must in the circumstances be difficult, as in each individual case years must elapse before the answer has a sure foundation. The longest continuous record that I possess runs from 1919 to 1922, and though the patient's left eye has remained almost blind (optic atrophy) he has been and still is in other respects perfectly well. Another observation suggesting that retrobulbar neuritis does sometimes fall outside the series we call disseminated sclerosis is the fact that it occasionally occurs at an age when disseminated sclerosis is no longer probable. I have notes of two patients (women) at 50 years and one (a man) at 43 years. It is very difficult to imagine the exact pathology of these cases of uncomplicated retrobulbar neuritis. Clearly the lesion must be within the orbit and must involve the trunk of the optic nerve. I have on two occasions seen an ocular paralysis associated with retrobulbar neuritis, so that the lesion is not always limited to the optic nerve; nor even when so limited is it purely the papillo-macular bundle that is involved, for the scotoma, while usually central, does sometimes extend so as to include a complete sector of the visual field. The association of uterine and menstrual disturbances with retrobulbar neuritis has sometimes been regarded as significant, but manifestly this does not cover the field, for men as well as women are among the victims.

There is a further group of cases in which the evidences of retrobulbar neuritis in one or both eyes (central scotoma, loss of colour vision, and even complete blindness) are found with conspicuous exudation at one or both optic discs. The most extreme examples of this combination I have seen have been in young girls, and one of the most impressive facts in the record has been the rapidity (a few weeks or months) with which sight is restored and the exudation removed. I have been able to observe some of these cases for a year or more (one over seven years) without any new disturbance either in the visual function or elsewhere. Yet there are instances in which permanent atrophic changes are established in one or both optic discs.

The group of cases last mentioned leads naturally to the papillitis occasionally noted in the subjects of chlorosis. In most of these cases resolution is complete, but I have occasionally seen permanent prejudice to vision from optic nerve atrophy. Some years ago I attempted to argue that the cause of optic neuritis in chlorosis is thrombosis of the intra-cranial veins or sinuses; also that retrobulbar neuritis may be due to peripheral venous thrombosis. I will not repeat the reasons for this suggestion, but if any members of the Section can throw any light on the topic I am sure their aid will be welcomed.

What I do propose as significant is the relations of retrobulbar neuritis (with its risk of nerve atrophy) as I have here endeavoured to sketch them. First, we have the neuritis associated with an acute inflammatory process affecting widely the nervous system (myelitis), and hardly to be explained apart from the presence of some toxic agency; next, with a less acute but equally widespread disease (disseminated sclerosis) that must own a not dissimilar influence; in a third group we find retrobulbar neuritis either alone or combined with obvious exudation at the optic discs; and, last of all, are cases of exudation at the optic discs, as in

chlorosis, without any suggestion of a retrobulbar lesion. In the first two groups we cannot doubt inflammatory changes (thrombosis with cellular and fluid exudations) due to a toxic agent, is it not probable that similar causes are responsible for the instances in which the mischief is confined to the visual tract? Certainly retrobulbar neuritis, in view of its several associations, is one of the most interesting of the causes that may lead to permanent visual defect by the establishment of a condition of atrophy in one or both optic nerves.

H.—J. HOGARTH PRINGLE, M.B., F.R.C.S.,

Surgeon, Glasgow Royal Infirmary.

ATROPHY OF THE OPTIC NERVE FOLLOWING DIFFUSED VIOLENCE TO THE SKULL.

THE theory most generally held at the present time regarding the mode of causation of monocular blindness arising from diffused violence applied to the skull is that it results from direct injury to the optic nerve, be it compression, a cutting, or tearing of its fibres at the foramen apicium in consequence of fractures of the bone involving the foramen or the bone in its immediate neighbourhood.

Another but much less accepted theory is that the blindness is due to compression of the nerve by blood effused into the nerve sheath formed by the prolodation of dura mater from the cranial cavity.

The theory of direct injury to the nerve owes its inception to Berlin (Graefe and Saemisch, *Handbuch*, vol. vi), who based his thesis on the *post-mortem* findings of his associate Hölder, who, on experience gained by *post-mortem* examination of 126 cases of fracture of the skull, found a fracture of the base in 88 of the subjects; in 80 of these the fracture involved the roof of the orbit, and in 54 of them it involved the optic foramen. It is to be noted, however, that of these 54 cases, 42 were the result of gunshot injury, of which, he said, "34 were more or less directly caused by shots into the mouth." Now with the great disruption of the base of the skull that follows upon gunshot wounds of this nature, it is not surprising that he found fissures of the optic foramen so often or that the optic nerves were "often" torn across—he once saw it torn completely across, but—and this is a rather remarkable statement—he "never found haemorrhage into the optic nerve sheath without a fracture of the foramen."

Berlin, and nearly every writer since his time, has accepted the findings of these fissures as the explanation of the blindness that was known to occur after blows upon the skull, and although many writers have mentioned the occurrence of haemorrhage into the sheath, it has received very little attention. Yet no one, as far as I can find out, has brought forward proof that a nerve lesion caused by bone injury existed in any patient who has been the subject of this monocular blindness following upon diffuse violence to the skull. If there is anyone here to-day who can, I hope he will do so.

My own belief is that this form of blindness results from the haemorrhage into the nerve sheath in the majority of cases. I admit the possibility of direct nerve injury by bone lesions, but I believe this must be a rare occurrence, and for the following reasons which I will endeavour to put before the meeting.

At the Royal Infirmary here a great many cases of head injury of all varieties except gunshot wounds are admitted. I have personally been responsible for the treatment of 395 cases of undoubted fracture of the skull, and at least an equal number of patients in whom there was no fracture or in whom its existence was uncertain, and of this latter class not one patient suffered from this form of blindness. Of the certain 395 fractures of the skull 186 patients recovered, and only one of them had loss of vision (in his left eye) after the accident; this man was trephined in 1902 for an open (compound) depressed fracture. At first he had no perception of light in his left eye; some weeks later his visual acuity had risen to 3/60 left eye, and it remains the same at the present time. He was seen a few weeks ago.

Of my 209 patients who died after a fracture of the skull, *post-mortem* examination was made in 174, and only 13 of these showed a fracture involving the optic foramen (both foramina in 3, the right in 8, and the left in 2 cases). Two of these are interesting, because both of them had the upper margin

of the foramen fractured, one with and the other without displacement of the small fragment, but in neither case was there any injury to the nerve nor any haemorrhage into the sheath.

It has been stated that the anterior clinoid process may be displaced as result of fracture and compress the nerve, but I do not believe this can be a frequent occurrence, for the process was found fractured in only 6 of the subjects, in only one of which was the optic foramen involved, and the nerve was not compressed, nor was there any haemorrhage into the sheath in any one of these 6 cases.

But regarding the occurrence of haemorrhage into the sheath of the optic nerve, it was found to be present in 16 cases (in 10 in both nerves, in 5 in the right, and only in one case in the left nerve). In one case both sheaths were distended with blood and there was also a haemorrhage into the substance of the right nerve as well, but there was no fracture near the orbits or the optic foramina. As none of these patients were conscious during any part of the time they were under observation, it is not possible to say whether the vision of any was affected or not.

Source of the Haemorrhage.

The haemorrhage may possibly be derived from one of three sources: (1) from the subdural cranial space; (2) from rupture of vessels passing between the nerve and its covering; (3) from the central vessels of the retina which run a short distance inside the dural sheath before they enter the substance of the nerve.

In 8 of these 16 cases with intravaginal haemorrhage the haemorrhage was seen in the sheath or the cut surface of the nerve as it presents after the brain is removed from the cranium, and in all there was blood in the subdural space in the middle fossa of the skull, but in 7 cases no blood showed on the cut surface of the nerve. The blood in these cases was only present in the orbital portion of the nerve, and in them it is certain the blood was effused into the nerve sheath in the orbital or distal side of the foramen. It seems certain from specimens that I have that the haemorrhage begins at the distal extremity of the nerve close to its entrance to the eye.

Further, in 2 of these cases there was no fracture of the orbital roof or of the optic foramen on either side, and I hold they prove that a haemorrhage into the optic nerve sheath may arise from rupture of blood vessels within the sheath as a result of the varying tensions produced in the tissues in the orbit by the violence. This being so, there is no reason to doubt that an intravaginal haemorrhage can result from violence applied to the head even though a fracture of the skull is not produced, and it seems quite certain that in many of the cases recorded no fracture of the skull was present.

Now the blindness that results in the type of case we are considering is due either to (1) blood effused, (2) depressed bone compressing the nerve, or (3) direct injury to the nerve. Putting aside gunshot wounds—and practically every case recorded has resulted from diffuse violence—is it not remarkable that in my series of *post-mortem* examinations on cases met with in civilian practice there should have been so few instances of fracture of the optic foramen, none of which showed any direct injury to the nerve, and that only 3 of the 13 cases where a fracture of the foramen was found showed haemorrhage into the sheath, and that of the 6 cases of fracture of the anterior clinoid processes neither injury of the nerve nor haemorrhage into its sheath was present? If this is the case where gross violence has been inflicted on the skull, it seems most improbable that direct injury to the nerve should have occurred in the comparatively slight injuries that have characterized most of the cases recorded of monocular blindness of this type.

Believing that this variety of blindness is due to haemorrhage I have operated in three typical cases (in one of which I feel convinced there had never been any fracture of the skull, and I am very dubious of its existence in the other two), and in each of them blood under tension was found in the optic nerve sheath. Can this blood in the sheath exert sufficient tension to compress the nerve? The sheath is strong and non-elastic, and if the drawings (life size) by Mr. Maxwell are looked at it will be seen on comparing them with a drawing of a normal eye from a fracture of skull case that

there is very marked diminution of its diameter, which can only have resulted from the compression by the retained blood. The ophthalmoscopic appearance presented by the optic disc of the affected eye is that of a primary atrophy.

It is of some practical importance that the actual cause of the blindness should be determined, for while some patients appear to have partially recovered their vision after an interval of time, it is evident from the reports of cases that in a large number the loss of vision has been considerable in degree and permanent. If the blindness be the result of actual injury of the nerve it is very improbable that any lesion such as division or partial laceration of its fibres could be repaired or that any good result would follow upon it could this be effected, for "time" is of the utmost importance in these cases. On the other hand, if this blindness be caused by an intravaginal haemorrhage, there is a possibility that vision would be improved, if not absolutely restored, provided the blood could be evacuated at an early date.

The three patients for whom I operated all came late for treatment (two weeks, four weeks, and three weeks respectively). Although in each of them blood was found under tension in the sheath, none of them recovered vision while under observation. It is known that brain cells have a very short life if deprived of their blood supply, and possibly the retinal cells resemble them in this respect. One patient, who received a blow over the left orbit at football, was dazed for a few minutes, but noticed no visual defect until the following morning, when he found the visual acuity of the left eye failing, and by night he could not see at all with his left eye. Four days later, when seen, his left pupil was medium, did not react directly to light but did consensually, and he could not distinguish between light and dark with the left eye. There was no evidence of fracture of skull. He declined operation, but two months later his visual acuity in the left eye was 6/24. In this case the sequel of events could only have been caused by some effusion of blood or other exudate (and blood is the most probable).

Unfortunately at the present time I cannot yet produce evidence of any patient recovering vision after evacuation of blood from the sheath, but the history given above of the patient injured at football is sufficiently encouraging to permit one to think that an early relief of tension might be followed by great benefit to the patients.

III.—H. M. TRAQUAIR, M.D., F.R.C.S. EDIN.,

Assistant Ophthalmic Surgeon, Royal Infirmary, Edinburgh.

THE CLINICAL DIFFERENTIATION OF THE VARIOUS FORMS OF OPTIC ATROPHY.

In its main features, which are essentially only two—pallor of the disc and visual failure—the clinical picture of optic atrophy is for the most part both simple and familiar. When, however, we direct our attention towards the identification of the underlying causal factor we encounter a problem which, though often comparatively easy, is not seldom extremely difficult, and, in some cases, in the present state of our knowledge, may admit of only a presumptive solution.

It would be impossible as well as unprofitable to attempt to deal fully with this question in a short paper, and I propose to confine my contribution to a somewhat limited consideration of the practical clinical aspect of the subject, referring only in the shortest way to anatomical and pathological details. At the same time, the study of these factors and their correlation with the symptoms must be regarded as of supreme importance in connexion with the problem of differential diagnosis. It will be useful, however, to remember that the visual path, like other sensory paths, consists of neurones of the first, second, and third orders, and that the so-called optic nerve is really a tract connecting nerve centres, and consists of the axones of the neurones of the second order, whose ganglion cells lie in the retina, and whose terminal arborizations are, as far as concerns the visual fibres, in the external geniculate body. Any lesion or defect of nutrition affecting the ganglion cells or their axones at any point produces functional impairment, and, if sufficiently severe or prolonged, optic atrophy, which spreads both upwards and downwards along the neurone. Thus we can understand how it is that in cases of interruption of conduction the visual failure precedes the visible pallor of the disc.

by an interval the length of which depends on the site and nature of the lesion. It seems probable that these lesions are of two kinds:

(1) Toxic or other injurious influences acting on the ganglion cells or their dendrons in the retina and producing ascending atrophy following the death of the cells.

(2) Nutritional impairment of the nerve fibres, producing both ascending and descending atrophy. This nutritional impairment depends chiefly on inhibited blood supply which may be caused in many ways, by processes which are essentially of inflammatory nature, by vascular disease, pressure, or injury.

The symptoms of conduction interference, however caused, are fundamentally the same, though differing in mode of onset, course, intensity, and extent, and it is by studying these variations and correlating them with the normal and morbid anatomy of the visual nerve path that we may hope to identify the various forms of optic atrophy which are met with clinically.

In dealing with a case of obvious or suspected optic atrophy several methods of investigation are available.

I. The study of the patient as a whole. (1) The family and personal history in its widest aspect. (2) The presence of signs of general disease or abnormality, especially indications of syphilis, nervous, vascular, or pituitary disease, mental or sexual deficiency, or of some form of intoxication.

II. The study of the local condition. (1) The symptoms described by the patient, their mode of onset, duration, and course. (2) The state of the orbit, nose, and teeth. (3) Radiological study of the sella turcica, optic canal, and nasal sinuses. (4) The examination of the pupillary reflexes. (5) Ophthalmoscopic examination. (6) The vision: central visual acuity, the visual field, and the light sense (light difference).

Every case of optic atrophy should be approached from the point of view that this condition is always a manifestation of some general disease or local lesion apart from the nerve itself, and while in any individual case an exhaustive application of all possible methods of investigation will not be necessary, the causes of optic atrophy are so numerous and so widespread that even a short series of cases will be found to require the employment of most of them. While the ophthalmologist must be able to discern what line of investigation is particularly indicated in a given case and to appreciate the use and significance of all methods, so that he may both guide and profit by the co-operation of his colleagues, he is particularly concerned with the study of the eye and the visual pathway—that is to say, with the fundus oculi, the vision, and the pupils—and it is to the visual symptoms that I propose more especially to refer.

The usual classification of optic atrophy, based on the appearance of the optic disc, recognizes two chief varieties—simple, primary, or so-called grey atrophy; and secondary, post-neuritic, or white atrophy. The term "consecutive" is sometimes used to designate atrophy mainly choroidal or retinal lesion such as It is unnecessary to discuss the ophthalmoscopic appearances, with which everyone is well acquainted. The ophthalmoscope enables us to detect the presence of atrophy and affords valuable help and guidance in regard to its causation, but ophthalmoscopic evidence alone is insufficient to lead to a conclusion. While simple atrophy is typically associated with tabs, and secondary atrophy with the result of increased intracranial pressure, and differentiation is easy in characteristic cases, confusion may occur in others in which the features are less pronounced. The appearance of post-neuritic atrophy tells us no more than that there has been a considerable swelling of the nerve head of some duration, while the appearance of simple atrophy is even less informative as it may follow even well-marked swelling if it has not lasted long and if sufficient time has elapsed for resolution. It may, moreover, be difficult to decide whether an apparently pale disc is really pathological and also whether atrophy is unilateral or bilateral—a point of great importance. In the end the decision as to whether a disc is normal or not rests on the clinical experience of the individual observer. The visual impairment is often roughly proportional to the degree of pallor, but by no means always, and the relation between the two depends on the stage at which the patient is seen and on the nature of the lesion. For example, in a commencing descending atrophy from pressure or in multiple sclerosis when the focus is not near the eye the visual loss may far exceed the pallor, while in an early tabetic atrophy or in a retrobulbar neuritis which has recovered the conditions may be reversed.

The condition of the vessels is important, but, like the appearance of the disc, may be somewhat inconstant, and

I have personally found it of even more value in differentiating between certain forms of simple atrophy than in deciding whether a doubtful case is of primary or secondary type. Lastly, one need hardly refer to the significance of signs of choroidal, retinal, or vascular disease in the fundus, apart from the optic nerve itself.

The examination of the field of vision, of which central vision should be regarded as a part, provides information which is unobtainable in any other way, and is a method whose possibilities have not yet been fully explored. By this means the conductivity of the nerve fibres and, to some extent, the site of interference may be investigated, and from the results obtained inferences may be drawn as to the nature of the lesion and its rate of progress.

Perimetry has two aspects—the technical and the interpretative.

In regard to the first it is important to adopt the quantitative principle and to employ a wide range of test objects graduated as to size, a method analogous to Snellen's test for central vision. In addition to white, one colour, red, also serially graduated, is required. It is not sufficient merely to chart one field with a single test object, but, as far as time will allow, a perimetric study should be made of each case. The correct interpretation of the perimetric evidence is based upon our knowledge of the anatomy, in the widest sense of the word, both normal and morbid, of the subgeniculato visual nerve path, and the more accurate our information in this connexion the better are we enabled to understand the significance of changes in the visual fields and to estimate the site of the causal lesion, its nature and its mode of action.

Only the most important anatomical features can here be briefly surveyed.

In the retina the nerve fibres are arranged radially on the nasal side of the optic disc and on the temporal side in an arching formation around the macula, those of the upper retinal quadrant being separated from those of the lower by a horizontal raphe which extends from the macula to the temporal periphery. A vertical line passing through the fovea divides the fibres into crossed and uncrossed, the former being partly radiating and partly arched, the latter entirely arched. In the nerve the peripheral retinal fibres lie peripherally and those from the central part centrally, except at its commencement. The crossed fibres lie mesially in the nerve; in the chiasma they spread widely out and lie mesially again in the tract. The uncrossed fibres lie laterally in nerve and tract and also in the chiasma, where they spread out, though not so widely as the crossed bundles. The macular fibres are similarly arranged and approximately centrally situated, except in the anterior part of the nerve, where they are superficial and lateral. The blood supply is from end arteries which do not anastomose; in the retina it is central, in the nerve both central and peripheral from the pial sheath, and in the intracranial part of the nerve, in the chiasma and tract, pial only. We must also bear in mind the relationship of the nerve fibres to the post-nasal sinuses, to the sharp upper margin of the intracranial end of the optic foramen, to the carotid and ophthalmic arteries and the frontal lobe, to the circle of Willis, pituitary body, and infundibulum; and, lastly, the relationship of the tract and external geniculate body to the temporal lobe, adjoining cranial nerves, internal capsule, and other neighbouring structures.

By making use of serially graduated test objects information is obtained not only as to the existence of impaired conduction but as to its amount and distribution over the cross-section of the nerve, and by correlating the field picture obtained with what is known of the course of the fibres we may to some extent locate the site of interference. Since certain morbid processes or lesions characteristically affect certain parts of the subgeniculato pathway, the location of the site, in conjunction with the other symptoms, gives valuable guidance in diagnosis. Further, by making examinations at intervals and comparing the results, the behaviour of the lesion may be studied, and from this deductions may be drawn as to its nature and probable future course.

The field changes with which we are concerned may be regarded as falling into two main classes—peripheral or concentric contraction, and changes corresponding to groups of nerve fibres, or nerve fibre bundle defects, including scotomata. The term "peripheral contraction" is commonly used as if the field were impaired peripherally only and unchanged centrally, whereas quantitative testing shows that the central area is usually also affected. If a graphic representation of the field is drawn out it will be seen to resemble the elevation of a mountain with a high central peak, and a sloping plateau, surrounded by a precipitous edge, perpendicular on the nasal and steeply sloping on the temporal side. If this outline becomes depressed without other alteration it is evident that its circumference at the previous altitude is reduced or contracted. "Depression" is, however, in most cases a more accurate term, and more explanatory of the state of the nerve. The first signs of this process will, it is evident, not be

detected either at the central peak or at the peripheral steep edge, but in the intermediate sloping zone. Thus commencing atrophy may be present in association with good central vision for Snellen's types and apparently normal field boundaries, or central vision for Snellen's test may be somewhat reduced while the periphery is normal in extent for a moderately large test object. By considering the field as a whole we recognize that reduced central vision with an apparently normal field boundary is not the same thing as reduced vision with a normal field which, *ceteris paribus*, is a contradiction in terms.

Nerve fibre bundle defects are the reflection in the field of the retinal distribution of the fibres. The raphe gives rise to the nasal step and the arching bundles to the curved or comet shaped scotomata which, in their fully developed form, extend from the blind spot to the periphery or to the raphe. These defects are common in optic nerve conditions and are, as is well known, most pronounced in glaucoma. Their presence indicates a process affecting the nerve fibres as against the ganglion cells, and they have never been described in toxic atrophies. In nerve lesions they cross the vertical meridian of the field, but in chiasmal or tract conditions they are limited by it. The constant relationship to each other of the crossed and uncrossed bundles in the nerve enables the affected quadrant of the nerve to be deduced from the position of the field changes, and peripheral field defects correspond generally with lesions of the outer layers of fibres in the nerve, allowance being made for the position of the macular fibres near the eyeball. Near the chiasma the separation of the bundles makes it possible for a localized lesion to produce a clearly defined quadrant or hemianopic defect in one field. The interlacing of the fibres in the chiasma itself makes lesions here, as far as is known, always productive of bilateral defects, though, to begin with, the lesion on one side may be very slight. In the tract, especially near its commencement, the fasciculi are separate again and a tract lesion may produce unequal bilateral hemianopic field defects or, if localized, even a unilateral defect.

In many cases in which one eye appears normal, by the test card and by the ophthalmoscope, it is desirable to test the field on the presumed normal side carefully for slight degrees of alteration. This can be quickly done with small test objects on the principle already mentioned, examining especially those parts of the field where slight defects are most easily demonstrable. The progressive or stationary nature of the condition may be demonstrated by comparing the fields for colour with those for white; if the colour fields preserve an approximately normal relationship to the white fields the atrophy is stationary or only very slowly progressing; should the colour fields be relatively much more depressed or contracted then the condition is advancing. This feature has been called by Roenné "proportionality" and "disproportionality." Lastly, by repeating the examination alterations can be observed and the progress of the lesion watched.

We are now in a position, in all but exceptional cases, to say whether one or both nerves are affected or whether the lesion is above the nerves, and we know something about its site and its behaviour, knowledge which, considered together with the history, the evidence provided by general medical examination, and the other ocular signs, is of the greatest value in our search for the causal factor.

In making a differential diagnosis the history is of very great importance, as is also the stage at which the patient is first seen. When a good history is not obtainable it may be impossible by any means of examination to be sure of the cause of an old atrophy.

Let us now briefly discuss the application of these principles to some of the forms of atrophy most commonly met with. For our purpose we may take the cases as they present themselves in clinical practice and place them in groups, which, however, will not be mutually exclusive.

- I. Both discs show simple atrophy: visual failure bilateral.
- II. One disc shows simple atrophy, the other being normal: visual failure bilateral.
- III. One disc shows simple atrophy, the other being normal: visual failure unilateral.
- IV. One disc shows simple atrophy, the other papilloedema: visual failure on the side or on both sides.
- V. Both discs show post-neuritic visual failure: one simple and one post-neuritic.
- VI. One disc shows post-neuritic atrophy, the other being normal: visual failure unilateral.

It is, of course, understood that the visual failure is not due to any peripheral cause, and the consideration of atrophy due to choroidal or retinal disease and glaucoma is omitted.

I. Both discs show simple atrophy: visual failure bilateral.

Group I is large and important and contains atrophies due to causes which act bilaterally. It includes the simple atrophy of tabes, atrophy following bilateral optic nerve lesions of the type usually classed together as retrobulbar neuritis whether of general or of local origin, atrophy following intoxications such as quinine or atoxyl, cases due to chiasmal or tract lesions, and some other varieties.

In this group tabetic atrophy is the most important form. Owing to the fact that peripheral field defects are often not appreciated by patients the condition is frequently well advanced before the visual failure is noticed and pallor of the disc is already present. As a rule the entire cross-section of the nerve is affected, producing a depression of the whole field—as shown by testing with serial test objects—which appears as a peripheral more or less concentric contraction if only one fairly large object is used. In advancing cases vision for red and green is relatively much more impaired than for white; in more slowly progressive cases colour vision fails proportionately with that for white. Less commonly large sector defects occur with fairly well preserved vision in the remaining portions, and in a rarer type great concentric contraction is associated with good central vision. Nerve fibre bundle defects, which are of a wider and grosser nature than those usual in moderately advanced glaucoma, are not uncommon and probably form the basis of the sector defects. Central scotoma is rare and, as in the case of hemianopic changes, such as bitemporal hemianopsia, suggests a complicating factor.

Apart from the history, the general condition of the patient, the reflexes, and the pupils, which usually suffice to settle the diagnosis, the well-developed pallor of the disc at the time when the patient first complains of visual failure is a valuable and characteristic sign. The arteries are of normal size, and the lamina cribrosa distinct, the amount of cupping depending on the type of disc previously present.

In cases of interference with the nerve path, by pressure, injury, or inflammation the failure of vision occurs some time before the pallor, showing that the atrophic process is not the precursor but a sequel of the impairment of conduction. It is characteristic of the tabetic type of atrophy that this interval is extremely short, so that, unless occasionally in the second eye, the pre-ophthalmoscopic stage is infrequently met with clinically—a feature which characterizes only one other chronic progressive atrophy, that of glaucoma simplex.

The absence of hemianopic signs in the fields excludes chiasmal and tract lesions and limits the investigation to conditions of the nerves. In all cases of optic atrophy of any variety in which there is any uncertainty as to the diagnosis the Wassermann reaction should be tested. The chief diagnostic difficulty consists in the separation of cases of tabetic atrophy in which no other signs are present from other forms of bilateral simple atrophy in which a positive Wassermann reaction has been obtained either in the blood or in the cerebro-spinal fluid. Although in tabes the atrophy is usually more advanced on one side than on the other, unilateral cases are so exceptional that the risk of confusion with a true unilateral atrophy need hardly be considered, especially if the visual function on the apparently normal side is thoroughly examined by adequate methods. The great rarity of central scotoma enables most cases of bilateral retrobulbar neuritis or interference atrophy to be excluded; it is for the most part only in some old cases of this type that pale discs are found with little or no trace of central scotoma, but in such cases the atrophy is not progressive. Descending atrophy from basal meningial syphilis may simulate tabetic atrophy, but often partakes more of the nature of a retrobulbar neuritis, being associated with early and severe loss of vision and optic neuritis. In some cases of disseminated sclerosis atrophy simulating the tabetic type but not so pronounced has been described, but the steady visual loss of tabes progressing to blindness is absent, and this condition is practically excluded by a confirmed negative Wassermann test. Progressive simple atrophy with peripherally contracted fields is rarely of toxic origin, but cases have been described in connexion with lead and arsenic compounds. Only in the most aggravated cases of tobacco poisoning is partial pallor of the optic discs present and paracentral scotoma is the most prominent field change.

A subdivision of this group contains cases in which the field examination shows signs of hemianopsia, either homonymous or bitemporal. The lesion is situated at or above the

level of the chiasma, and as the atrophy takes some time to descend visual failure is noticed before ophthalmoscopic signs become evident. Thus most of these cases appear in ophthalmic clinics before the stage of visible atrophy in one or both discs.

Bitemporal hemianopsia in typical cases appears first as a defect in the upper outer quadrant of the field, soon invading the lower outer, and then, often after an interval, the lower inner quadrant. The upper nasal quadrant is last involved. In progressive cases a scotoma is present in the central area which develops in the same way, so that the central field behaves like a small field within the field. The defects progress clockwise in the right field and counter-clockwise in the left, and are always more advanced in one field than in the other. Sometimes by using graduated test objects the whole series of changes may be demonstrated at one sitting. Atypical cases are not uncommon in which a different sequence of the defects occurs, but the quadrant type is always present. When a tract is affected the hemianopsia is similar in type but homonymous, two corresponding upper quadrants being usually first involved. The most important causes are pituitary tumours and basal syphilis, and therefore it is essential to have an x-ray examination and a Wassermann test. Most of the tumours are intracellar, and by the time the field is affected, and still more when visible atrophy is produced, the sella is definitely altered. Suprasellar tumours of infundibular origin may produce no sellar alteration until large. As a rule when the sella is normal the tumour is probably growing from the olivary eminence or its neighbourhood, or the cause is most likely syphilis. The syphilitic cases are characterized by more rapid and intense field changes of the same general type, and when first seen the atrophy may not be pronounced or may be absent. In tract interference the atrophy is, of course, partial, and the contralateral disc is said to be the paler since the majority of the fibres cross. This one would only expect to find in a complete and uncomplicated interruption of one tract.

Other causes of atrophy operating in this region which have been described are compression of the nerves against the upper edge of the optic foramen, producing horizontal hemianopsia with inferior field defects, and indentation of the nerves by hardened and thickened adjacent arterial trunks, giving rise to binasal hemianopsia. Softenings and nutritional failure owing to arterial disease may occur at any part of the subgenieulate path, and doubtless account for some cases in which the cause is difficult to ascertain.

The causation of bilateral simple atrophy following those conditions usually classed together as retrobulbar neuritis is often difficult to ascertain, especially when the case is seen some time after the active stage. There may have been no swelling or considerable swelling of the nerve head, and yet the final ophthalmoscopic picture is that of simple atrophy. The fields are characterized by central scotoma, sometimes with sector defects extending to the periphery, and arching nerve fibre bundle defects may be present. After the lapse of time bilateral pallor of the discs, with more or less visual impairment, with or without a definite central scotoma, remains. In other cases field changes may be extremely difficult to demonstrate, and central vision may be good. If first seen in the stage of stationary atrophy it may be very difficult to assign a cause to cases of this kind. This question sometimes arises in connexion with children, ponsivers, or compensation cases. Bilateral retrobulbar neuritis is relatively rare; it may occur after infections such as influenza or measles, in syphilis, myelitis, disseminated sclerosis, inflammation of the nasal sinuses, and other conditions, and is of unknown origin in Leber's disease. Amongst toxic conditions the atrophy following quinine is characterized by narrowed arteries and peripheral field constriction; most other agents, except arsenic compounds, cause central scotoma. As most of these conditions are essentially retinal, nerve fibre bundle defects are absent in the fields.

II. One disc shows simple atrophy, the other being normal: visual failure bilateral.

These cases really belong to Group I, but only one disc shows pallor at the time when the case is seen. The other disc usually becomes pale sooner or later. Chiasmal interference is the most common cause. A careful examination of both fields will enable cases of this kind to be placed in their proper position in Group I.

III. One disc shows simple atrophy, the other being normal: visual failure unilateral.

In this group is included the numerous class of unilateral atrophies. Most of these are due to retrobulbar neuritis, injury, vascular obstruction, or some other cause acting unilaterally. The apparently normal side should be very carefully examined to make sure that the case does not really belong to the second group. The field characters already discussed and the history help to identify the majority of such cases. The thread-like vessels and the retention of a patch of vision around the blind spot, pointed out by Coats, is characteristic of obstruction of the central artery. In obstruction of a branch the field defect corresponds to the distribution area of the vessel concerned.

Progressive cases belonging to this group are rare. Signs of the separate involvement of the crossed bundle point to interference at the inner side of the nerve near its junction with the chiasma and indicate examination of the opposite field at intervals. The following case is an example.

Mrs A. B., aged 40, seen May, 1921. Sudden partial loss of sight of right eye six months previously. Orbital pain at the time. Stigmata of teeth and sella normal. L.V. 6/6 part, disc normal. R.V. 6/60, disc very slightly paler than left. Patient neurotic and difficult to test completely satisfactorily, but the left field was normal, the right showed a small temporal hemianopic scotoma with relative defect of the temporal field, especially in the upper quadrant. Diagnosis: Interference at inner side of termination of right optic nerve, probably by a growth from the dura over the olivary eminence. Two months later the right disc was definitely pale. The temporal defect was increasing and the visual impairment spreading across the vertical meridian into the nasal field. V=6/60 barely. L.V.=6/6 part, disc and field normal. Evidently the crossed fibres of the nerve were now becoming involved. Three months later the condition was much the same but with more involvement of the crossed fibres. Patient went abroad; her eyesight began to get worse in two months, and when last heard of two months later, or fourteen months from the appearance of the first symptoms, the left vision was 6/12 with a temporal field defect.

This case was therefore for a year in Group III, is now probably in Group II, and will eventually enter Group I.

IV. One disc shows simple atrophy, the other papilloedema: visual failure on the side of the simple atrophy or on both sides.

In this small group of cases, to which attention has been drawn by Foster Kennedy and Uhthoff, an intracranial tumour or abscess, so situated as to compress the intracranial portion of one optic nerve and prevent the access of fluid to its sheath—for example, in the frontal lobe—produces oedema of the other in the usual way. The field on the side with simple atrophy shows a central or paracentral scotoma, while the vision of the other eye may be unimpaired or may show commencing failure with contraction of the field. At the stage when these cases come under observation there is usually papilloedema on one side and commencing atrophy or a normal disc on the other. Presumably in time post-neuritic atrophy would supervene upon the papilloedema, with the corresponding visual changes.

V. Both discs show post-neuritic atrophy, or one simple and one post-neuritic: visual failure bilateral.

The majority of bilateral post-neuritic atrophies are due to increased intracranial pressure from causes such as cerebral tumour, hydrocephalus, or tower-skull. This subgroup is characterized by slow visual failure and concentric contraction of the field, or concentric contraction plus hemianopsia when the visual path is directly involved. The last part of the field to disappear is often in the neighbourhood of the blind spot, so that a resemblance to a binasal hemianopsia is produced. Should central scotoma be present direct interference with the intracranial portion of the optic nerve may be presumed.

A second subgroup contains those cases in which direct interference with the nerves forms the main feature of the condition. Here the visual loss is usually rapid and intense, showing as a large central scotoma with wide sector defects, while subsequent improvement is the general rule. Syphilitic disease around the terminations of the nerves and the chiasma is the usual cause. Since the original swelling of the disc may be much greater on one side than on the other, one disc may finally show the appearance of simple atrophy, and it may be difficult to demonstrate the remains of a scotoma in the field if the case is seen for the first time in a late stage. In most cases of this group the question of diagnosis arises in the pre-atrophic stage.

VI. One disc shows post-neuritic atrophy, the other being normal: visual failure unilateral.

In the last group are found cases of unilateral post-neuritic atrophy with a normal disc and unimpaired vision on the opposite side. Such cases are necessarily due to some local condition affecting one nerve which causes a swelling of the optic disc sufficient in degree and duration to produce the appearances of post-neuritic atrophy, and are not common.

Of two cases seen personally, in one a large central scotoma was present, indicating a local nerve condition. Vascular obstruction in the nerve was diagnosed during the stage of gross visible swelling; the patient had cardio-vascular disease. Had the case been seen first in the stage of atrophy the diagnosis could only have been presumptive. In the other example proptosis was present and the field showed interference with the crossed fibres. X-ray negative. A tumour, probably of the nerve sheath on the inner side near the apex of the orbit, was diagnosed. At operation a swelling of the chlamid, just in front of the mesial lip of the optic foramen, was found.

I am fully aware that this presentation of the subject is by no means exhaustive. Much that is of interest has necessarily been omitted or curtailed, and if attention has been somewhat concentrated on one method of examination in connexion with the clinical aspect of optic atrophy it is with full appreciation of the value of others, all of which are of importance in varying degrees in individual cases. That the problem of causation will not be solved in every instance must be admitted, but we may be confident that by painstaking investigation the proportion of unexplained cases will gradually be reduced.

DISCUSSION.

Mr. A. F. MACCALLAN, C.B.E. (Director, Egyptian Ophthalmic Hospitals), said: For many years we, at the Egyptian Ophthalmic Hospitals, have noted that there were a large number of cases of optic atrophy, but it is only during the last few years that a classification has been adopted which enables the origin of the condition to be understood. We divide the causes of optic atrophy into: (1) primary, as in spinal disease and arterio-sclerosis; (2) the result of retrobulbar neuritis; (3) post-neuritic atrophy; (4) the result of disease of the retina and choroid; (5) after compression or injury of the nerve; and (6) unknown causes. Among the interesting cases reported during 1921 were 114 cases of optic atrophy. By far the larger number of these were of the post-neuritic type, 46 in all. Primary atrophy was met with 19 times, in 16 of which the cause was stated to be unknown; in one case the patient had disseminated sclerosis, in another chronic myelitis, in a third spastic paraplegia. Retrobulbar neuritis was met with in 24 cases, 23 of which were patients who had recently suffered from an acute infectious disease, generally typhus; 11 cases were secondary to various forms of retinal disease; 3 were the result of compression or injury of the optic nerve. Finally, all cases were not sufficiently defined in their appearance to enable an accurate diagnosis to be made, but approximated in type to the primary form of atrophy. During the present year the increased interest in this condition will lead, it is hoped, to the reduction of the unknown forms in our statistics by increased pertinacity in obtaining the patient's history, and in the examination of his general condition.

Dr. PERCIVAL J. HAY (Sheffield) mentioned a case of optic atrophy occurring in a child about 18 months old after an attack of acute meningitis. The child was first seen soon after the attack, when the optic discs appeared to be normal. Three months afterwards they were quite white, the child being otherwise quite well.

Dr. L. WEBSTER FOX (Philadelphia, U.S.A.) said that he was particularly interested in the history and the causes of optic atrophy. There was one condition and source which had not been mentioned, and that was wood alcohol. The optic nerve showed a pallor of the head of the nerve which was even whiter than a post-neuritic atrophy. He had seen a patient of this character where the poison was only imbibed twenty-four to thirty-six hours previously. Why injury of the visual centres should take such a long period of time before ophthalmoscopic evidence showed—although blindness had been present for months—and wood alcohol such a short time was a question which their pathologists had yet before them to decide.

Mr. N. BISHOP HARMAN (London) said: The subject under discussion covers so much clinical ground that it is difficult to handle. There is scarcely a case of uveitis of any

severity which does not cause some optic atrophy, there is no congenital defect causing partial blindness which is not associated with some atrophy, and even a case of ophthalmia neonatorum may be held accountable for the same atrophy, for in after years we find those who have suffered from this disease without consequent corneal injury have poor vision with defective fixation and nystagmus, as a result of the lack of development of the macular elements owing to the closure of the eyes during the early weeks of life. Strictly speaking, all these cases should come into the category of optic atrophy, but no doubt we are to limit this discussion to cases where the atrophy is manifest to the eye of the observer by means of the ophthalmoscope or by other appropriate tests.

Last year I gave to this Section a report on some 4,000 cases of blindness. I have picked out from this collection the cases of optic atrophy. The cases fall into three groups: (1) babies, (2) school children, (3) all ages.

1. Amongst 63 blind babies there were 7 cases of optic atrophy, or 11 per cent. Of these, 2 were due to irido-cyclitis of great severity arising from cerebro-spinal meningitis; 5 were uncomplicated optic atrophy—2 from meningitis, 2 combined with undoubted cerebral defect, and of one the cause could not be ascertained.

2. Amongst the 1,855 blind school children there were 355 cases of optic atrophy, or 19.2 per cent. Macular defects, albinism, congenital nystagmus, and sympathetic ophthalmitis are excluded from the count. The greater number of cases (210) were associated with disseminated choroiditis and definitely due to syphilis, and a further 19 were probably due to the same cause; 39 were uncomplicated cases of atrophy the cause of which could not be ascertained, 16 were post-febrile (scarlet fever, diphtheria, influenza, one each, and 12 unknown), 20 meningitis, 6 cerebro-spinal meningitis, 4 from head injuries, 7 familial atrophy, 4 familial choroiditis with partial atrophy, 39 retinitis pigmentosa, and 17 buphthalmia. Of the 355 cases of optic atrophy, no less than 230 were due to congenital syphilis, or 65 per cent.

3. Amongst the group included under all ages, in which, naturally, adults predominate, there were 270 cases of optic atrophy in 925 blind and partially blind persons, or 28 per cent. Forty-eight were uncomplicated atrophy: 25 of these were primary (of which 6 were definitely syphilitic), 2 Leber's disease, 11 tabes dorsalis, 5 pituitary disease, 5 hemianopsia. Vascular disease accounted for 53: of these 8 were embolism or thrombosis of retinal vessels, 25 renal retinitis, 13 diabetic retinitis, and 7 retinitis pigmentosa. Glaucoma accounted for 67: with buphthalmia 6, chronic 43, and acute 18. There were 102 cases of atrophy with choroiditis: with gross macular disease 26, central senile choroiditis 45, syphilitic disseminated choroiditis 19, and 12 with disseminated choroiditis from other causes. Among this all-ages group 36 cases were definitely due to syphilis, or 14 per cent.; but how many of the vascular and senile atrophies were due to degenerative processes primarily set up by this disease we can only speculate. Vascular diseases account for the highest total of atrophy, for we must include with these not only those definitely assigned to vascular disease, but also those degenerative changes in which there is a senile or pre-senile wasting of essential portions of the nerve. It is noteworthy that there were no cases of toxic atrophy. It is true that there were 7 cases of tobacco amblyopia, but since there was reason to believe that they recovered these do not come into the count. No cases of lead or wood alcohol poisoning or other similar toxic blindness were recorded.

The special point that arises from these figures on the etiology of optic atrophy is the increase of the incidence as age advances, from 11 to 28 per cent., and the predominance of different factors at different ages: in infants, meningitis; in school children, congenital syphilis; in all ages, syphilis and vascular diseases. The disastrous effects of congenital syphilis are such that no efforts should be spared that will ensure the effective treatment of syphilis before parenthood is undertaken.

Mr. J. GRAY CLEGG (Manchester) said that he had looked up all his private notes and found 160 cases in which atrophy of the optic nerve was the chief lesion. They could be grouped as follows: primary atrophy 78, of which 49 were bilateral and 29 monolateral; post-neuritic 51; consecutive 10; toxic 2; traumatic 19, of which 17 were monolateral and 2 bilateral. In reply to one of Dr. Hawthorne's queries he said that personally he had never seen an atrophy of the optic nerve that could be attributed to the use of arsenical

parations. In tobacco amblyopia there was frequently no pallor of the discs, but it was most advisable never to let examination for glycosuria in cases apparently due to that cause. Mr. Pringle's explanation of sudden blindness in cases of comparatively slight blows on the skull was interesting because he had felt for some time that fracture through the optic foramen was often a mere assumption. Radiograms would help in settling the question as to the frequency of fracture. He had been struck, in looking over his private notes, by finding as many as 19 cases of traumatic blindness due to skull injury, of which two were bilateral.

Haemorrhage into the sheath of the optic nerve could not be the only cause of the sudden loss of sight, for in two cases had come across altitudinal hemianopsia from a slight concussion. One resulted from a fall in a boy, and the upper half of the field was lost. The other occurred in a woman against whose nose a door banged. No local bruise appeared, but an inferior altitudinal hominopsia resulted in the opposite eye, and blood was seen extending from the disc margin into the retina. In both cases the corresponding half of the disc eventually atrophied. It might be assumed that were the explanation merely haemorrhage into the optic nerve sheath the limitation of damage would not be so definite.

Mr. INGLIS POLLOCK (Glasgow) mentioned the case of a girl, 10 years of age, with a dermoid of the pituitary fossa, in which the only symptoms were double optic nerve atrophy and possibly, on x-ray examination, slight enlargement of the pituitary fossa. The dermoid was found by Mr. Pringle on operation to be of the size of a large walnut. There was no sign of intracranial increased pressure found at the operation. Mr. Pollock stated that he had seen one case of optic atrophy due to syphilis, but he had also seen cases of syphilitic optic neuritis recover after a course of salvarsan or neo-salvarsan. He had also sent one of the traumatic cases to Mr. Pringle, who found, four weeks after, blood clot compressing the optic nerve.

Dr. J. C. DOUGLAS (Newcastle, New South Wales) desired to discuss two points in connexion with the papers which had been read. The first was the classification of optic atrophy. He had been very much struck with the confusion which seemed to exist in the minds of many ophthalmic surgeons, and still more in the minds of students, as to the different forms and types of atrophy. Some talked of primary and secondary, others of simple and post-neuritic, others again of tertiary atrophy, or consecutive atrophy, or primary atrophy of retinobulbar type. One well-known London ophthalmologist classified them as atrophy of retinal origin, of disc origin, and of retinobulbar origin. That was good so far as it went, but when they came to details it was found that in those of retinal origin he placed retinitis pigmentosa—a form which, according to the textbooks, was supposed to commence in the choroid and not in the retina at all. When an ophthalmic surgeon found optic atrophy in the course of a routine examination he might ask himself to what type did the case conform, and might seek to draw conclusions therefrom as to the possible cause. It was there that most students found great difficulty.

The speaker recognized three distinct types of atrophy which, when they were well marked, bore very little resemblance to each other. Type 1 was the grey atrophy of ataxia, which might have a bluish or greenish tinge according to whether the patient was fair or dark; the vessels were not reduced, and there was no pigmentary disturbance in the fundus and no white lines along the vessels. Type 2 was inflammatory atrophy. The disc was very white in colour, the edges ill defined and irregular, connective tissue filling the cup and along the vessels, and the vessels were distinctly reduced in size. Type 3 was vascular atrophy. The disc was waxy and yellow, the vessels were extremely reduced in calibre, and there was much pigmentary disturbance in the periphery or great pallor of the whole fundus. Such a classification as that suggested would be, in his opinion, an improvement on the existing forms, and at the same time would be more complete, and the names "primary" and "secondary" could be abolished altogether. He suggested that some cases of atrophy following injury to the skull were due to simple pressure either by displaced bone or by blood clot or traumatic periosteal swelling—a condition which might be temporary and capable of cure by surgical interference. It was, in fact, a condition of "physiological block," such as

Cushing had described as occurring frequently in pituitary tumours, and which he had found to recover when the tumour had been removed or a pituitary cyst had ruptured spontaneously. Such a case of semi-temporary optic atrophy with recovery, following upon an injury to the head, was reported in a recent number of the *Australian Medical Journal*.

Dr. JAMES ALEXANDER WILSON, O.B.E. (Cambridge), said that the optic nerve emerged from a rigid bony ring into a space where there was provision for mobility, and he understood the suggestion of Mr. Pringle to be that the jolt from a fall or blow on the head caused laceration of blood vessels at that locality. He had notes of three cases of head injury from falling in which there was no evidence of fracture. In one of these defective vision was noticed within a few days and in the other two only after several months. All finally presented monocular optic atrophy. He had seen other cases of monocular and binocular optic atrophy for which he could not find any cause. Mr. Pringle by his persistent investigations had been able to give some valuable information about the cause and possible treatment in the traumatic group. Dr. Hawthorne had approached the subject from the wider outlook of the physician, and incidentally had demonstrated the value of the ophthalmic examination. With Dr. Traquair working backward through the various causes and all converging on one cause of optic atrophy, he exhibited the success that could be obtained by co-operation or team work. Last year we had an interesting paper on the causes and prevention of blindness by Mr. Bishop Harman, and to-day that investigation was being continued. Many questions remained unanswered, and he wished he could persuade the Glasgow ophthalmic surgeons to continue this investigation and present a report on it to the next Annual Meeting. An end-result was being considered and it was necessary to get back to early stages and so on to causes. All roads ultimately led to prevention. The more important work of the ophthalmic specialist of the future would involve knowledge and skill in the art of preventing disease, or of preserving the eyes in a condition of health and efficiency. All thanks to those who were helping towards that goal.

Mr. THOMAS H. BICKERTON (Liverpool) remarked that in forty-one years of practice he had seen many cases of complete monocular blindness. In these cases of traumatic origin, the character of injury clearly indicated in many cases damage to the optic nerve by fracture of skull or haemorrhage. In other cases, while there was definite history of injury to the head—usually to the brow or the back of the head—it had been of so trivial a character that it would require an elastic imagination to attribute the condition either to fracture or haemorrhage. In other cases, again, no history of injury could be obtained, even after the most careful inquiry. Absence of history of injury did not necessarily exclude injury. He had recently seen a girl of 13 who had "gone blind suddenly"—a case of white atrophy of the right eye. Careful inquiry elicited no history of injury. A few days later her mother called to say that on making inquiries in the family the child's grandmother remembered that three years previously the child when staying with her returned one Sunday with the story that a girl companion had pushed her and she fell, striking her head. Her head ached and she lay down for two hours, went to Sunday school that afternoon, and next day to school as usual. Whether in this class of case there had been injury or not, his knowledge of the intimate cause of blindness at present belonged to Mr. Bishop Harman's classification, "cause unknown." The practical importance to be borne in mind in this class of case was: (1) Individuals holding accident insurance policies would be wise to report to the insurance company any accident that occurred to the head, however slight. (2) Medical men might wisely warn patients coming to them with head injury, however slight, not to settle with insurance companies until six months had elapsed.

Mr. J. HOGARTH PRINGLE, in reply, said: The idea is that the haemorrhage is due to altered tensions in the orbital cavity the result of the violence. The slight cases showed a full ampulla, and from that one finds all states up to an absolutely full optic nerve sheath. Whether the intravaginal haemorrhage is the cause of the blindness or not I do not know, but it is certain that in this type of case the optic nerve is compressed by blood within its sheath.

SECTION OF PATHOLOGY (HUMAN AND
COMPARATIVE).Professor ROBERT MUIR, M.D., F.R.C.P. Edin., F.R.S.,
President.BOVINE ACTINOMYCOSIS, ITS PATHOGENESIS
AND TREATMENT BY VACCINES.BY
W. M. SCOTT, F.R.C.V.S.,
Bridgwater.

The life history of the organism of actinomycosis, to those who admit its saprophytic existence, is practically unknown. Medical opinion appears to incline to the view that it leads a saprophytic existence upon the alimentary mucosa, its parasitic propensities developing with an abrasion of that membrane. When it is remembered, however, that cases of pyorrhoea and dental caries in man are legion, one would think that in these circumstances more cases of actinomycosis of the jaw would be seen. The practitioner of veterinary medicine inclines strongly to the belief that the organism leads an active existence on vegetable matter, and one is almost tempted from practical experience to go so far as to conclude that the vegetable kingdom is the natural habitat of the fungus, and animal tissue its accidental home. Certain it is that some farms are more predisposed to the disease than others, and further that some fields on these farms produce a larger number of cases. Moreover, climatic conditions appear to exercise a considerable controlling influence on the growth of the fungus, as the number of cases is largely seasonal. Thus, the dry summer of 1921 and the abnormally dry succeeding winter reduced my springtime cases by 75 per cent., while the very wet summer of 1917 gave an abnormal increase. In that year lingual actinomycosis was particularly rife, and I attributed this fact partly to the wet season and in part to the excessive growth of thistles, the prickles of which acted as an excellent "inoculant." On this point it may be interesting to note that lingual actinomycosis is very common in oxen. These animals prehend their food with their tongue, consequently if there is any hard fibrous or prickly element in the fodder that organ becomes an easy victim to inoculation. Equines, on the other hand, scissor their food with their incisors, and in these animals the tongue is very seldom seen infected. Further, permanent pasture land is a more prolific source of infection than land which is under cultivation, pointing again to the possible fact that reproduction of the parasite outside the animal body does take place under unmolested conditions, and, speaking from my own experience, where I see one case on cultivated farms, I see ten to fifteen cases on permanent pastures.

The region of the head and neck in cattle being the most common seat of the disease strongly suggests that the active germ is ingested with the food. A perfectly healthy and unabraded mucous membrane conceivably offers in itself sufficient resistance to mycelial infection. Greater facilities of infection, however, occur in those cases where the mucous membrane is abraded, as, for example, in the eruptive phases during dentition. Hence it is that young cattle are more predisposed to the disease than older animals. The most common seats of infection, as far as my own records go, work out at the following ratio: tongue 35 per cent., jaws 33 per cent., lips 3 per cent., submaxillary 7 per cent., subparotid 15 per cent., pharyngeal and retropharyngeal 7 per cent. Primary infection of the skin is very rare indeed, but secondary contamination is not at all uncommon. I have encountered several infections of the mamma in pigs, probably a dozen in all, six in the cow, and two in the goat, the channel of infection in these cases pointing to the milk duct. The internal organs are also occasionally infected, although seldom diagnosed during life. Observers in charge of abattoirs have detected the disease in the alimentary and respiratory systems, the liver, spleen, kidneys, testicles, uterus, and brain.

Pathogenesis.

No sooner does the organism invade the tissues than a rapid development of the cellular elements takes place as the result of the inflammatory reaction. Some of the filamentous fragments and coccoid-like bodies are taken up by the phagocytes and carried into the healthy adjacent tissues, and always with the possible result that where the organism is not destroyed fresh infective foci are established. Where

the tongue is the seat of infection consequent upon bacterial stimulation, that organ undergoes rapid fibrosis, attains an enormous size, often protrudes from the mouth, and, losing its contractile power, unless relief is obtained, the animal dies from inanition. The dorsal surface and sides of the tongue present an irregular appearance as the result of nodular elevations. These nodules are firm in consistence, and of a greyish-yellow colour. When the tongue is cut into the parenchyma is hard and fibrous, showing numerous circumscribed projecting centres varying in size from a milletseed to a pea, or even larger. Some of these areas present advanced degenerative changes. In the larger and older nodules the substance may be cheese-like. Surrounding these areas are dense masses of newly formed connective tissue cells, penetrating between which one may detect under the microscope mycelial elements.

Occasionally the deep lingual lymphatic glands are affected. This added infection seriously hampers therapeutical measures, a fact that has struck me on many occasions. In advanced and very aggressive cases ulcerative changes take place on the mucous membrane, and extension to the buccal mucosa by contiguity is not uncommon. If these ulcers are carefully examined they will be found studded with angry bluish-red granulations between which are small yellow or greyish-yellow nodules. The edges of the ulcers are usually well defined. Where the jaw-bone is involved the first step is an acute ulcerative inflammation of the mucosa in the vicinity of the teeth at the seat of inoculation, followed by an acute alveolar periostitis, which extends and enlarges the bone. In the meantime the medullary elements become invaded, giving rise to a rarefied granular osteitis with the formation of cavities packed with infective elements. As the disease advances the teeth may loosen and fall from their sockets, or infection may spread towards the cutaneous structures, which in due course become involved, break down, and from the sinus infective pus discharges, an angry-looking cauliflower-like growth developing on the bone at the point of exit.

In the pharyngeal region the disease manifests itself as an infective granuloma varying in size from a hazelnut to a cricket ball, or even larger. These may eventually become distended by purulent accumulations, or they may remain hard and fibrous throughout and tending to increase and to embarrass respiration and deglutition. In the submaxillary and parotid regions the neoplasm takes on a round or oval shape, the salivary glands seldom escaping infection. At first it is surrounded by an oedematous effusion, giving an irregular contour to the growth. In due course this becomes absorbed, leaving the growth, which at this stage is hard and fibrous, sharply defined. In time it tends to soften in the centre and discharges an infective pus. In the lungs the disease may simulate the milky form of tuberculosis, the nodules being of a greyish-yellow colour, or large purulent cavities may develop in the parenchyma. In the mammary gland one or more soft degenerate infective centres develop surrounded by dense fibrous elements.

Pus, in the truest types of actinomycosis, is a somewhat rare quantum, and in some cases is not present at all, especially in the early stages. It would appear in this slow-growing disease that a rapid and hyperactive fibrosis, commencing almost at the outset, thwarts the suppurative processes. This may be due to a rapidly developed antitryptic content on the part of the host's blood or a low tryptic power of the pus itself, or both of these factors may be acting in unison. In this the disease closely resembles discomycosis equi. In old-standing cases where pus is much in evidence it would appear that the usual pus-producing organisms are the primary factors. In a typical case the pus is usually thin, watery, and sometimes sanious, suggesting a lack of leucocytosis, but occasionally one comes across a case where the pus may be defined as "laudable." These latter, in my experience, are the most amenable to treatment. On the other hand, the worst cases are those where the pus is thin, ichorous, and emits a sickly penetrating smell. If a close search is made in such a case a foreign body will invariably be found, such as a blade of grass, straw fibre, barley or rye, grass awns, etc.

Biological Therapy.

With regard to treatment by vaccines a very common fallacy exists in the minds of some practitioners who look upon vaccine therapy as the alpha and omega of all treatment and are content to ignore collateral measures which go to facilitate recovery. To inject a vaccine into an animal

with active mycelial foci surrounded by and maybe almost cut off from adjacent healthy tissues and expect immune bodies activated by the antigen to reach the bacterial zone is really asking for the impossible, and in like manner to anticipate a large fibrous growth, surrounded by a dense matrix in the centre of which is a cavity distended with pus, to disappear is also unreasonable. In the case of lingual involvement, where the animal is seen early, fibrosis being present only in a moderate degree, and where the lymphatic glands are quite healthy and active, vaccines alone have given me satisfactory results, but I am of opinion that even here additional treatment with iodine expedites recovery.

After an experience of 43 cases treated by vaccines, I consider the treatment has a high therapeutical value. I always use autogenous vaccines, and where secondary infections are in evidence, these bacteria are also embodied in the antigen. The initial three or four doses are sterile, the succeeding half-dozen attenuated, while the subsequent doses are virulent. In injecting virulent cultures, after a degree of immunity has been established, I have never seen any untoward results of importance, while as therapeutical agents they are far ahead of sterile vaccines. It may be of interest to note that the cases which made the best recoveries were those where the organism grew best under aerobic conditions, and, *per contra*, those which preferred anaerobic methods proved the most obstinate.

Tabular analysis of the cases treated by vaccines works out as follows. Some of these were taken in the early stages, and responded well to treatment, some were moderately advanced but made good responses, the remainder were old-standing neglected cases requiring very prolonged and persistent measures.

Tissues Affected.	No. of Cases.	Recoveries.		Failures.
		Complete	Partial.	
Tongue	16	15	—	1
Jaw	15	11	1	3
Parotid	6	4	1	1
Pharyngeal	3	2	—	1
Jaw and parotid ...	3	1	1	1

Summary and Conclusions.

1. The bacteriology of the group actinomycetes is most complicated and unsatisfactory, giving ample scope for the joint action of human, comparative, and plant pathologists.

2. If the parasite does lead a separate existence outside the animal tissues its habits and habits should be investigated, for until this point is cleared up preventive measures must ever be empirical.

3. How the salts of iodine act therapeutically in cases of actinomycosis is an interesting field for speculation, and possibly by investigations carried out along these lines other side-tracks in the large field of chemical therapy might also be discovered.

4. Although the clinical data of actinomycosis are generally based upon an oven and more or less regular plane, the same observation cannot be applied to the *causa causans*, this latter being most diverse and confusing. It must be confessed, however, that cases are seen in practice occasionally which simulate actinomycosis and are not so save in macroscopical appearances only.

5. Vaccine therapy is a valuable adjuvant in the therapeutics, virulent antigens giving by far the best and most uniform responses.

THE HEALING OF GASTRIC ULCER.

BY

MATTHEW J. STEWART, M.B.GLAS., M.R.C.P.LOND.,

Professor of Pathology, University of Leeds.

THE spontaneous healing of gastric ulcer in man is a problem about which very diverse views have been expressed. In general, it may be said that most physicians believe that gastric ulcer frequently heals spontaneously, most surgeons that such an occurrence, especially in the case of chronic ulcer, is exceptional, and that even when healing does take place there is a great tendency for the scar to break later.

For the past eighteen months, in the *post-mortem* room I have been carefully examining the stomach and duodenum for evidence of scarring, while noting at the same time the incidence of ulceration in these viscera. As might be expected, scars have been found with much greater frequency during this period than in previous years, in fact more scars were found during 1921 than in any three of the eleven years immediately preceding. There can be no doubt that this is due to failure to find scars which were present, and the figures for the eleven-year period 1910-20 must be regarded as quite unreliable.

The routine method of examination adopted is to distend the stomach with water to a moderate extent, and then to lay it open with scissors along the line of the greater curvature. The scissors cut is continued through the pylorus along the concavity of the duodenum. By this method the great majority of gastric and duodenal ulcers and scars escape injury. The mucosal aspect of the stomach is then washed completely free from food debris, and if there is any adherent mucus this is gently removed, either by a stream of water, or if that fails, by wiping with pledgets of wet cotton-wool.

When looked for in this way, most scars are easily made out. In the stomach they usually present an almost perfectly smooth surface, but are conspicuous by reason of their whitish colour and the presence of numerous radiating whitish streaks round about. Almost invariably there is a localized area of fibrosis, with similar radiations, on the peritoneal aspect of the scar, with or without a band of adhesions to some adjacent structure. On section, the scarred area is thinner and tougher than normal, and is of a dead white or yellowish-white colour, instead of the normal grey of the stomach wall. Most of the scars found in this way have been submitted to microscopical examination, with verification of their presence in every instance. In the duodenum also the fact of scarring is easily determined in most cases, but a larger proportion of doubtful scars is met with.

Histology of Scar Formation in Stomach and Duodenum.

In each case either the whole stomach, or a considerable portion of it including the lesion, has been pinned out flat on a board, which has then been floated, specimen downwards, in a large tank of Kaiserling solution No. 1. After three or four days' fixation fairly large blocks of tissue have been taken through the scarred area, including, wherever possible, a margin of healthy stomach at either end. These have then been embedded in paraffin.

The presence of scarring is indicated microscopically by fibrosis of the muscular coat. In most of the scars included in this series the fibrosis involves the whole thickness of the muscularis, clearly indicating, I think, that this coat had been completely perforated by the ulcer. In most cases the centre of the scar consists of fibrous tissue only; in others a few thinned and atrophied strands of muscle are also present, embedded in the fibrous mass. Blood vessels are few in number in the central area, and those present are little more than endothelial tubes. They are clearly a new formation and not a relic of the former vascular arrangements of the part. At the margin the fibrous tissue merges gradually into the surrounding muscle. Fibrous thickening of the peritoneal coat is also present in many cases. For the demonstration of these scars Mallory's connective-tissue stain (acid fuchsin, aniline blue, orange G) has proved most satisfactory. The dense fibrous tissue of the scar is stained bright blue, the muscular tissue red, and any elastic tissue which may be present yellow.

In the duodenum the muscular wall is normally much thinner than in the stomach, and the microscopic evidences of scarring are therefore the less conspicuous. Many duodenal scars, especially those of the posterior wall, are firmly adherent to the pancreas, and this organ may show considerable fibrosis in consequence. In the floor of chronic gastric and duodenal ulcers, as well as in the resulting scars, one often sees blood vessels which are the seat of a chronic obliterating endarteritis and endophlebitis, while a striking feature of many is the way in which large numbers of nerves become implicated in the fibrotic process.

Incidence of Gastric and Duodenal Scars.

In the following table the *post-mortem* findings are analysed, as regards both ulceration and scarring, during the year 1921. Those figures are admittedly too few to satisfy statistical requirements, but they afford sufficient evidence to show that healing of gastric and duodenal ulcers is a common event.

TABLE I.—Analysis of 602 Post-mortem Examinations at the Leeds General Infirmary, 1921.

	Cases.	Per Cent.
Gastric ulcers (18 cases):		
Chronic	8	1.3
Acute (multiple 7)	10	1.7
Duodenal ulcers (31 cases):		
Chronic (multiple 7)	28	4.7
Acute (multiple 1)	3	0.5
Gastric scars (multiple 4)	14	2.3
Duodenal scars (multiple 1)	10	1.7

Table II shows, for comparison, the post-mortem statistics of the Leeds General Infirmary during the twelve years 1910 to 1921 inclusive. As already stated, the figures for gastric and duodenal scars here given cannot be accepted as a true criterion of the frequency of these lesions, but they probably afford evidence of value as to the relative frequency of single and multiple scars in the viscera concerned. This is of importance when one attempts to determine the possibilities for healing of chronic as distinguished from acute ulcers.

TABLE II.—Twelve Years' Post-mortem Statistics, Leeds General Infirmary, 1910-21 inclusive.

	Cases.	Per Cent.
Post-mortem examinations	5,900	
Cases of gastric and duodenal ulceration	337	5.7
Gastric ulcer cases	170	2.9
Duodenal ulcer cases	179	3.0
Chronic gastric ulcer	137	2.3
Chronic duodenal ulcer	171	2.9
Acute gastric ulcer	35	0.6
Acute duodenal ulcer	12	0.2
Gastric scars (50):		
Single	40	
Multiple	10	
Duodenal scars (34):		
Single	32	
Multiple	2	

It is concluded from the figures given in Table III that in 5 out of 6 cases acute ulcers of the stomach are multiple, while chronic ulcers are almost invariably single. In the duodenum the same general rule holds good except that in the chronic lesion a double ulcer is present in no fewer than 1 case in 7.

TABLE III.—Acute and Chronic,* Single and Multiple Ulcers.

	No.	Single.	Multiple.
Gastric ulcer:			
Acute	35	6	29
Chronic	137	135	2 (2 ulcers)
Duodenal ulcer:			
Acute	12	2	10
Chronic	171	145	26 (2 ulcers)

An interesting comparison may be made between the ratio of chronic and acute ulcers and that of single and multiple scars. In the stomach chronic ulcer is four times more common than acute, single scars are four times more common than multiple. Similarly, in the duodenum chronic ulcer is fourteen times more common than acute, single scars are sixteen times more common than multiple. From a consideration of these various figures it is suggested that chronic ulcers have as good a chance of healing as acute ones.

In 12 out of the 50 cases of gastric scarring mentioned in Table II there was a quite separate and independent chronic ulcer in another part of the stomach, which suggests that the well-known recurrent nature of this lesion may be due in many cases to fresh ulceration, and not to breaking down of the old scar as is commonly supposed.

Scar Incidence.

The chief point of interest emerging from this part of the investigation is that whereas chronic gastric ulcer is somewhat commoner in men than women (60 to 40), the reverse is the case with regard to scars (46 to 54).

Hour-glass Stomach and Stenosis of the Pylorus and Duodenum.

Those are some of the less common but still very serious complications of gastric and duodenal ulcer, and all are

* The differentiation of acute and chronic ulcer was made on anatomical grounds, both naked-eye and microscopical. In the stomach there is usually little doubt as to the category to which a given ulcer belongs: acute ulcers clean-cut, punched out, often with portions of slough or altered blood clot adherent to the floor, and showing little or no evidence of chronic reactive inflammation; chronic ulcers with thickened, rounded, often raised margins, and showing abundant deposition of fibrous tissue, both in the base and in the walls. In most cases, including all doubtful ones, the specimen was submitted to microscopic examination, when the chief criterion of chronicity taken was the amount and density of the fibrous tissue reaction around and in the base of the ulcer. This is much more difficult to determine in the stomach

directly attributable to the healing process of cicatrization. In the present series of 5,900 post-mortem examinations there are 19 cases of pathological hour-glass contraction of the stomach due to ulcer, and 11 cases of simple pyloric stenosis. In two of the cases both lesions are present, giving a total of 38 cases in all. In addition, there are two cases of simple duodenal stenosis, the result of extensive old scarring. Nine of the cases of hour-glass stomach had scarred completely; 10 were still the seat of active ulceration. The condition would appear to depend on the size and position of the ulcerated area rather than on the chronicity of the pathological process. All the cases in this series were situated somewhere in the middle third of the stomach, usually nearer the pyloric than the cardiac end, and the appearances suggested that the causative factor in most was cicatrization of a large saddle-shaped ulcer of the lesser curvature. In this series the number of cases of chronic gastric ulcer and scarring taken together is 175, which gives an incidence rate for hour-glass stomach of 11 per cent. Inasmuch, however, as the figures for gastric scarring are clearly very far short of the truth, it is suggested that the real incidence of hour-glass stomach is probably a good deal less than this—say in the neighbourhood of 6 per cent. of all cases of gastric ulceration. If the incidence of gastric scars shown in the figures for 1921 be taken (Table I), then the incidence of hour-glass stomach in all cases of scarring works out at 6.5 per cent. This in turn gives an incidence of about 8 per cent. in healed chronic ulcer. The sex incidence of hour-glass stomach shows a marked preponderance for females—namely, 13 to 6.

Of the 11 cases of pyloric stenosis, 6 were due to old scarring in the stomach, 3 to still active gastric ulceration, and 2 to scarring in the duodenum. The two cases of duodenal stenosis were associated with extensive cicatrization, about three-quarters of an inch beyond the pylorus. In both there was great hypertrophy and dilatation of the stomach.

Relation of Scarring to Carcinoma.

The relation of gastric ulcer to carcinoma has been much debated in recent years, and the tendency has been to attribute increasing importance to the chronic inflammatory lesion as a cause of the malignancy. Wilson and McCarty of the Mayo Clinic have gone so far as to say that in 71 per cent. of the cases the malignant process is engrafted on a simple one, that cancer is really due to a secondary change which starts in the edge of an ulcer of long standing. It is not my intention to discuss this problem now, as it does not properly come within the scope of the present paper; but it may be stated that in a series of 98 stomach specimens received from the operating theatre and submitted to microscopic examination the incidence rate of cancer in cases of simple chronic ulcer was 11.5 per cent.

The relation of gastric scarring to cancer is even less clear. The most painstaking naked-eye examination of a large number of stomachs removed by the surgeon for cancer would be necessary to establish such relationship, as well as the most extensive and detailed histological study of each specimen. One small piece of evidence against any such relationship emerges from the present work. In none of the 19 cases of hour-glass stomach with extensive scarring included in the present series was there any evidence of the development of carcinoma.

Conclusions.

1. Healing of gastric and duodenal ulcer is a common event. Statistics are given to show that, in the post-mortem room, scarring is met with almost as frequently as gastric ulceration, while duodenal scars occur with about half the frequency of duodenal ulcers. This difference may be partly accounted for by the greater liability of duodenal ulcers to perforate.

2. Single and multiple gastric scars are met with in the ratio of 4 to 1, which is exactly the same as the ratio of chronic to acute ulcers. It is suggested from this that acute and chronic ulcers have an equally good chance of healing.

3. Hour-glass contraction of the stomach is met with in about 6.5 per cent. of all cases of completely healed gastric ulcer—that is to say, in about 8 per cent. of cases of healed chronic ulcer. The incidence of pyloric stenosis is little more than half this.

4. There is no evidence from the present observations that carcinoma arises in connexion with gastric scars, whereas in a series of 98 stomach specimens received from the operating theatre and submitted to microscopic examination the

incidence of carcinoma in cases of simple chronic ulcer was 11.5 per cent.

5. Gastric scars are not always conspicuous, and must be carefully looked for after gently wiping away adherent mucus or food materials. The presence of adhesions or of fibrous thickening on the peritoneal coat is confirmatory, and, on section, is replacement of the soft greyish muscular wall by dense white fibrous tissue.

6. Conclusive histological evidence of scarring is afforded by the presence of fibrosis of the muscular coat. This can be most conveniently demonstrated by means of Mallory's connective-tissue stain (acid fuchsin, anilin blue, orange G), which is especially suitable for naked-eye and low-power work.

7. It follows from 5 and 6 that only ulcers which have definitely involved the muscular coat leave a permanent scar, and one which can be unmistakably recognized both by naked eye inspection and by microscopical examination. The most striking scars are, of course, those of ulcers which have completely perforated the muscular coat.

8. When an ulcer heals the continuity of the mucosa is completely restored, but it is usually thinner than normal, and less well supplied with glands. There is no evidence as to whether or not a gastric or duodenal scar readily re-ulcerates, although it is perhaps a legitimate assumption that the thinner mucosa together with the less vascular fibrous tissue underneath will be more vulnerable than the normal mucous membrane. It is possible, on the other hand, that certain ulcer-producing factors may have disappeared as a result of this cicatrization, and there is evidence to show that the well-known recurrent character of the lesion may be dependent rather on the formation of a new ulcer or ulcers than on a breaking down of the old.

INTRA-VITAM STAINING: ITS APPLICATION TO PATHOLOGICAL INVESTIGATION.*

BY
D. F. CAPPELL, M.B.,

McCunn Research Scholar in Pathology, Glasgow University.

(From the Pathological Laboratory of the University and Western Infirmary, Glasgow.)

INTRA-VITAM STAINING may be defined as the process of staining selectively certain groups of cells in the living animal, while the other tissues remain free from the dye. This end may be attained by the use of certain dyes of the benzidine group (for example, trypan blue), the triphenylmethane group (for example, isaminé blue and pyrrhol blue), and by the use of certain other agents such as lithium carmine. When these substances are administered to the animal by subcutaneous, intraperitoneal, or intravenous injection, they appear in the vitally stained cells in the form of granules. These granules accumulate in the cytoplasm until the cell may be crowded with them, but the nucleus remains unaffected. When, however, death of the cell has taken place the cell stains diffusely throughout both cytoplasm and nucleus.

Intra-vitam staining appears in certain groups of cells, and, while these cells are of diverse morphology and have received many different names, it is proposed to follow the nomenclature adopted by Evans, and designate them "macrophages," thus uniting the whole group of cells by their common property of response to the acid colloidal dyes. The fundamental meaning of vital staining is not yet clear. Goldmann, the pioneer in this branch of biological investigation, thought that the granules were composed of internal or external secretion which stained specifically by a chemical union with the dyes. More recently Evans and his co-workers have sought to identify the property of vital staining with that of phagocytosis. These workers base their contention on the similarity between the reaction of the vitally staining cells to such different agents as the following:

- The acid colloidal dyes.
- The ultramicroscopic particles of the colloidal metals.
- Particulate matter at the limit of visibility—for example, Indian ink.
- Coarser particulate matter, as in carbon suspensions, bacteria, etc.

The macrophages consist of five main groups of cells:

1. Macrophages of connective tissue, variously known as clasmatoocytes, wandering connective tissue cells, rhagiocrine cells.

2. Endothelial macrophages, lining the blood channels of the liver, spleen, bone marrow, and haemolymph glands, and the lymph sinuses of lymphatic glands. It is noteworthy that the endothelium of blood vessels in other situations does not take up the dyes, at least not to any notable extent.

3. Probably closely related to the above group 2 are the reticulum cells of bone marrow, lymphatic and haemolymph glands, and of the spleen, together with the phagocytic cells of the spleen pulp.

4. The cells between the mesothelial layers of the mesentery and omentum, including the cellular collections known as the "*laches latentes*."

5. The large free wandering cells of the serous cavities, which are probably derived from group 4.

In addition to the cells mentioned above, the following cells take up certain of the vital stains, but remain unaffected by others. These are:

- The cells lining the convoluted tubules of the kidney.
- The interstitial cells of Leydig in the testis.
- The theca cells of the maturing Graafian follicles in the ovary.

In striking contrast to these vitally staining cells, the leucocytes of normal blood (including all types) do not take up granules of the acid colloidal dyes used as vital stains.

Thus intra-vitam staining appears capable of yielding a criterion by which, in the tissues, cells of connective tissue and endothelial origin may be distinguished from those which have migrated from the blood.

PRIMARY CHRONIC INTERSTITIAL NEPHRITIS AND ARTERIO-SCLEROTIC KIDNEY.

BY

JOHN SHAW DUNN, M.A., M.D.,

Professor of Pathology, University of Birmingham.

THE problem of classification of contracted granular kidneys is recognized to be one of great difficulty, and until the etiology of these conditions is made more clear this difficulty in the definition and delimitation of groups must to some extent remain. At the same time it appears to the writer that a greater amount of confusion has arisen in relation to two important groups of contracted kidneys than is warranted by the available information, and that a reconsideration of certain views may not be without value.

For the purpose of this paper it is sufficient to formulate provisionally three main groups of contracted kidney, of which two are specially to be dealt with:

- Secondarily contracted kidney.
- So-called "primary chronic interstitial nephritis."
- Arterio-sclerotic contracted kidney.

The first of these will not be considered at length, but it is necessary to mention it shortly for the sake of clearness.

Secondarily Contracted Kidney.

The definition of this group does not appear to present very great difficulty, and the following summary will probably be generally agreed to. When such cases are finally summed up it is common to find that there has been a history of antecedent nephritis of a more or less acute type, or that there has been a prolonged history of fairly definite renal symptoms. Death commonly occurs from uraemia or from intercurrent infection, but may result from high blood pressure and cerebral haemorrhage.

On post-mortem examination the kidneys are contracted and granular, and the cortex is much narrowed and deformed. The colour of the organ varies; it may be pale and yellowish if there is much fatty degeneration, but frequently it is reddish or distinctly red owing to congestion of vessels in the overgrown fibrous tissue. Histological examination reveals changes in the glomeruli of a definitely inflammatory nature; usually every tuft is affected, but the degree of involvement varies in different tufts. There is much total destruction of tubules, and the tubules which persist are highly abnormal; their epithelium is of a low type and shows much fatty degeneration and catarrh. Some segments may have higher epithelium, but this is usually abnormal, being oedematous, or laden with lipoids or with hyaline droplets. The interstitial tissue of the cortex is universally but not uniformly thickened, being least so where the tubules are least atrophied. The extent to which the arteries of the kidney are affected varies in different cases, but it is common to find endarteritis

* A portion of the expenses of this work was defrayed from a grant by Trust to Dr. C. H. Browning.

obliterations, especially in vessels of medium size; atheroma, or degenerative thickening of the intima, may also occur, however, in similar and in larger arteries. In these cases in general there is abundant evidence, especially in the glomeruli, that the late fibrotic lesions have arisen from earlier acute inflammatory phenomena.

When the second and third groups, B and C, come to be considered it appears to the writer that very different views are entertained by various authorities regarding their scope, the relation of one to the other, and even the possibility of distinguishing one from the other. These differences of view are not merely dependent on the use of different terminology, but are fundamental and have regard to the very nature of the diseases; they are dependent on differing interpretations of the criteria which are available in the identification of types. It is recognized that this statement forms a criticism of a serious character, and that it refers to a matter of the greatest practical importance, so that it is essential that it should be fully and clearly justified. The position as it appears to the writer may be stated as follows:

"Primary Chronic Interstitial Nephritis."

This expression, in this country at any rate, has been applied to a type of case which is fairly readily definable, both clinically and pathologically. Regarded from the clinical aspect these cases are most frequently characterized by the comparatively rapid or even sudden onset of serious symptoms, due to a chronic renal lesion, in an individual who has previously been apparently healthy and who is not known to have had renal disease. There is usually no oedema, while common features are polyuria, difficulties in vision, high blood pressure and cardiac enlargement, and naemia. Death commonly results from uraemia or cerebral haemorrhage, but it may be from pericarditis or an intercurrent infection. At the *post-mortem* examination the kidneys are small, with adherent capsules and harshly granular surfaces; they are firm and fibrous in consistency and are often red in colour, but may be mottled red and grey. On histological examination they present much fibrosis, which is very uneven in distribution: severely fibrosed areas, in which the glomeruli and tubules are much diseased and atrophied, alternate with areas in which the interstitial tissue is less increased or may appear normal, while the renal elements are better preserved and are usually hypertrophied. There is a marked contrast between the advanced degeneration of glomeruli in the fibrosed areas and the hypertrophy of those in the more normal areas, while intermediate stages of damage of these structures appear to be scanty or even absent. The non-atrophic tubules may appear to show little abnormality apart from hypertrophy and dilatation, but their cells may exhibit deposits of fat and cholesterol ester. The arteries, including the afferent arterioles, show extreme degrees of thickening of their intima, mostly of degenerative type, and they form a conspicuous feature in the general picture.

This type of condition has long been recognized as differing from secondarily contracted kidney, both on clinical and pathological grounds, the main distinctive clinical features here being the more stealthy development of the symptoms, the absence of renal oedema, and the predominance of symptoms referable to high blood pressure and to naemia. Pathologically it is distinguished by the more patchy fibrosis, the apparent absence of definite evidence of old glomerulitis in those tufts which remain recognizable, and the more obvious and widespread thickening of arterial walls with narrowing of lumina. It has been variously named "primary chronic interstitial nephritis," "granular kidney" proper, "renal cirrhosis," and, by the Germans, "genuine *Schrumpfniere*." Various suggestions have been made regarding its etiology, and one common assumption is that it is due to some slow poisoning occurring over a long period of years.

Arterio-sclerotic Kidney.

As this expression probably conveys different ideas to different observers, an attempt to define it will be made in the first place only from the pathological aspect. It is universally agreed that a contracted shrunken kidney with a uneven surface is frequently the result of narrowing or actual closure of arterioles owing to degenerative thickening of their walls, apart from the occurrence of inflammation in the organ in any ordinary sense. It is further recognized that fairly large branches of the renal arteries are irregularly affected the result is the appearance of fairly large and well-defined areas of chronic infarction or atrophy—a picture

which is macroscopically very readily recognizable. The latter type of lesion is described by some, especially German writers, as the arterio-sclerotic kidney proper. On the other hand, where only minute arterioles, the afferents of the glomeruli, are much involved by narrowing the result is a fairly uniform and it may be a fine granularity of the surface of the kidney corresponding microscopically to the occurrence of multiple minute areas of atrophy of tufts and tubules. This type of lesion might be described, as it is by the Germans, as "arteriolo-sclerotic kidney"—*nephro-cirrhosis arteriolo sclerotica*.

It is obvious that if such a process as has been described were to reach a severe degree of development the result would be such an atrophy and irregularity of the kidney as might simulate to some extent the condition described under B—"primary chronic interstitial nephritis."

The question that now arises is essentially this: Are B and C entirely distinct entities, or is B to be regarded merely as the maximal development of the process of arteriolo-sclerotic atrophy? To this question it would appear that different authorities would give different answers. Reference will be made to the views expressed by several, beginning with two textbooks of pathology which are widely used in this country.

Hewlett¹ describes chronic interstitial nephritis as either (1) secondary, the result of past acute or subacute nephritis (corresponding to A above), or (2) primary (corresponding to B above), a condition of obscure origin but probably due to a mild irritant acting for a long period. Under "arterio-sclerotic kidney" he describes changes attributed to narrowing of arterioles, but very similar in nature to those mentioned as characteristic of primary interstitial nephritis. The two conditions are regarded as etiologically different, but it is not clear how they are to be differentiated.

Beattie and Dickson² classify chronic nephritis as:

1. Small red granular contracted, or arterio-sclerotic kidney.
2. Large pale granular contracting.
3. Small pale granular contracted.

It is clear that of these 2 and 3 are to be regarded as corresponding to stages of A—secondarily contracted kidney, as described in this paper. From the description of 1, coupled with the fact that no separate mention is anywhere made of "chronic interstitial nephritis," it would appear that these authors regard the latter as a severe form of their arterio-sclerotic kidney.

Aschoff,³ who gives a very clear and comprehensive account of the various forms of contracted kidney, with appropriate reference to the accompanying clinical phenomena, places the arteriogenic forms of damage quite apart from chronic nephritis of inflammatory origin. Under the latter heading he describes only what would correspond to A—secondarily contracted kidney. On the other hand, in his description of "nephro cirrhosis arteriolo-sclerotica," he includes kidneys which show a maximal degree of damage due to miliary atrophy, as the "genuine *Schrumpfniere*," or granular atrophy of the kidneys; these show severe patchy destruction of renal tissue with fibrosis, while intervening areas show hypertrophy of elements. As uraemia is mentioned as a common cause of death in these cases, "when the stage of renal insufficiency is reached," it is quite clear that Aschoff is here referring to cases which would correspond to our "primary chronic interstitial nephritis."

Kaufmann,⁴ on the other hand, describes "genuine *Schrumpfniere*" in terms similar to our account of "primary chronic interstitial nephritis" and separates it both from "late stage of glomerulo-nephritis" and from arterio-sclerotic atrophy. Further, he states that it may possibly be the late stage of an unrecognized acute nephritis occurring at a much earlier date.

Maccallum's account⁵ is essentially in agreement with Aschoff's. He describes as the late result of glomerulo-nephritis what has been referred to above as "secondarily contracted kidney," and he makes no separate mention of chronic interstitial nephritis. On the other hand, under "arterio-sclerotic kidney" he describes conditions due purely to narrowing of arterioles, and includes in these one type with diffuse sclerosis of small arterioles, which results in a small hard kidney with thickened adherent capsule and mottled surface with yellow-grey or pinkish granules separated by red scar tissue. His reference goes on: "the gross appearances of such a kidney differs in no way, therefore, from the end-result in a protracted glomerulo-nephritis" and "except

about these two cases was the prominence of arteriolar degeneration. Many of the afferent arterioles exhibited characteristic hyaline thickening and when suitably stained showed much fatty degeneration. As will be seen this was a very striking feature also in the purely arterial cases, but on the other hand it was not entirely absent in some of the other cases in Table I which were decided to be "secondary" in type.

TABLE II.—Kidneys in Arterio-sclerosis with High Blood Pressure.

No.	P.M.	Sex.	Age.	B.P.	Cause of Death.	Heart (grams).	Kidneys (grams).

* Heart dilated. C.H. = Cerebral haemorrhage.

In Table II there is given a list of 27 cases where there was evidence of high blood pressure, either from actual measurement during life, or from the enlargement of the left ventricle, or in many instances from both. These cases have been arranged in order according to the weights of the kidneys and it is seen at once that in 12 out of the 27 the kidneys weighed 300 grams or over—that is, they were at least of the normal weight, so that they do not necessarily come into a discussion which refers to contracted kidneys. In the remaining 15 cases the following would be a fair description of the kidneys. The capsules generally stripped fairly readily and without tearing of the renal substance; the organs were of almost normal consistence, sometimes rather firmer, but never of the dense fibrous texture described in chronic nephritis. The surfaces were always uneven—usually finely and almost uniformly but rather faintly granular, not rough and barsh. In some the granularity was coarser and more uneven, and in one there were large sunken atrophic areas in addition. On section the cortex was narrower than normal. Usually where the superficial cortex was much thinned the interpyramidal cortex was hardly affected. The cortical markings were frequently fairly distinct in most areas and did not give the impression of distortion which is characteristic of chronic nephritis. On the whole, apart from the diminution in size, which was fairly marked—250 grams or less in 13—the naked-eye changes in the kidneys were not of a striking character and were very definitely in contrast with those described in Table I.

The histological appearances in these 15 kidneys were very markedly in agreement one with another, and one description will suffice for most. The first impression in all was that the renal changes were even less than might have been expected from the appearance of the surfaces to the naked eye. The bulk of the renal substance was of normal aspect, and this was interrupted only by the occurrence of small areas of atrophy, especially towards the surface of the cortex. The atrophic areas showed almost total atrophy of the tubules, and the glomeruli were represented by round sharply defined nodes of dense hyaline fibrous substance with very few cells. These hyaline nodes were drawn together owing to the collapse of the normally intervening tubules. The

fibrous tissue in these atrophic areas was condensed, but was seldom much increased in amount. The impression was always obtained that while a certain number of tufts had become functionless and sclerosed, none of them had been totally abolished so as to leave no trace. It will be recollected that in the cases described as primary chronic interstitial nephritis the total disappearance of all trace of many of the tufts was one of the most characteristic features. The further important features of the group of kidneys in Table II were best seen in frozen sections stained for fat by Sudan III. This revealed the fact that there was widespread hyaline thickening with fatty degeneration in the walls of afferent arterioles, especially those in the atrophic areas. On the other hand, the tubular epithelium was usually free from any trace of degeneration, so that the affected arterioles stood out with startling clearness. The larger arteries showed less constant changes, but hypertrophic thickening of media and intima was common and atheromatous degeneration fairly frequent. Only in one case was the atheroma in large vessels a marked feature, and in that case the surface of the kidney showed large atrophic foci in addition to a finer and fairly even granularity (No. 13).

From this description it is clear that the shrunken kidneys in Table II would not be liable to be mistaken for any form of chronic nephritis and that there was a very considerable difference in the characters and extent of the changes from those described in the two "primary chronic interstitial nephritis" in Table I. In the cases in this table the histological picture was quite in agreement with the view that the renal damage was purely the result of arteriolar narrowing and these, if any cases, might well be named "nephro-cirrhosis arteriolo-sclerotic." And now it becomes of the first importance to note the clinical aspect of the cases with shrunken kidneys in Table II. In all the heart showed hypertrophy of the left ventricle; in all except two the weight of the heart showed a well-marked increase, which is probably a more reliable evidence of the existence of the high pressure during life than is a single examination of the blood pressure shortly before death. Further, none of these 15 cases gave any history of nephritic symptoms of any kind, and in 12 out of the 15 death occurred from cerebral haemorrhage.

Regarding the 12 cases (1-12) in Table II in which the kidneys were of normal size or actually enlarged, it need only be said that histological examination in all of these showed more or less degenerative sclerosis of the afferent arterioles and that in the majority there were numerous minute atrophic foci, but atrophic changes were naturally less than in the shrunken organs. There was in all an absence of old glomerulitis and of serious alterations in the renal tubules. One important point as to the clinical characters of these 12 as compared with the other 15 is that in 5 death resulted from failure of the heart with venous congestion and oedema, whereas this termination resulted only in one out of the 15 cases with diminished kidneys.

Conclusions.

The evidence which is brought forward in these two tables is neither extensive in amount nor complete in detail, but it is in general agreement with impressions which have been gathered from previous examinations of many chronically damaged kidneys, and is very suggestive in certain directions.

It would appear that while arteriolar sclerosis and narrowing is a frequent cause of shrinkage of the renal cortex, it does not by itself produce a condition which is likely to be mistaken for chronic nephritis, either macroscopically or microscopically. Further, it is doubtful if the loss of renal substance occasioned in this way is ever sufficient to cause uraemia; death almost invariably results from cerebral haemorrhage. It is possible that the very common occurrence of this type of lesion in the kidneys is to some extent overlooked because the macroscopic changes are so comparatively insignificant; they do not usually make good museum specimens.

On the other hand, the condition which has been referred to as "primary chronic interstitial nephritis," or renal cirrhosis, which is regarded by some authors as the maximal development of arterio-sclerotic atrophy of the kidney, is quite a distinct condition; it is often characterized clinically by a tendency to failure of renal function in its later stages, and pathologically it is distinguishable by the greater degree of derangement of the renal architecture. There is a greater, often a severe, fibrosis of the cortex; the amount of renal substance lost is greater, necessitating hypertrophy of that which remains; there is usually, if not always, evidence of old glomerulitis in the tufts which remain recognizable, and it is suggested that the total destruction and disappearance of many tufts is also due to an earlier inflammatory process. As has been pointed out, where glomeruli are damaged by arterial closure alone they become sclerosed, but remain visible as hyaline nodules, often in considerable numbers. In many ways renal cirrhosis is more difficult to separate both clinically and pathologically from secondarily contracted kidney, and it is probable that the differences here are more apparent than real. Lorrain Smith has regarded them as essentially similar in nature but distinguished by the lesions being diffuse in secondarily contracted kidney and focal in renal cirrhosis; in the former the renal function

suffers at an earlier stage in the disease; in the latter the renal function is carried on successfully for a prolonged period by undamaged areas of cortex which hypertrophy. With this view the writer is entirely in agreement and would regard the so-called "primary chronic interstitial nephritis" as a latent chronic nephritis derived from an acute glomerulonephritis of focal distribution.

The fact that in these cases there is no history of an antecedent acute attack is not against this view, for in recent years it has been abundantly shown (Herxheimer,⁶ Dunn and Thompson,⁷ Bell and Hartzell⁸) that the lesions of acute glomerulonephritis are of frequent occurrence in cases of septicaemia, but it is only comparatively seldom that they are sufficiently extensive and diffuse to occasion a failure of renal function at that stage. Where recovery takes place from acute lesions of this kind the healed cicatricial stage may well appear years afterwards in the form of renal cirrhosis.

According to this view the arterio-sclerosis of minute and other arteries which is so prominent in so-called primary interstitial nephritis must be secondary in development. There is nothing very improbable in this, considering the frequency of arterio-sclerosis in kidneys without nephritis. Further, it is found that arterio-sclerosis appears to some extent in secondarily contracted kidneys. It is possibly not without significance that this feature was observed only in the older of the cases in Table I.

I have much pleasure in acknowledging my indebtedness to my colleagues at the Birmingham General Hospital for the use of the clinical notes of cases in the preparation of this paper.

THE RELATION BETWEEN OXYURIS VERMICULARIS, APPENDICITIS, AND LOCAL EOSINOPHILIA OF THE APPENDIX WALL.

BY

E. H. EASTWOOD, M.B., CH.B.,

Department of Pathology, Sheffield University.

[Abstract.]

DURING the last twenty-five years many writers have produced evidence either for or against the thesis that *Oxyuris vermicularis* is directly or indirectly a cause of appendicitis. The arguments implicating oxyuris are mainly two: (1) that the worms are more frequently present in the inflamed appendix than in the normal; and (2) that they are capable of burrowing into the mucous membrane, and so forming a track along which infecting organisms can pass. On the other hand, many authorities have found oxyuris in approximately the same proportion of normal and diseased appendices, and have been unable to find any evidence of the aforesaid oxyuris burrows apart from fissures which can be explained on the ground of artefacts produced in section cutting.

No writers, as far as I can ascertain, have investigated the eosinophilia found in the appendix wall with relation to the presence of oxyuris in the lumen, although it is reasonable to suppose, on analogy with the local eosinophilia produced by *Trichina spiralis*, that oxyuris, if sufficiently pathogenic to produce burrows, might cause a local eosinophilia.

Altogether 73 appendices removed at operation from cases of definite appendicitis and 50 normal appendices from the post-mortem room were examined in this series. Of the former group oxyuris was found in 19.2 per cent. and of the latter in 28 per cent.—that is to say, if anything, somewhat more frequently in the controls. They were found much more frequently in the cases of both series under 15 years old, and no evidence of burrows was seen.

The histological investigation was directed chiefly to local eosinophilia, and cell counts were made on sections of both the normal and diseased appendices. Eosinophils were found

almost constantly in the appendices of both groups, usually immediately beneath the epithelium, and although they were considerably increased in numbers in the cases of appendicitis, this increase was entirely independent of whether the appendices carried oxyuris or not. The one striking point was the relation of the numbers of eosinophils to the stage of the inflammatory process as indicated by the number of days after the onset of attack.

The eosinophils were found to be above normal even twenty-four hours after the onset and then to rise fairly rapidly to a maximum in eight to twelve days, subsequently showing a gradual decrease but remaining well above normal even in the third or fourth week. The neutrophil polymorphonuclears showed the usual steep rise in the first twenty-four to forty-eight hours and then an almost equally steep fall very nearly to normal in six to seven days; and the lymphocytes, after a preliminary rather inexplicable drop in the first twenty-four hours, showed a rise to slightly above normal, thereafter remaining more or less constant. This local eosinophilia of the appendix seems to correspond with the eosinophilia found in haemothorax and certain infections of the peritoneum in guinea-pigs (possibly also in lymphadenoma and the convalescence from acute infectious fevers) where eosinophils appear to be at their maximum at the time when resolution or fibrosis is occurring.

Some points noted from the cell counts of the normal appendices were that the lymphoid tissue as estimated by enumeration of the small mononuclear cells showed an increase up to the tenth year of life, thereafter retrogressing with age; that the thickness of the muscular coat showed a gradual and regular increase up to the age of 60 years; and that the numbers of eosinophils bore no relation to any particular disease or any special age.

Pigmentation of the appendix wall was fairly frequently noted both in the diseased and normal appendices, and did not appear to be related to appendicitis, as it was just as common in the normal appendix. In no case did it give the prussian-blue reaction for iron. It was usually associated, as other writers have pointed out, with chronic intestinal stasis.

THE CHOLESTEROL CONTENT OF THE BLOOD IN ANAEMIA, AND ITS RELATION TO SPLENIC FUNCTION.

BY

WILLIAM MACADAM, M.A., M.D. GLASG., M.R.C.P. LOND.,

Lecturer in Pathology, University of Leeds;

AND

CECILIA SHISKIN, B.A. CAPE, M.D. GLASG.

[Abstract.]

IN anaemias of all kinds we have found that the cholesterol content of the blood plasma is diminished, although often the decrease is not striking until the red cell count is less than 50 per cent. of the normal. There is no noteworthy difference between the cholesterol findings in cases of secondary and of idiopathic anaemia. The cholesterol of the red cells also shows a slight decrease, but the corpuscular content is much less subject to variations than is that of plasma.

The spleen is generally regarded as the organ in which the red blood cells are destroyed. Experimental splenectomy in dogs has been found by King to produce in the blood an increased amount of cholesterol, which is well recognized as an antihæmolytic agent against certain substances. Through the courtesy of Sir Berkeley Moynihan we have been enabled to investigate this relationship from the clinical standpoint by following up the changes in the cholesterol content of the blood resulting from removal of the spleen in three cases of alcoholic familial jaundice and one case of splenic anaemia.

In the cases of hæmolytic jaundice the cholesterol rose from approximately half the normal content (the average normal is 0.160 gram per 100 c.cm. blood plasma) to values of 0.160, 0.234, and 0.259 gram per cent. respectively, while in the case of splenic anaemia a value of 0.308 gram per cent. was obtained. There is little deviation from normal (0.110 gram) in the cholesterol of the corpuscles before and after operation. The red cells increased by 25 per cent. on the average, there having been usually some degree of anaemia present.

In the cases of hæmolytic jaundice the fragility of the red cells persisted even five months after splenectomy. The

¹ The complete paper will be published in the forthcoming number of the *Quarterly Journal of Medicine*.

icterus and urobilinuria usually disappeared within ten days of operation.

It appears, then, that in acholuric jaundice, as also in splenic anaemia, splenectomy is followed by a marked increase in the cholesterol of the blood plasma, while at the same time the signs of abnormal haemolytic activity disappear. But we do not know in what way and to what extent this hypercholesterolaemia is related to the cessation of splenic function. Certain workers have attempted to associate the haemolysis with an excess of unsaturated fatty acids in the blood plasma. Their experimental data, especially in relation to the effects of splenectomy, are, however, not convincing.

MEDICAL, SURGICAL, OBSTETRICAL.

DEGENERATIVE DISEASES OF THE LIVER.

In the discussion at the last Annual Meeting of the British Medical Association on degenerative diseases of the liver (*BRITISH MEDICAL JOURNAL*, December 2nd, p. 1055 et seq.), I found no mention of a condition I recently came across.

A woman, aged 57, was sent to me complaining of pain in the back for the preceding few months, with loss of energy and a gradual enlargement of the abdomen. She had a large, ill-defined, somewhat tender tumour in the right hypochondriac and lumbar regions. It felt slightly elastic, and a provisional diagnosis of hydatid of the liver or retro-peritoneal growth was made. I did an exploratory laparotomy, and found the liver extremely enlarged owing to the presence of countless cysts, two of which were very large and occupied about half the liver, one being in the dome of the right lobe. The more superficial one was incised and the deeper one tapped through this, a large drainage tube being inserted. The contents were clear watery fluid, and there was no sign of any hydatid membrane or daughter cysts. The patient died a few days later. At the post-mortem examination the liver was found to consist of a mass of cysts of varying size; there were some present also in the spleen. The lungs showed evidence of old tubercle. Sections of the liver were sent by Dr. Mackaroll, who reported that the cysts appeared to be dilations of the bile ducts and were lined by columnar epithelium.

I have never come across a similar case, and can find very little about the condition in the literature on the liver.

Leicester.

F. BOLTON CARTER, M.S., F.R.C.S.

HYSTERICAL SIMULATION OF FRACTURE.

The following case is perhaps worth recording. The patient, a girl of 22, came to see us one afternoon with the following history. She had been running to catch a train the previous evening when she slipped and fell heavily with her left arm under her. She got up and continued her journey. The pain was so severe when she got into the train that she fainted; the train was stopped and she was taken back to the house where she was living, and she remained there for the night. We have seen her on several previous occasions, but have never looked on her as hysterical. We found the left arm in a position of extreme rotation inwards, the elbow-joint extended, and the forearm supinated, the palm of the hand facing forwards, with the thumb pointing directly outwards. The region of the elbow was swollen and the hand and distal part of her forearm very blue. The elbow-joint could not be flexed at all, either voluntarily, or by the exercise of slight force, an attempt causing great pain. The bony parts of the elbow were obscured. We wasted no time on further examination, but sent her straight to hospital, as it appeared to be a bad fracture dislocation of some sort.

At the hospital she was seen by the house-surgeon and two members of the staff, who decided as we had, and anaesthetized her before attempting to make an exact diagnosis. As soon as she was under the anaesthetic they found the joint to be freely movable, and, except for the swelling, quite uninjured. We have seen the patient once or twice since, and find that both her elbow-joints are capable of hyperextension, which condition naturally increased the appearance of deformity; also her knee-joints became slightly subluxated on extreme extension, and her wrists and finger-joints are capable of more than normal extension.

CLINICAL AND SCIENTIFIC PROCEEDINGS.

NORTH LANCES AND SOUTH WESTMORLAND BRANCH.

Mental Deficiency.

A highly successful meeting of the North Lances and South Westmorland Branch of the British Medical Association was held at Lancaster on November 29th, when thirty members of the Branch were present. The members were entertained by Mr. WELCH, vice-chairman, and Dr. W. H. COUPLAND, medical superintendent of the Royal Albert Institution for Feeble-minded Children, and were shown round the work-rooms and saw the various grades of intellects being trained to useful occupation.

Dr. COUPLAND, in an interesting paper on certification under the Mental Deficiency Act (England), 1913, dealt with the procedure necessary to be followed in sending a mentally defective individual into such an institution, and showed the difficulties in the way and pitfalls to be avoided. He explained the technical meaning of such terms as idiot, imbecile, moron (higher grade feeble-minded), moral imbecile, etc., and showed how the "mental age" of each was ascertained by the Binet-Simon tests. Examples of the following types of cases were exhibited: Mongolian, cretin, hydrocephalic, microcephalic, paralytic types, a case of epilepsy with craniectomy, illustrating congenital deformities, scaphocephaly, hemicollis, Madelon's deformity, etc. Dr. Coupland said that it was very important that cases of adolescent insanity should not be certified under the Mental Deficiency Act. Defectives might, however, become insane and thus pass under the Lunacy Act, having then to be certified according to its procedure. Cases of simple stupor, or mild dementia praecox, might be tried first under the Mental Deficiency Act, remembering, however, the provision "from birth or an early age." Children who had taken a good position in school and gained prizes, but who mentally changed at 14 to 16 years, becoming untidy, unsocial, and stuporose, etc., were probably not mentally defective at all. Carried to an extreme the psychology of Freud was dangerous. Freud's ideas explained much of the conduct of the abnormal child and the mental stresses of puberty. He showed forcibly that the "unconscious" was a dynamic force in our mentality, and was not merely a quiescent receptacle for impressions stored in the unconscious region of the brain. A practical difficulty in dealing legally with abnormal children occurred in cases of mental disturbance following encephalitis lethargica. Those and similar cases required institutional treatment, but legally could not be properly certified as mentally defective, nor should they be dealt with under the Lunacy Act as of "unsound mind." Such stigma should, in his opinion, be avoided whenever possible.

After the reading of the paper, Dr. Cross proposed and Dr. COCHRANE seconded a vote of thanks to Mr. Welch, Dr. Coupland, and Dr. Henderson, and Mr. WELCH briefly replied.

NORTH GLAMORGAN AND BRECKNOCK DIVISION.

Miners' Nystagmus.

At a large and representative meeting of the North Glamorgan and Brecknock Division held at Pontypridd on November 30th, Dr. FREDERICK ROBINSON of Penarth gave an address upon miners' nystagmus. He dealt with the influence of the metamorphosis of coal, chiefly in its volatile characteristics, upon the incidence of nystagmus, and gave detailed evidence of the change in volatile percentages in the coals of the South Wales coalfield, illustrated by graphs and charts. He showed that as the seams passed across the coalfield from east to west and south to north debilitation occurred. He also pointed out that the volatile content of coals in other parts of the kingdom, having characteristics similar to those of South Wales and Monmouthshire, gave rise to a high percentage of nystagmus in mines with coals of the highest volatile content. The same principle appeared, therefore, to run through all the coalfields—namely, that a coal of high volatile content appeared to give rise to an increase in the incidence of nystagmus *per se*, and when computed in number of men employed. The variations as found statistically in the topographical distribution were reflected also in the

stratigraphical relationship of the seams to nystagmus as found in pits examined. Anthracitization of coal seams took place perpendicularly from upper to lower measures, at least in a large number of pits examined (Drs. Strahan and Pollard), and Dr. Robson found that nystagmus incidence had some correlation with the coals passed through from the upper to the lowest seams, and that increase of depth, with corresponding increase of temperature and pressure, had activating influences upon the etiology of the ailment. It was found that hard coals, with least volatility at greatest depth, gave a high percentage of nystagmus and higher than coals of greater percentage of volatility at more superficial levels—in other words, in hard coals temperature, depth, and pressure appeared to balance coals of softer composition with lower temperature and more volatility in the genesis of nystagmus. Dr. Robson said that volatile matter in a coal was not *per se* the actual cause of nystagmus, but that it was the index of the kinds of coal which appeared to give rise to the highest percentage of this ailment. It was found that, both in a linear or horizontal direction and stratigraphically, coal seam analytical variations were correlated with the incidence of nystagmus, soft coal measures giving rise to most cases and hard coal to least, except in so far that temperature and depth become provocative agents in nystagmus etiology. Dr. Robson next considered lumps and illumination, and gave detailed particulars of the rise and fall of nystagmus during the years 1909 to 1919. He showed that the portable electric lamps had not had any appreciable influence on the reduction of the ailment, but, *per contra*, nystagmus in those eleven years had increased by a very high percentage. He then discussed the possible toxic factors in the causation of nystagmus which was possibly due to mine gases, and his opinion was that the ailment was the result of a toxæmia or anoxæmia, or both. The toxicité was mostly evident in the bituminous coals, with high volatility, and was least in the anthracite coals.

Dr. MORGAN REES showed a case of nystagmus with exaggerated signs and symptoms, the head movements involving large excursions, which communicated themselves to the trunk and arms. Speech was hesitant, gait uncertain; words were slurred over and indistinct.

Dr. ROBSON said that this was one of the most pronounced cases that he had seen, and appeared to support the claim that nystagmus was a defect in the central nervous system.

BRIGHTON DIVISION.

At a clinical meeting held at the Royal Alexandra Hospital for Children, Brighton, under the auspices of the Brighton Division of the British Medical Association, the following cases were shown by the honorary medical and surgical staff:

Clinical Cases.

Mr. L. A. PARRY showed a case of hypertrophy of the right upper extremity, the enlargement being, as usual, most marked at the distal end of the arm. Mr. Parry also showed a case of "hypertrophy of the knee." The patient was shown as a text for advocacy of the "treatment as carried out at Leysia and Alton." The patient, that he had applied to the town council for the use of a certain number of beds at the sanatorium for the purpose of treating children suffering from tuberculosis, rickets, malnutrition, etc. It was pointed out that the results were never carried out quite as thoroughly as in the mountain country as in the mountains of Switzerland, but the results obtained at Alton, in Hampshire, were so good that there was no reason they should not have a thorough trial at other suitable places.

Dr. WALTER BROADBENT showed a boy suffering from tuberculous meningitis, whom he had shown six months ago with tuberculous pericarditis; the cerebro-spinal fluid contained 85 per cent. lymphocytes. He also showed a boy, aged 3, who had been twice in hospital comatose for some days with all the signs of meningitis, but had recovered with the aid of lumbar punctures and urotropin. In this case the cerebro-spinal fluid was under great pressure during the attacks but contained no abnormal cells. A third case was that of a boy with severe aortic regurgitation, who had a well-marked presystolic murmur and thrill—Dr. Flint's murmur, which did not signify any mitral stenosis at all. He had well-marked systolic and diastolic murmurs at the base of the heart and a water-hammer pulse.

Other cases shown included: A girl, aged 16, who had a large soft symmetrical goitre; a case of gland associated with a pulse rate varying from 100 to 120 a minute. She was free from exophthalmos, tremors, vasomotor disturbances, or gastro-intestinal symptoms; catamenia had recently become established and was regular.

A case of extensive paralysis of both legs in a girl aged 10, following acute anterior poliomyelitis in infancy. The case had been shown six months previously with, in the left leg, a flail-like and paralysis of the gluteus maximus and, in the right leg, paralysis of the quadriceps extensor cruris. Since then the left

foot had been stabilized by an arthrodesis of the subastragaloid joints after removal of the scaphoid, and the right knee had been treated by transplantation of the biceps into the patella. The patient could now walk well without apparatus, except a high boot on the left foot; there was a considerable limp due to the gluteal paralysis, but the left foot was strong and stable and the right knee balanced and steady in walking, though the transplanted biceps was not yet strong enough to extend the leg against gravity.

A case of acute anterior poliomyelitis in a child aged 8, dating from infancy. When first seen there was severe equino-valgus deformity of the foot and complete paralysis of the fibular anticus on the right, with 1 and 1 1/2 in. shortening. The case was treated by lengthening the tendo Achillis and transplanting the peroneus brevis into the internal cuneiform bone. The foot could now be inverted voluntarily, and the child walked well with a high boot, but no other apparatus.

A case of equinus and pes cavus, with slight eversion of the foot. In a boy, aged 9, due to the shortening of the limb from old infantile paralysis. The condition was treated by lengthening of the tendo Achillis, tenotomy of the plantar fascia, and transplantation of the extensor proprius hallucis into the neck of the first metatarsal bone, and arthrodesis of the interphalangeal joint of the great toe. The boy walked almost without a limp with a boot raised to correct the shortening.

A case of intussusception in a boy, aged 6, with some unusual features. There was a history of an attack of acute appendicitis six months previously, in which operation had been advised and refused. Twenty-seven hours before he was seen there was an onset of acute abdominal pain and constant vomiting, with absolute constipation. When seen on November 6th the child looked ill, with temperature 98°, pulse rate 116; in the right iliac fossa was a firm and tender mass in the region of the caecum. An immediate laparotomy was done on a diagnosis of appendicitis. On opening the abdomen the appendix was found adherent, but not inflamed, and the mass was in the caecum above it; it proved to be an ileal intussusception, passing through the ilco-caecal valve and lying in the caecum beyond the hepatic flexure. This was reduced and the ileum was sutured; the last portion to reduce was an invaginated ileal intussusception which had formed the apex of the intussusception. The patient's condition was not very good the abdomen was closed and the removal of the appendix and the diverticulum left to a future operation. His recovery was uneventful. (The Meckel's diverticulum and the appendix—which was adherent to the caecal wall—were removed on November 21st. The parts of the small intestine involved in the intussusception showed no pathological changes.)

Reports of Societies.

THE USE OF ERGOT IN OBSTETRIC AND GYNAECOLOGICAL PRACTICE.

At a joint meeting of the Sections of Obstetrics and Gynaecology and of Therapeutics and Pharmacology of the Royal Society of Medicine on December 7th, Dr. T. W. EDEN presiding, a discussion took place on the use of ergot in obstetric and gynaecological practice, with special reference to the position of ergot in the *Pharmacopoeia*.

Dr. H. H. DALL, in introducing the subject, said that such a discussion ought to promote a closer co-operation between the pharmacological laboratory and the practice of medicine. There had been too great a tendency for the laboratory worker to shut himself off in the pride of the more exact methods of measurement which he could use and the stricter experimental controls which he could apply; and, on the other hand, for the clinical observer to form the opinion that the laboratory investigator was an impractical pedant whose results had small relation to practice at the bedside. Such a problem as was suggested by that evening's discussion was one that could never be settled unless the laboratory experimenter and the clinical observer joined forces in some kind of agreement. Experimental work, say on living animals or on isolated organs and tissues, although it had great advantages in that its results could be recorded mechanically and measured exactly, could lead only a very little way when the matter at issue was the influence which drugs had upon the function of the parturient uterus in the human being, and could lead hardly at all when it was a question of readjusting an abnormal menstrual function. His own duty in that discussion was to put forward the position which could be reached by the methods of experimental pharmacology, but in the ultimate those methods were bound to fail, and the final decision must in any case be left to the practising physician.

The position of ergot in pharmacology and therapeutics was anomalous. It owed its introduction into therapeutics originally to the purely empirical observation of its effects on the human being, and while no definite knowledge existed as to the nature of the active principles of ergot, the methods adopted for preparing extracts from it for therapeutic use

were similarly settled largely by tradition, partly by experience, but by experience at best very vaguely and imperfectly recorded. About the middle of last century two types of preparation came into vogue, to each of which was given the name "ergotine"—an unsuitable name because it suggested something in the nature of a pure active principle. The preparations were made according to the fancy of individuals, and were merely crude extracts. In one of them the extraction began with water, and a certain amount of alcohol was afterwards added; in the other the preparation started the other way about. These were the extracts, in the present edition of the *Pharmacopœia*, which had had the greatest vogue. They were very much alike, and he did not think that either of them contained much of the essential active principles of ergot. There was another preparation in the *Pharmacopœia*—namely, ammoniated tincture of ergot, which from the scientific point of view ought to be much better than either of the others, but he believed it had been much less used in general therapeutics. The first substance obtained from ergot in a pure condition was ergotinin, a beautiful crystalline alkaloid, obtained as long ago as 1875. This was associated with a quantity of material which appeared to its extractor, Tanret, to have an identical chemical composition, but which differed from the crystalline substance in that he was unable to crystallize it in any way. Tanret's conclusion that the amorphous ergotinin was identical with the crystalline rather put back the clock for some time, because investigators took the crystalline in preference to the other; and it was not until Barger and Carr, fifteen years ago, worked out the matter that the so-called amorphous ergotinin was found to be really a different substance, of an intense activity, as he (Dr. Dale) was able to show by physiological experiment. This substance, now called ergotoxin, might reasonably have been regarded, so far as laboratory experiments were concerned, as the principle responsible for the therapeutic action of ergot, and it had a stimulant action on plain muscle, conspicuously on the plain muscle of the uterus. But such experiments as were made clinically did not seem to arouse any enthusiasm for its therapeutic properties, and among other contrary factors was the consideration—and he did not take so purely a laboratory view of pharmacology as not to admit that there was cogency in the argument—that the majority of practitioners were already using the liquid and the other extract given in the *Pharmacopœia*.

During the last few years a new point had arisen which for him had rather revived the interest of the question. A very able chemist, Dr. Stoll, who since the war had entered the service of a pharmaceutical firm in Basle, had extracted from ergot as a new alkaloid what was described as being at last the long-sought-after active principle of ergot—a substance producing all the action of good ergot and free from all the undesirable associated effects which the crude ergot might produce. On the face of it, it was evident that the new alkaloid, to which the name "ergotamin" was given, was very closely related to the old ergotoxin. It seemed quite possible that what Stoll had obtained was something which differed from ergotoxin only slightly in chemical composition. On the other hand, certain preliminary physiological experiments on the substance, published by Professor Spiro, professor of biochemistry at Basle, conveyed the suggestion that here was something on a different footing from anything previously described. He got into correspondence with the professor and arranged for an exchange of specimens—his own ergotoxin for the other's ergotamin—and in the result both of them agreed that the substances were absolutely identical, quantitatively as well as qualitatively. He showed tracings illustrating the similar action of both substances on the uterus of the cat and of the guinea-pig. Whatever might be the truth about the chemical relationship, practically the two were identical.

The question to be answered was whether the specific alkaloids of ergot—of which ergotinin citrate was one preparation, and ergotoxin and its salts another—alone give the therapeutical results. If so, then ergot must be included in the *Pharmacopœia*. It was clear also that if ergot was retained in the *Pharmacopœia* on account of its specific alkaloids, the old methods of preparing the official extracts ought to be revised so as to ensure that the alkaloids were present in the finished product, and not for the most part thrown away as they were now. On the other hand, if the non-specific putrefactive alkaloids, like tyramin, embodied in the modified formula of extra-pharmacopœial preparations, produced all the effects claimed for ergot, then it was equally

clear that ergot had no place in the *Pharmacopœia*, because these others could be more easily and economically obtained. He hoped that the discussion might do something to clear up these points, for he felt that the present position of this problem was not quite worthy of scientific medicine.

The Chairman, Dr. Evers, said that Dr. Dale had been very modest about his own share in these researches, but they would understand how important his work had been in elucidating the action of this drug. The fashion in obstetrics had altered in recent years, and there was a tendency for pituitary extract to replace ergot. But ergot could not really be superseded, because 50 per cent. of the confinements which occurred in the country were attended by midwives, into whose hands pituitary extract must not be given for free use, so that a uterine stimulant was wanted which did not possess any markedly toxic effects. It was difficult to form an opinion as to the clinical value of this or any drug. Some observers of a sanguine temperament appeared to get good results every time; others were unable to form any decided opinion. Yet the action of ergot on the uterus was so simple and specific that one would think there could not be much room for mistake in the clinical impressions formed. He had often wondered whether pharmacologists could not assist in the scientific record of the action of ergot on the parturient uterus. He himself had formed a very strong opinion as to the value of ergot as a uterine stimulant during and after labour, but in recent years there had been difficulty in getting suitable preparations. He was doubtful about the action of ergot in gynaecology, and would speak on that only with great reservation. He did not know that ergot had much effect on the quiet uterus. He urged that the editors of the *British Pharmacopœia* should endeavour to move the Government to furnish a grant of money, so that, at any rate, the more important drugs in the *Pharmacopœia* might be properly tested.

Sir NESTOR THIRARD (senior editor, *British Pharmacopœia*) said that he did not know whether he was expected to take the position of defending counsel or of the defendant himself, but he wanted to give the meeting some idea of the trouble that was taken in producing the current *Pharmacopœia*. It was not quite the fact that the compilers had gone on from one issue to another, following some hallowed tradition. They were not quite so blind as that. They had endeavoured to act on information received. They had taken a great deal of trouble to ascertain the wishes of the medical profession. They had sent round to nineteen licensing bodies a form of inquiry for any additions, alterations, or omissions which might be suggested, and the authorities in most cases, though not in all, were good enough to make some suggestions. Not one of the nineteen bodies, however, suggested the omission of either of the extracts of ergot. One body—he believed it was the University of Manchester—suggested that the preparation might be improved, but that was a pious opinion which might be held with regard to every pharmacopœial substance. Another suggested that only the active principle should be employed, and another that it should be standardized physiologically. Here was the crux of the matter, for the compilers of the last *Pharmacopœia* had no power to standardize anything physiologically. The Germans and Americans, who had Government institutions which controlled physiological experiments, were in a different position, but there was nothing of the kind in this country at present, though it was hoped that in the future some Government standardizing authority might be set up. It appeared from a recent report that Dr. Dale had found that the preparations of pituitary extract stood in need of as much revision and control as those of ergot. It was no indication that a drug was not used to find that it was not present in a large number of prescriptions. The compilers of the *Pharmacopœia* had asked a large number of chemists to analyse some 48,000 prescriptions, and in not one of these did any official preparation of ergot appear. It might be concluded from this that it was not wanted, and could be deleted; nevertheless, it was known to be used largely when required, though happily it was not the practice to give patients prescriptions containing what must be regarded as a dangerous drug if improperly used. The compilers of the *Pharmacopœia* wanted to know the wishes of the profession. If the profession generally employed any drug—not in an ephemeral way, because it had become a fashion—so largely that it was desirable that its composition should be controlled, it should make its wishes known through the licensing bodies so that such wishes might be conveyed to the *Pharmacopœia*.

Committee of the General Medical Council, where they would receive adequate attention, and if the Government set up a State laboratory where experimental work could be controlled and standards laid down, the information received could be referred to such a laboratory.

Professor W. E. DIXON said that one of the most remarkable facts which had come to light in medicine during the last twenty years was the fact that the body worked by means of substances not very far removed from the crystalline alkaloids of pharmacology (he referred to such things as adrenalin). It was of interest that some of the crystalline substances found in ergot were also manufactured in the alimentary canal as a matter of course, and as these substances were readily absorbed they were no doubt responsible for the signs of alimentary toxæmia which he supposed everyone suffered from to a greater or less degree. The normal stimulus to the uterus, especially under certain conditions, was excretion of pituitary, and it was interesting to find that gynaecologists had discovered this fact for themselves and preferred pituitary, which they know produced a definite effect, to ergot, which might or might not produce a certain effect. In 1915 in Germany a number of experiments were performed on parturient women in which the movements of the uterus were recorded in a manner similar to that in which pharmacologists recorded the uterine movements in animals. The results were published in the *Münchener medicinische Wochenschrift* in six or eight papers. These showed that when pituitary extract was injected into the patient the pains became quicker, but there was comparatively little increase in tone; with certain samples of ergot, on the contrary, the pains were increased five or ten minutes after injection, but the tone of the uterus was also considerably increased. With regard to the preparations given in the *Pharmacopœia*, pharmacologists were perfectly clear that the American liquid extract was infinitely superior to the British liquid extract, the latter being frequently without action at all. He understood that the compilers of the *Pharmacopœia* took the position that it was not their business to suggest useful substances, but to accept suggestions; they followed in the wake, they did not lead the profession. It was a little difficult to see where any advance was to be made along these lines.

Dr. HERBERT SPENCER said that for the last thirty years he had never prescribed in private any other preparation of ergot than the ammoniated tincture; he had found this from experience to be by far the most potent, much more so than the liquid and the other extract. He emphasized the importance of the association of pharmacological laboratories with clinical work. Professor HENRY BRIGGS said that for his part he had not used ergot for quite twenty-five years, and had never felt the lack of it. He emphasized the need for close contact between laboratory and bedside. Mr. ALECK BOURNE said that during the last few weeks there had been established at Queen Charlotte's Hospital a means of measuring alterations of intruterine pressure. The work had been done in connexion with the committee appointed by the Obstetrical and Gynaecological Section to investigate the action of pituitary extract. Very little had as yet been done, but the results would be communicated at the proper time. It was impossible for those who worked clinically to give impressions of any value as to the action of drugs. There were too many variables; the patient, the disease, and the drug were all variables. He suggested that another committee should be appointed *ad hoc* to thrash out the matter in connexion with ergot and its derivatives.

Dr. DALE said that Sir Nestor Tirard had put forward a position which, of course, was quite understandable. The function of the *Pharmacopœia* Committee was not to lead the profession but to follow it. If the committee waited for some indication of dissatisfaction from the profession before it moved the position was rather hopeless, for the profession was apt to regard the *Pharmacopœia* as an authority, setting up a standard, not only of what was actually prevalent, but of something which had at any rate a reasonable theoretical basis. He noticed that in the last edition of the *Pharmacopœia* (1914) there was a slight change in the process given with regard to extract of ergot, and he wondered whether that was made in response to any widely expressed desire.

Sir NESTOR TIRARD said that the compilers were controlled, not only by the wishes of the profession in this country, but by an international agreement, and Dr. Dale would have to educate not only obstetricians in this country but obstetricians in all the signatory countries.

Dr. DALE remarked that in 1885, instead of the present ammoniated tincture of ergot, there was a plain tincture. For some reason that was altered, and he was not sure that it was an improvement. Mr. Bourne was rather pessimistic about the possibility of clinicians collecting any useful evidence, and Dr. Dale agreed that if the Obstetric Section could appoint a committee to thrash out the ergot question in the same way as the pituitary question was being thrashed out it would be the best way of furthering the matter.

The CHAIRMAN said that the Section of Obstetrics and Gynaecology would do its part in the formation of such a committee, but the committee ought to be a joint one, in which the Section of Therapeutics and Pharmacology would participate.

PRE-NATAL CARE:

At a meeting of the Liverpool Medical Institution held on November 30th, with the President, Professor J. HILL ABRAM, in the chair, Mr. A. LEYLAND ROBINSON read a note on pre-natal work and puerperal mortality. He said that an analysis of 222 fatal cases showed that the causes of deaths in childbirth could be divided into four big groups: (1) haemorrhages and obstetric accidents; (2) the toxæmias of pregnancy; (3) sepsis; (4) pre-existing or intercurrent disease. In general hospitals pre-existing or intercurrent disease was the most important; in maternity hospitals the haemorrhages and accidents of labour; sepsis was insignificant in both and must therefore arise chiefly among patients delivered in their own homes. Only a small proportion of the cases described had received any treatment during pregnancy, although preventive measures might have saved many lives. He considered that pre-natal care was especially valuable in the prevention of convulsive eclampsia and the accidents of labour; its relation to the haemorrhages (accidental and placenta prævia) and to many general diseases required further investigation but offered a wide field for research. Routine examination during pregnancy would enable the practitioner to diagnose and correct many abnormalities before the onset of labour—this would undoubtedly reduce the number of emergency operations now performed under unfavourable conditions in patients' homes and therefore reduce sepsis, which most commonly follows this type of case. In conclusion Mr. Leyland Robinson urged that the training of medical students and midwives be amplified, and that the general public should be made to realize that pre-natal supervision is essential to the welfare of all expectant mothers.

Professor BRIGGS maintained that the sources were as important as the figures in statistics. The strength of an official midwifery service depended on fully equipped maternity wards and their influence on the home district practice. This had been repeatedly and fully illustrated and never more effectively than in Liverpool by the paper read that night by Mr. Leyland Robinson.

Dr. JOHN HAY emphasized the value of ante-natal supervision and treatment in all pregnant women suffering from valvular disease of the heart. During the last twelve months he had had under observation at a rest home 14 such cases, 4 of them being advanced valvular disease of the heart of the mitral type in whom fibrillation was present; 10 cases were non-fibrillating, and 9 of the 10 suffered from mitral stenosis, the other one being an aortic regurgitation. In pregnant women suffering from valvular disease the patient must be treated as a cardiac case. Dr. Hay thought that the advantage of supervision in such cases was that an opportunity was afforded for materially improving the reserve power of the heart in preparation for the strain of labour. In fibrillating cases the response to digitalis could be estimated, and in the graver degrees of cardiac embarrassment an opportunity was afforded for considering the question of operative interference.

Dr. FRANCES IVENS considered that ante-natal care was a very important factor in the lessening not only of puerperal mortality but of puerperal morbidity. It diminished the necessity for instrumental interference with its added risk of maternal injury and infection. In a series of 305 consecutive maternity cases in which she had made a careful examination during pregnancy forceps had only been required in less than 3 per cent.

Mr. FRANK JEANS read a note on a modification of technique in intestinal obstruction, which he had practised in removing growths from the large gut. It consisted of Paul's method with immediate destruction of the "spur" by scissors and

suturo and the use of a large Paul's tube for the double-bore exit. It combined the safety of Paul's method with a shortening of the convalescence and was more rapid than anastomosis with drainage.

Mr. K. W. MONSARRAT considered that Mr. Jeans's suggestion was a valuable point in technique when the type of operation to which Mr. Jeans referred was chosen. In the presence of acute obstruction, however, he was in the habit of performing a caecostomy in most cases to be followed by resection of the growth and anastomosis. Even in cases without acute obstruction he believed this or some similar proceeding to be preferable to leaving a temporary anus at the site of the resection.

Mr. T. H. BICKERTON read the original *Memoir of Dr. John Rutter*, Founder of the Institution. The memoir was written by Dr. Rutter's nephew, Mr. John Rutter Chorley, in 1839. Mr. Bickerton eulogized Dr. Rutter's services to the medical profession and the city of Liverpool.

RELAPSING PYREXIAS OF LYMPHADENOMA.

A MEETING of the Sheffield Medico-Chirurgical Society was held on November 23rd in the Medical Library of Sheffield University, with the President, Dr. RUFERT HALLAM, in the chair, when Professor ARTHUR J. HALL read a paper on the relapsing pyrexias of lymphadenoma.

Professor HALL began by drawing attention to the fact that the disease occurred in two forms—a "macroscopic" form, in which there were obvious glandular swellings, and an "occult" form, in which glandular enlargement was absent and in which the diagnosis was always difficult. Further, in this occult form there was one subclass of case in which the diagnosis was definitely considered, but there was also another subclass in which it was never even thought of until autopsy declared it. He then proceeded to discuss that type of lymphadenoma originally described by Pel and Epstein, in which there was a recurrent pyrexia over a long period of time. Although admittedly a rare type of the disease, some of its apparent rarity might be due, he said, to difficulty of prolonged observation, in that patients might not be seen by the same medical man in successive attacks, and owing to the intervals of comparative good health the subjects of this disease were averse to prolonged hospital residence. One of the chief difficulties in getting a clear mental picture of the condition, at any rate so far as the pyrexia was concerned, lay in the very cumbersome temperature charts which must be scrutinized if a case was completely recorded, and in order to overcome this difficulty Professor Hall had devised a standardized type of chart whereon in a very short space could be expressed the morning and evening temperatures over a very long period. A series of these charts were thrown on the screen, showing the pyrexia in such conditions as pneumonia, empyema, tuberculosis, etc., for comparison with which the standardized charts of all the published cases of the Pel-Epstein type of lymphadenoma were also shown. In a study of these cases, and also of two of his own, Professor Hall demonstrated the extraordinary regularity of the recurrent fever. The period of recurrence varied in different cases, although the average seemed to be about twenty days, but was constant for any individual case. So regular was this periodicity that in one of the published cases, before its completion, the time of the return of the pyrexial wave was accurately predicted merely from a careful examination of the previous pyrexial periods, a prediction which was later verified. So striking was this recurrent type of fever that the possibility of some protozoal infection was very strongly suggested, and the lecturer related one case of lymphadenoma of that type which was for some time treated as a case of malaria. At the same time he pointed out the criticism that in all the diseases where protozoa were responsible for recurrent pyrexia, rat bite fever, malaria, etc., the apyrexial periods were short, and the twenty days' interval of lymphadenoma was unusual; but at the same time some of the cases showed a short apyrexial period, as in one published by McNalty.

Dr. R. HALLAM, Dr. A. E. NAISH, Dr. T. ROBERTSON, and Dr. A. E. BARNES took part in the discussion which followed the address.

X-Ray Treatment of Malignant Disease.

Mr. REGINALD A. MORRELL read a paper entitled "The application of modern x-ray apparatus to the treatment of malignant conditions." In his preliminary remarks Mr.

Morrell pointed out that the problem which had engaged the attention of the radiotherapists in the past—namely, that of conveying a sufficient dosage to a sufficient depth—was on the way to being solved by the latest apparatus and technique evolved in Germany. Moreover, great advances had been rendered possible as regards standardization and measurement of dosage, and by these means we were getting within measurable distance of the point when radiotherapy might be considered an exact science. While admitting that the newer apparatus and methods of the German schools constituted a great advance, Mr. Morrell maintained, however, that the present claim of the Erlangen school to treat primary malignant disease by radiotherapy in preference to surgery was indefensible, as it was based on a fallacy—namely, the minimum lethal dose, the very existence of which was disputed in many quarters and could not be substantiated in practice. Moreover, this system of massive dosage did not take into account the danger of diminishing the patient's resistive powers. Other reasons were advanced to show that we were very far from any universal cure, even in those cases which were most favourably situated. On the other hand, those newer methods were likely to be of the greatest service in treating inoperable cases, and where from the very nature of things greater risks were justifiable. Mr. Morrell concluded with a reference to the various methods, still in their experimental stages, by which malignant growths might be rendered more sensitive to radiotherapy. In the event of these being successful many of the objections which had been raised would be negatived and the use of the apparatus would be firmly established. In any event, the treatment was essentially one for an institution, as it demanded the services of a properly qualified whole-time medical officer and the co-operation of the surgeon and the pathologist.

AFTER-EFFECTS OF LETHARGIC ENCEPHALITIS.

A MEETING of the Royal Medico-Chirurgical Society of Glasgow was held on November 17th, when Dr. GRACE ANDERSON read a communication on the sequelae of lethargic encephalitis in the child. Her observations were made on 33 cases that recovered from the primary attack. These children had suffered from disturbances so similar and so typical that those disturbances had become regarded as conclusive evidence of a previous attack of encephalitis lethargica. In many cases the sequelae had proved the nature of the primary attack. The sequelae in the order in which they appeared were: (1) nocturnal wakefulness and excitability, and (2) psychical disturbances, which included changes in disposition, mental impairment, and habit peculiarities. The nocturnal wakefulness was characterized by persistent insomnia with extreme motor unrest and excitement during the night, followed by more or less marked lethargy during the day. The prognosis as regards complete recovery was bad. Of the psychical disturbances, which in most cases had followed a long period of nocturnal insomnia, change of disposition was the most important. Disobedience, bad temper, cruelty, even kleptomania, had appeared in previously good children. Mental impairment or interference with memory was absent, but the children were unable to check the impulse to do wrong. In 10 cases there was definite mental impairment without much change of disposition. The habit peculiarities most frequently met with were spitting and hysterical dyspnoea. These Dr. Anderson considered to be late sequelae, because they persisted long after the normal sleep sequence had been regained. The former was not a true sialorrhoea, as the habit could be controlled for a long period without accumulation of saliva. Hysterical dyspnoea was characterized by paroxysmal attacks of "panting like a dog."

Professor EDWIN BRAMWELL (Edinburgh) communicated a paper entitled "Remarks upon lethargic encephalitis, with special reference to the late symptomatology and persistent after-effects of the disease." Professor Bramwell explained that the official figures of mortality were apt to give an exaggerated impression as to the fatality of the disease. This was due to the fact that mortality figures were based upon notified cases. Among 56 cases observed up to 1919 only 9 died, and from a larger number of cases seen a mortality of not more than 20 per cent. occurred. This corresponded with the conclusions arrived at by the Committee of the American Association for Research in Nervous and Mental Disease appointed to study the subject. Of the deaths probably four-fifths occurred within the first month,

and thus the risk of a fatal issue was small after the first four or five weeks. The speaker's opinion was that complete recovery was exceptional. The effects of the disease tended gradually to improve, although relapses tended to occur even one to two years after the primary attack. Dr. Brainwell considered that some of the so-called sequelae should be regarded as a disease progressive for the time being rather than the consequence of a pathological process which was no longer active. The most common after-effect was probably a general lack of physical and mental energy. Initiative, discrimination, and judgement appeared to be impaired, as also were memory, concentration, decision, and many other individual characteristics. Some of these symptoms probably were directly dependent upon the pathological process, and some might be accounted for by a superimposed neurosis consequent upon the patient's mental attitude towards his case. The mental phenomena observed in the child often differed materially from those observed in the adult, because in one case it was the developing and in the other the developed brain that was attacked. Various pareses or paralyses of more or less sudden onset were not infrequently caused by encephalitis lethargica, and even the Argyll Robertson pupil might be a result. Diagnosis from brain tumour might be very difficult when an encephalitis manifested its presence by producing a progressive hemiplegia. In some cases abnormal movements recognized months after the acute attack might appear when the patient was well on the way to recovery. Coarse tremor, general motor restlessness of choreic type, twitching of the face, pouting and puckering of the lips, irregular movements of the diaphragm, purposeless movements of one or more limbs were among the phenomena observed. One patient increased greatly in weight, an observation which was not unique. The Parkinson syndrome was not uncommon, and again and again the physiognomy gave the clue to a diagnosis of lethargic encephalitis, although the certain diagnosis from true paralysis agitans might not always be easy in the absence of a history of an acute illness with febrile disturbance and, it might be, diplopia. The Parkinson syndrome was met with in children as well as adults, whereas paralysis agitans was essentially a disease of later life, and was extremely rare under 30 years of age. Tumour of the brain and lethargic encephalitis were not always readily diagnosed differentially.

Dr. HENRY J. WATT reported the results of his application of the Binet (Burt) tests to a score of children who had had lethargic encephalitis. The mental ratio was found to be, on the average, 68 ± 8 . This figure might be compared with the average mental ratio of 114 children in the Royal Hospital for Sick Children, Glasgow—namely, 88 ± 16 . The difference seemed significant. The intelligence of the child was apparently distinctly impaired by the disease. The number of cases examined by the method did not yet, however, warrant very definite statements.

Dr. JOHN THOMSON (Edinburgh) thought that it was interesting, though probably not of any great importance, to notice how many resemblances there were between the clinical symptoms in some of the slighter cases of epidemic encephalitis in children and those often seen in severe chorea. For example, in both conditions there was a mask-like facies, irregular, imperfectly controlled muscular movements, irregular, imperfectly controlled emotional disturbances, also a striking change in the child's character, and obstinate insomnia. There was, of course, no question of the two diseases being due to a common cause, but the local lesions set up in the brain were not dissimilar. The recent work of Poynton and Holmes, of Greenfield and Wollsolun, and of various Continental pathologists seemed to show that the essential lesions in chorea consisted in a slight diffuse or disseminated encephalitis, which was not very unlike that in lethargic encephalitis either in its appearance or its distribution. Dr. Thomson also spoke of the great frequency and importance of noisy hyperpnoea as a symptom of epidemic encephalitis in children, although it was a comparatively rare manifestation of the disease in adults. This sort of "heavy breathing" or "panting" was a very noticeable feature from the first in the youngest case he had seen—that of a girl baby whose earliest symptoms occurred on the twenty-first day of life. It was also noticed early in the oldest case of the kind he had had in a child—a girl between 14 and 15. In his experience it was a prominent symptom in a large majority of the cases seen in children, and, as Dr. R. D. Clarkson had pointed out to him, it probably helped more than any other of the symptoms in coming to a diagnosis, when the other

manifestations of encephalitis lethargica were indefinite and no proper history was available.

Professor MORRO, after referring to the now well-known syndrome in the adult group, spoke of the symptoms in children and of the intermediate cases. He suggested that the so-called sequelae were possibly due to a lighting up of an old lesion—that the disease was still active after a year or two. The late symptoms were a Parkinsonian condition, weakness of muscles, and fixity of features, often without tremor. He was not familiar with severe mental derangements.

Dr. D. K. HENDERSON spoke of the condition from the point of view of the psychiatrist. In institutions a fairly acute type of organic reaction was what was generally met with. There was not so much a defect in memory, etc., but a defect along the line of emotional life. The end-result seemed to be more a state of emotional dulling or stupor with retention of memory and intelligence. Dr. Henderson questioned the value of Dr. Watt's tests.

Dr. ILY MACKENZIE also doubted the value of Dr. Watt's tests. He stated that in over 100 cases he had not seen one case of complete recovery nor one of genuine alienation. Many cases were able to return to work. He had seen many children whom he would send to an asylum, but principally because they could not be looked after at home. He expressed doubt as to the probability of recurrence of infection.

Dr. LEONARD FINDLAY referred to the difficulty of diagnosis in many early cases, and stated that it was possible in many cases only after long observation. Like Dr. Mackenzie, he considered that there was no complete recovery in most cases. Many cases were only diagnosed from the sequelae. It was uncertain whether the late symptoms were due to a fresh outbreak or to the results of cicatricial contraction. There was never febrile disturbance. He considered Dr. Watt's tests good and as proving that the children tested were inferior to the age at which the disease developed.

SOME MEDICAL RARITIES.

A MEETING of the Medical Section of the Royal Academy of Medicine in Ireland was held at the Royal College of Physicians, Dublin, on November 24th, with the President, Dr. T. G. MOORHEAD, in the chair. The President welcomed the Fellows and Members to the first meeting of the session and then delivered a short address on the principles of therapeutics.

Sir JOHN W. MOORE read two papers, one on xanthoma diabeticorum, and the other on myelogenous leukaemia.

Xanthoma Diabeticorum.

The first case was an example of intractable diabetes mellitus in a girl of 14 years. The disease had lasted nine months when she came under observation on February 20th, 1922. Occasional attacks of acidosis occurred, but yielded to treatment. A persistently low body temperature was a marked feature. It was not, however, until August, 1922, that the condition which lent unusual interest to the case supervened. On August 12th the girl's mother reported that a "rash" had broken out on her daughter's elbows and knees. This consisted of crops of papules on the extensor aspect of the elbows and knees, and some of the papules showed a yellow coloration. A diagnosis of xanthoma diabeticorum was made. A photograph taken at the time showed the distribution of the "rash" and also the extreme emaciation of the patient. Subsequently, similar papules developed in other regions of the arms and legs. Many of them became unhealthy—ulcerating and crusting in such a way as to suggest degeneration of some secondary infection. Death ensued on October 8th.

The second case was leukaemia in a boy aged 11 years, who ing. His illness began about two months before admission, but acute symptoms, such as violent pain in the front and the left side of the abdomen and transitory feverishness, set in only a fortnight before he came into hospital. Extreme prominence of the abdomen and lower part of the left chest proved to be caused by an immense spleen, smooth and firm. The differential blood count, on October 9th, showed red cells 3,200,000, haemoglobin 50 per cent., white cells 400,000 per c.m.m., and myelocytes, large lymphoid cells, polymorphs, mast cells, and normoblasts were also present. The treatment consisted of the internal administration of liq. arsenicalis in 3-minim doses, at first twice and later thrice daily, with galvanism to the abdomen and afterwards x-ray exposures. On November 3rd the leucocyte count had fallen to 300,000 per c.m.m. and the spleen had shrunk considerably; this was before the first x-ray sitting, which took place on November 13th. On November 23rd the blood count showed that the white cells had fallen to 185,000, a diminution of about 38 per cent.

Dr. CROFTON said that in regard to Sir John Moore's remarks on insulin he had brought before the Academy in

1910 an extract very similar to that referred to. He was of opinion that the Allen diet did harm, caused distress to the patient, and was a most illogical proceeding.

Sarcoma of the Kidney.

Dr. HARVEY described a case of tumour of the kidney, with precocious sexual development, which had recently been under his care in the Adelaide Hospital.

On admission, the patient, a girl of 2½ years, had been having regular menstrual periods for some nine months. She was a small, thin child of apparently normal mental development for her age, but having well-developed secondary sexual characters. There was a coarse growth of hair on the face and neck, a markedly adult type of hair on the arms and legs, and a tumour on the left side involving the kidney and suprarenal, and extending across the abdomen. The temperature was subnormal, the pulse rate 100 to 120, the bowels confined, and the urine normal. The systolic blood pressure was 130, the diastolic 85. The red blood corpuscles numbered 6,000,000, the white corpuscles 5,000 per c.mm.; colour index 0.7; Wassermann reaction negative. Family history was healthy and the patient's child, but weakly from birth. X-ray examination showed no abnormality in the bony development. Mr. Gunn and Dr. Madill operated, but found the tumour incapable of resection. The child lived for some five weeks more, and died on October 17th, having wasted to a mere skeleton. She did not seem to have been in pain and her only symptom was a persistent craving for fluid.

Professor O'Sullivan made the post-mortem examination. The body and limbs were wasted to the last degree. The abdomen was greatly distended. Breasts measured 1½ inches in diameter and were elevated above the surface. The nipples were 9/16 inch in diameter. The tumour occupied the greater part of the abdominal space, and weighed 6 lb. 1 oz. It was 10½ inches in length by 6 inches in breadth; on the lower side was a cystic lobule 3½ by 3½ inches. On section it was found to be composed of a brain-like substance, white in colour, with patches of canary yellow and streaks of green. It was loosely divided into lobules, and was very vascular. The attached lobule was a cavity filled with a clear fluid mixed with blood. The smooth and shiny walls were partly tumour and partly connective tissue. In places in the brain-like mass kidney substance could be recognized. The thymus was practically non-existent, and the left ovary was cystic, while the right kidney was hypertrophied. Other organs appeared normal, but were reserved for further examination, microscopic and otherwise. A preliminary microscopic examination of the tumour showed it to be a very cellular and vascular sarcoma.

Dr. Harvey exhibited photographs, lantern slides, post-mortem specimens, and a microscopic slide of the tumour. He stated that the further pathological examination of the case was proceeding.

The President recalled that Dr. Gordon Holmes had reported a case of a girl who up to the age of 16 was not abnormal; at 17 a tumour developed in the abdomen; coincident with this, male secondary sexual characteristics appeared. The tumour was removed, the male characteristics disappeared, and the female ones again appeared.

Professor PRINGLE, Dr. CROFTON, and Dr. G. E. NESBITT also spoke, and Dr. HARVEY replied.

ARTHRITIS.

At a clinical meeting of the Devonshire Hospital Research Society, Buxton, held on December 1st, the following cases were exhibited and discussed:

1. A case of septic (non-purulent) arthritis of the knee following a pedicle wound. The joint had been quite stiff but was gradually recovering movement.
2. A case of generalized infective arthritis commencing at the age of 12 and now at 18 years of age showing a considerable degree of recovery. No cause had been discovered, but a tonsillar infection was suggested.
3. A case of spondylitis deformans affecting the dorsal region in a young woman. The disease appeared to be quiescent and the question of exercises or immobilization as a line of treatment was submitted for discussion. The general opinion was in favour of exercises of a suitable character.
4. A case of multiple symmetrical arthritis probably of the nature of a periarthritic fibrositis of twenty years' duration. Recently small painless swellings appeared round the joints lasting two or three days.
5. A group of cases affecting the larger joints with much morning and little pain and free movement. Skiagrams showed marked erosion of the bones and no hypertrophic changes. One was of twenty years' duration affecting elbows, knees, and wrists. The patient, a weaver, worked at his trade until quite recently. Another of five years' duration worked as a craftsman in the army and subsequently at his trade in spite of his arthritis. The possibility that cases of this type (differing in many ways from the more common type of infective arthritis) might be due to some specific organism was suggested, but venereal infections were excluded.
6. A case of solid oedema of one leg extending to the knee of seventeen years' duration. A scar above the knee marked the site

of an abscess which had developed six years subsequent to the onset of the oedema. No cause could be elicited in the history or by clinical examination.

7. A case sent in as sciatica which proved to be acute tuberculous disease of the hip. The man was 30 years of age and had a similar attack at 18 but no trouble in the interval. He was treated by extension, dry cupping, and tuberculin. In the course of six weeks all pain disappeared, the temperature became normal and he was now about to be discharged on a Thomas's splint. A skiagram showed that extensive absorption of the head of the femur had taken place.

8. A case sent in on account of polyarticular gout of many years' ago the patient began to stammer and now has coarse tremors of hands and tongue; he has an aspect suggestive of Parkinson's disease.

Although the case was not typical this was regarded as the probable diagnosis. The reflexes were normal.

9. A man of 35 who has had pains in his calves for ten years with gradual wasting. There were no sensory symptoms beyond the pain, no Babinski sign, and the knee and Achilles jerks were normal. He walked in a leaning forward position. No definite diagnosis was arrived at.

10. A man of 25, admitted as a convalescent after rheumatic fever. He had mitral and aortic regurgitation and was shown on account of his blood pressure, which was 160 systolic and 0 diastolic. The cardiac sounds could be clearly heard over the radial artery, the sphygmomanometer marking zero.

A general discussion took place on the cases.

At a meeting of the Bath Clinical Society held at the Royal United Hospital on December 1st, with the President, Mr. W. G. MUMFORD, in the chair, Dr. D. A. MITCHELL showed a case of chronic osteomyelitis and one of chronic bursitis, Dr. J. M. COATES showed a case of cysticercus cellulosa, and Dr. V. S. LEVIE two cases of mother and daughter with fatty tumours in the arm. Mr. A. L. FULLER exhibited a gall stone which had caused acute intestinal obstruction, also several renal calculi and a large vesical calculus removed from the same patient. The President showed two specimens of kidneys removed for pyonephrosis. Dr. W. H. DUNCAN, in a paper entitled "Notes on some common ailments," dealt with migraine and spasmodic asthma, and gave his experiences with regard to treatment. The paper was discussed by various members.

A MEETING of the Aberdeen Medical-Chirurgical Society was held in the society's hall on December 7th. The meeting took the form of a clinical evening, and a number of interesting cases were shown and discussed. Dr. GRIDDIE showed a child, aged 15½ months, with osteogenesis imperfecta. Mr. MITCHELL showed two cases of regeneration of the lower half of the femur after subperiosteal resection for acute septic osteomyelitis. He also showed a case of congenital club-foot corrected by manipulation, the position being maintained by insertion of a silk ligature from the fifth metatarsal to the anterior border of the tibia. Professor ASHLEY MACKINTOSH exhibited a woman, aged 53, with the appearance of myxo-oedema; she had some interesting vascular and arthritic features, probably luetic in origin. Dr. A. GREIG ANDERSON showed a case, aged 22, of Milroy's disease; the onset was at the age of 8, in the left leg, after an operation in the groin; the right leg became swollen at the age of 14. Mr. Greig Anderson also showed a case of lipo-dystrophy progressiva, with extreme wasting of the fat of the face and the upper part of the body down to the pubes; the legs and buttocks were normally developed. Mr. WILLIAM ANDERSON showed a case of subcutaneous rupture of the extensor communis digitorum. Sir H. M. W. GRAY showed a case of tumour of right thigh for diagnosis; in his opinion it was probably a lipoma. He also exhibited a case of arteriovenous aneurysm of the femoral artery and vein. Mr. F. K. SMITH showed a case, aged 27, where a tibial bone graft was used to replace the upper half of a humerus, lost over a year previously through osteomyelitis; x-ray photographs of various stages were shown, and the result was very satisfactory. He also showed a case of syphilitic ulceration of a breast in a woman, aged 65. Mr. COLT showed two cases for Professor MARNOCH: (1) Myositis ossificans of the left elbow in a male of 47 who had dislocated the joint eleven weeks previously; (2) sero-cystic disease of the left breast of five years' duration in a woman of 44, who twenty-five years before had been confined, but had no subsequent pregnancy and no dysmenorrhoea; three of the cysts had ruptured during the last five years, discharging serous fluid, latterly blood-stained. Dr. SANDEMAN showed a case of a young girl with calcinosis. Dr. CROLL showed a case of mediastino-pericarditis, and discussed the value of the various signs thought to indicate this condition. Dr. INNES showed two cases of dextrocardia, with transposition of viscera; three members of the family—two brothers and one sister—had the same condition. Skiagrams illustrating the condition were exhibited.

Rebichus.

FLETCHER MOULTON.

JOHN FLETCHER MOULTON was born in 1845; he left school in 1861, taking a scholarship at the matriculation examination of the University of London; after that for three years and a half he was a schoolmaster; in 1864 he graduated B.A. London and went up to St. John's College, Cambridge, with a scholarship; in 1868 he was Senior Wrangler and first Smith's Prizeman, and was elected Fellow of Christ's College. All this before he was 23. In 1873 he was called to the Bar; in 1885 he took silk; and for the next twenty-one years he was acknowledged supreme in the line of practice to which he had devoted himself. In 1906 he was made a Lord Justice; in 1912 a Lord of Appeal. He began his war work in September, 1914, and soon after it was finished died, in his sleep, on March 8th, 1921.

Here is a brilliant career, but one which might be paralleled by the lives of many successful lawyers. The reason why he was asked to undertake certain war work is the reason why his biography,¹ written by his son, is of much interest to us of the medical profession. Moulton was not merely a quick-witted advocate who crammed up a scrap of science to conduct a case; he was himself a man of science, imbued with its spirit and understanding its methods. He got into big practice just at the time when science was becoming of first-rate importance to industry. Patent law and practice were cumbersome and antiquated; Moulton did very much to put them on a rational basis. His biographer writes of the difficulty he had in addressing judges "wholly without scientific knowledge," who "often seemed to have neither the desire nor the capacity for appreciating scientific matters." We would not care to go quite so far, and would prefer the more charitable explanation, at which the biographer hints, that their inability to understand was due to the defective education then given in the public schools. Nor would we agree that the veil has altogether passed away, or is wholly confined to judges. Mr. Fletcher Moulton was concerned in the inquiry which followed the establishment of the fact that beer from a certain brewery, the drinking of which had on medical grounds been shown to be associated with a set of cases of illness observed in Manchester hospitals, contained arsenic. This is how the biographer puts it: "The natural curiosity of the doctors and students led to a number of questions being put to the victims, including queries as to whether [*sic*] and what they drank, and it was found that they all drank beer and patronized certain public-houses, which were all found to draw their supplies from the same brewery." We would like to have heard Lord Moulton on this, but we must not too severely blame his biographer when we find a writer in the chief literary review of the day, evidently learned and clearly desirous of being open-minded, speaking of science "in its broadest sense of the investigation and interpretation of the experiences of human life and its environment, not only by our sense-observation, but also by our mental powers." It is an odd platitude to find in such a place.

Lord Moulton in the evidence he gave to the Royal Commission on experiments on animals (1906) rendered a great service to medicine by his masterly explanation of the value of the experimental method with special reference to its application in physiology and pathology. He argued on the broadest lines, those applicable to every department of science, and incidentally exposed the cruelty and inhumanity of the people who call themselves antivivisectionists. Experiment, he said, was observation made under defined, limited, and exact conditions, and illustrated his point by a simile drawn from his own profession:

"Experiment is like cross-examination; you can put the question you want, and Nature always answers it. She does not answer the question you meant to put, she answers the question you did put. . . . She does not care in the least what you meant to ask, but she does care what you asked, and she answers it with perfect truthfulness. And the consequence is that when you adopt experiment the great experimenter can put a question the answer to which lets the whole secret out."

Lord Moulton again did valuable and valued service for medicine as chairman of what is now the Medical Research Council from its institution in 1912 until 1916, when the pressure of his war work compelled him to resign. In a notice on Lord Moulton's life published in our columns

shortly after his death it was said that he brought to the work of the Medical Research Committee in its first critical year not only the general authority and support expected from an eminent man set to preside over a committee of experts, but that "his familiarity not only with the content of scientific knowledge, but also with the daily realities of the laboratory and of the ward, greatly enriched and steadily guided his influence. . . . Individual members of the profession and many scientific workers drew encouragement and inspiration from the subtle play of his critical insight, given freely in private talk or emerging with easy opulence among the catholic charms of his remarkable conversational powers."

THE DIAGNOSIS OF SOME RESPIRATORY DISEASES.

PROFESSOR ÉMILE SERGENT'S book on diseases of the respiratory system² does not aspire to be a comprehensive treatise on pulmonary ailments, but is a series of monographs—the majority of which have already been published in the journals—dealing with various affections of the lungs, pleura, and mediastinum. It is a book by an eminent clinician written pre-eminently for clinicians. The first part opens with a study of the value of pupillary inequalities in the diagnosis of pulmonary tuberculosis. Such inequalities, we are told, may be either apparent or latent; in the latter case they may be provoked by the instillation of atropine. In the majority of early cases of tubercle—especially those affecting the pleuro-pulmonary dome—a mydriasis occurs on the affected side, whereas in chronic cases, owing to the destruction of the dilatory sympathetic fibres, it tends to be replaced by a myosis. The test is fully described and a warning given of several possible fallacies that may be encountered. A considerable amount of space is devoted to syphilitic affections of the respiratory tract. There is a long discussion on the differential diagnosis between tubercle and syphilis, and the author shows how difficult it may be, since they are frequently associated in the same subject, to apportion the exact quantum of blame to each. There follows a section on the sequelae of chest wounds, in which it is said that it is uncommon for tuberculosis to follow on traumatism; the few cases in which this does occur are attributed more to prolonged hospitalization in a confined atmosphere with its associated loss of appetite than to the wound itself. Similarly with gas poisoning, tubercle seems to be quite an unusual complication; the ordinary sequence in severe cases is emphysema and broncho-pulmonary sclerosis. Finally, the question of intratracheal injection is considered, and its possible value in combating pneumonia and phthisis suggested.

The second part of the book deals entirely with radiography. It is designed to instruct those who have been unable to study this branch of investigation, in the uses to which it may be put in the diagnosis of chest diseases. There is no question of technique; he writes not as a radiographer, but as a clinician. What can be learnt from screen examination, what from plate photography, and what from the two taken in conjunction is fully considered. Particular stress is laid on interpretation. Fallacies are exposed in which too much has been expected, especially with regard to the nature of certain lesions. Cases are quoted in which a clear space, diagnosed by x rays as a hydatid cyst, turned out to be a neuro-fibroma, and in which "bullets" removed from the chest by the surgeon proved to be calcified nodes. The various portions of the chest, from the thoracic wall to the mediastinum, are dealt with in turn, the text being illustrated with photographs. The whole burden of this part is to show just how much is to be expected from x rays. They are to be used as aids in diagnosis; they cannot be permitted to take away the responsibility of the clinician himself. It is he who is the supreme factor, and he must use them—just as he uses the findings of the pathologist and the bacteriologist—as means wherewith to elucidate the problem before him. It is for him to interpret, and it is for him to correlate the results received. The book is written with all the freshness of one who is speaking from personal experience. Nothing is glossed over, and, even at the risk of banality, the fundamentals of every argument are laid down, with the result that his clarity of expression is only exceeded by the interest of his subject.

UROLOGICAL METHODS.

DR. WIENER'S *Propédeutique et Technique Urologiques*³ is intended for students and medical practitioners wishing to familiarize themselves with the very exact methods of examination and treatment that the advances of the last ten years have placed at the disposal of the urologist. A very brief inspection of the book is sufficient to show that the author has a real appreciation of the particular difficulties that the uninitiated are likely to encounter during their course of apprenticeship; this appreciation has enabled him to produce a work which is eminently practical. Although the subject is treated with considerable fullness the book is not a work of reference, for it contains no bibliography, and is but little concerned with theory or pathology.

In the first chapters methods of examination of the urino and of the various genital secretions are described. Then follows a description of instruments employed in the examination of the genito-urinary system and how they are used. An account is given also of special methods of anaesthesia applicable to urinary surgery. Dr. Wiener is a partisan of epidural anaesthesia according to the method described by Cathelin. A good description of the technique of this somewhat difficult proceeding is furnished, as well as that of high epidural anaesthesia according to the method of Schlimgert and Kehler. Dr. Wiener recommends Cathelin's method in such operations as incision of a prostatic abscess or perineal prostatectomy, in all operations on the penis and urethra, or in such proceedings as the closing of a perineal fistula, intravesical operations, and lithotripsy. He also has found it of great use in the cystoscopic examination of irritable bladders—for example, those affected with tuberculous cystitis.

The description of methods of examination and of treatment includes a discussion on renal function tests applicable to the investigation of surgical lesions, as well as to the so-called medical affections of the kidney. The author has indeed treated this subject in great detail, and may possibly be accused of having provided for his readers a meal that will prove too heavy for their digestion. Although our knowledge of renal function has certainly advanced in the last decade, it is not yet sufficient to permit of the use of exact mathematical formulae in estimating the worth of a kidney. The employment of such constants as those of Anbar and Broinberg is, in our opinion, premature, although there is every hope that some day the activity of a kidney may be stated in figures. For this reason the chapter on renal function tests will be of interest to experts rather than to those seeking for a practical guide to urology.

The final chapters of the book are concerned with the general symptomatology of urinary diseases, and are extremely valuable. To the section on haematuria has been appended a synopsis which furnishes the reader with numerous causes of bleeding in the urinary tract, and the methods by which they may be diagnosed.

Dr. Wiener's work is illustrated by diagrams and line drawings, and only where it is absolutely necessary have plates been introduced. The illustrations have been well chosen, and are a much better aid to an understanding of the text than the expensive plates and photographs with which some modern textbooks abound.

In his preface the author expresses the hope that his work may assist medical men making use of methods which, except by specialists, are as yet little practised. Although the standard that Dr. Wiener sets is perhaps too high, and some of the chapters in his book beyond the reach of those not making a specialty of this subject, his book is one of the best guides to the technique of urology that has yet appeared.

THE PHYSIOLOGY OF MIND.

DR. FRANCIS X. DERCUM has written *An Essay on the Physiology of Mind*⁴ in which he endeavours to account for the psycho-physical organism on a mechanistic basis. The argument of the book is directed against a "dual" conception of human existence, and the author's theory of life and mind is developed at length by bringing together a large number of interesting and significant biological and other data which

serve to support it. Dr. Dercum regards the phenomena embraced under the term "mind" as in their essence physical, and he criticizes the tendency to view these phenomena as if they were altogether peculiar in character—as though a difference essential and intrinsic separated them by a wide and hopeless gap from all other phenomena of nature. For him the problem of life is merely one of chemistry and physics; and at the conclusion of the essay he expresses the view that the modern study of the atom, which reveals it to be but an expression of energy, indestructible, persistent, and unknowable, has caused the difference between the old conceptions of "material" and "immaterial" to become obliterated.

The author's views are well and clearly expressed; they are based upon many years' thought, a wide knowledge, and much original investigation as a neurologist. At the same time it may be suggested that he tends to take a mechanistic explanation of life rather too much for granted. After all the view that the behaviour of living organisms is explicable on a purely physico-chemical basis is no more than an hypothesis, and one which some physiologists have found inadequate to account for the facts of life.

NOTES ON BOOKS.

WHAT one does not know after reading Dr. ATKINSON'S book entitled *Lessons on Tuberculosis and Consumption*⁵ simply is not worth knowing. It is wonderful what he has succeeded in introducing. Written in a popular style for the average man, it deals with the problem of tuberculosis in a purely egocentric manner. The patient regards himself as the centre of the universe; he is taught to be entirely self-dependent; he is told everything; how to diagnose his disease in the first place; how to select his physician; how to treat himself without one; how to arrange his cure; how to raise the foot of his bed when he has a haemorrhage; how to get over the blues; how to feel up when he is down, and how not to feel down when he is up—everything, in fact, except perhaps how to prevent himself being thoroughly dangerous to others. Possibly the author is dealing with an exceptional audience—one strangely gifted with the sense of discernment—and for this he has spared no pains in inculcating the lesson of self-efficiency. Undoubtedly his intentions are excellent. But, as Mark Sabre might have said after much wrinking and contraction of his funny little nut: "Oh, you sickening fool! I didn't say I was sticking up for him; but I think I see what he means."

The first edition of *A Key to Health and Long Life (The Secret of Healthy Nutrition)*⁶ appeared in 1914, when the author, Mr. F. W. D. MITCHELL, was in his seventieth year and a quarter of a century after he had gone through the five years' course for the qualification of the Conjoint Examining Board in England, the final examinations for which he was prevented from taking by the demands of other work. To the second edition little has been added, but in the preface attention is drawn to the suggestions for the detection and prevention of failures of gastric digestion, and it is stated that the author was the first definitely to trace auto-intoxication to the miscarriage of the stomach's functions. The thesis of this pleasantly written book is that indigestion is the root of all, or nearly all, the diseases which are not due to infection, and that an unwise diet is responsible for the dyspepsia. Too much emphasis is laid on a uratic deposit in the urine as proof of indigestion otherwise latent. Mr. Mitchell's conclusions are better than his arguments, which are not always convincing to the medical reader, though they are fortified by a catholic use of quotations from various authorities; but if the public for whom it is more suited read and follow its directions the result will be all to the good.

Dr. WILLIAM BROWN has made a few minor alterations and additions in the second edition of his volume on *Suggestion and Mental Analysis*.⁷ In a short concluding chapter he emphasizes the importance of a sound knowledge of general medicine, and especially of urology and psychiatry, if the psychotherapist is to be a reliable help to persons in mental difficulty. He points out that psychiatric experience is most desirable if mistakes are to be avoided, as the incipient stages of the psychoses are apt to show features

³ *Propédeutique et Technique Urologiques*. By Dr. G. Wiener. Bruxelles: Boeckmann; Paris: Masson et Cie. 1922. (Roy. 8vo, pp. 422; 153 figures. Fr. 40.)

in common with "nervous breakdown." The first edition contained a passage in which it was implied that the subjects of melancholia were susceptible to therapeutic suggestion. As such a view does not harmonize with the experience of most psychiatrists, we feel that Dr. Brown has wisely substituted the more indefinite term "depression" for "melancholia" in the present volume (p. 111). We observe an additional sentence on page 104 in which the author expresses the view that the increased suggestibility of light hypnoidal conditions may be utilized for the treatment of backward children. Since the treatment and diagnosis of these cases present problems of considerable difficulty, it might be well that in his next edition Dr. Brown should give some details of cases treated by suggestion, with a record of the progress made.

Our Unconscious Mind and How to Use It,⁸ by Mr. FREDERICK PIERCE, provides a popular account of the principles of the "new psychology." The aims of the writer are practical, and a chapter on advertising and selling introduces a somewhat new feature. The author describes good advertising as "the active association of one's goods with an acquisitive complex already existing at the unconscious level; and a definite avoidance of all associations which can entail resistance." The chapter contains some sound common sense, but the thought of a psychologist-salesman is somewhat alarming.

Messrs. T. J. and J. SMITH are well-known makers of diaries of many different kinds. Among some samples the firm has sent us the largest is rather over a foot long, 8 inches wide, and an inch thick; the smallest is 3½ inches long, 2½ inches wide, and a quarter of an inch thick. We are glad to see that the firm is developing what we believe to be a very convenient feature—namely, to give a separate page to every day; this is accomplished in some of the smaller pocket diaries as well as in an octavo volume for the desk called the Official Diary. The prices of such pocket diaries vary from 1s. 6d. to 6s. 6d., the latter being for a pocket diary in four quarterly parts. Loose-leaf pocket diaries are also supplied. Another desk diary (No. 23) is a quarto volume, three days on a page, arranged for half-hourly appointments from 9 a.m. to 7.30 p.m. The paper used in all is good. The bindings are of various types. Finally, we may mention *Smith's Medical Visiting List*,⁹ which has many points to recommend it to the medical man. Its main section is devoted to a well-arranged visiting list (for 25, 50, 75, or more patients, in different editions of the volume) and a journal, with adequate space for obstetric engagements, addresses of patients and nurses, and for notes of books, instruments, and other things lent. There is a table for calculating the period of utero-gestation, a list of the principal poisons and their antidotes, a compendium of the doses of many drugs in common use, and some useful notes on professional fees, including the fees legally claimable by medical men in courts of law.

⁸ *Our Unconscious Mind and How to Use It*. By Frederick Pierce. London: Kegan Paul, Trench, Trubner, and Co. 1922. (Demy 8vo, pp. 323; 8 figures. 10s. 6s. net.)

⁹ *Smith's Physicians' and Surgeons' Visiting List, Diary, Almanac, and Book of Engagements for 1923*. Seventy-seventh year. London: Hazell, Watson, and Viney, Ltd. 1923. (No. 2A, cloth, 8s.; morocco, 11s.)

THE STANDARDIZATION OF SERUMS.

A YEAR ago a conference was held in London, at the instance of the League of Nations Health Committee, to discuss the standardization of serums and serological tests. An account of the work it did was published in our issue of December 24th, 1921 (p. 1080). The subject is of considerable practical interest, but the details of the laboratory methods of standardizing the serums and tests are highly technical. For this very reason it is important that standardizations should be fixed by international agreement, so that a practitioner when using a serum may be confident that it is of the strength of previous specimens he has been in the habit of using. When the conference came to an end last year it was decided to hold another, and this took place from November 20th to 25th at the Pasteur Institute, Paris. Taking the subjects in the order in which they were dealt with last year, we give the text of the resolutions adopted in Paris.

DIPHTHERIA.

The Committee accepted the proposal contained in Dr. Madsen's report on the Geneva Conference that the Ehrlich standard unit should be finally considered as the international standard for the measurement of the diphtheria antitoxin, and that, in order to ensure that the serums used as standards by the various States have identical titre, the Sero-therapeutic State Institute of Denmark should arrange for comparative studies of such serums to be carried out every year.

The present conference adopted the following resolutions:

1. The Ehrlich unit having once been adopted as the international unit, it would be very desirable to induce firms in all countries to supply phials containing uniform quantities of antitoxic units for preventive and therapeutic injections.
2. An inquiry should be made with a view to ascertaining the quantities of antitoxic units at present contained in the phials offered for sale.

The Health Committee of the League of Nations will ask the various institutes and firms for samples and will report on the inquiry at a later session.

TETANUS.

The last paragraph of Section 3 (tetanus) of the Geneva Conference resolution was modified to read as follows:

The decision of the Geneva Conference implies the necessity of further experiments in order to define in detail the technique to be used for the titration of antitetanic serum with the new standard.

The decision referred to was the adoption in principle of a new international unit. As a preliminary step the ratios of the units now employed in America, Germany (new), and France were determined as 50, 100, and 2,500 respectively.

ANTIMENINGOCOCCUS SERUM.

In order to secure a uniform international classification and nomenclature of meningococci, it was resolved:

1. That an interchange of meningococcus cultures and monovalent antimeningococcus serums be made between the different laboratories. Cultures representative of the different types will be selected by the different laboratories, and monovalent serum prepared in animals from each of these cultures.
2. That the classification of meningococci should be based as far as possible (1) upon a primary division into groups to be designated by numerals—for example, I, II (according to the present classification of Gordon)—and without prejudice to other groups which may be recognized later; (2) upon a subdivision of the main groups into subgroups or types to be designated by letters, and the numeral of the main group under which they are to be classified—for example, Ia, IIb, etc.

The primary division into groups is to be based upon agglutination alone. The groups comprise cultures which are agglutinated similarly in high dilution of monovalent serums which are relatively free from heterologous agglutination. The secondary division into types is to be based upon distinctive characters as determined by the results of both the agglutination and absorption tests with monovalent serum. Cultures which cannot be accurately

classified should be placed under Group X.

that for the study of the standardization

1. A new series of tests shall be made with monovalent and polyvalent serums, with respect to their comparative content in agglutinins, amboceptors, opsonins, and antitoxins. The serum used shall be collected ^{from} the patient ^{and} last infection. The serum must ^{be} given ^{and} must not be heated. Precise ^{regarding} the method of preparation, the date of bleeding and the presence of antiseptic and, if possible, of the therapeutic action of the same serum on human cases of meningitis. So far as possible the same culture shall be used for immunizing the horses and for testing the serum. Only meningococci obtained from the cerebro-spinal fluid of cases of meningitis shall be used for this study.

2. Studies be made of the effect of heat, especially tyndallization (56° C. for one hour during three successive days), on the properties of the serum.

3. Careful studies should be made of the immunological reactions with the meningococci recently isolated from cases of meningitis in which the serum has not been effective.

4. The exchange of cultures and serums should be made through the medium of the Central Institute at Copenhagen.

ANTIPNEUMOCOCCUS SERUM.

1. The classification of pneumococci into different serological types is fundamental for all further researches on serum therapy, vaccination, and epidemiology, and the three chief types—I, II, and III—defined by the workers of the Rockefeller Institute as standard types for international purposes were accepted; strains not conforming to any of the above three types should be classified provisionally in a group "X." As pneumococci in certain circumstances may undergo change in their immunological characters, the classification of the types for epidemiological purposes should be based upon the agglutination reactions with freshly isolated strains, or preferably upon the results of the test with the peritoneal exudate of a mouse injected with sputum or other material taken directly from the patient.

2. With regard to the distribution of the types of pneumococci in different parts of the world the wish is expressed that, in addition to further researches in Europe and the United States, investigations along the same lines should be undertaken in tropical and other countries where the climatic and social conditions differ widely. Primarily, cases of lobar pneumonia should be studied, but observations on other forms of pneumococcal infection should also be recorded.

3. A study of the therapeutic action in the treatment of early cases of pneumonia should be made with antipneumococcus serum which has been found to be highly protective for mice. Such studies should be made only in institutions fully equipped for such a purpose.

4. Without expressing an opinion in regard to the therapeutic value of the serum in the treatment of pneumonia, the test by titrage in the mouse, when controlled by a standard serum, affords a basis for the international standardization of the serum. Therapeutic serum may be titrated in mice either by injecting intraperitoneally a fixed quantity (0.2 c.cu.) of serum mixed with a highly virulent broth culture in doses ranging from 0.1 c.c.m. to 0.4 c.c.m. or more; or by injecting smaller and varying quantities (0.001 or 0.0001 c.c.m.) of serum intraperitoneally, and three hours later a moderate dose of culture—for example, 0.0001 c.c.m. The virulence of the culture should be such as to kill mice in doses of at least 0.0000001 c.c.m. within forty-eight hours. For every titration a standard serum must be used.

5. Further research should be made into the mechanism of recovery from pneumonia and into the mode of action of anti-pneumococcus serum.

6. A study of is desirable.
7. Standard and standard therapeutic
serums are to be Institute of Copenhagen.

DYSENTERY.

The following resolutions were adopted:

1. It is necessary to continue the experiments in order to determine the choice of the animal to be used for standardization of antidyenteric serum. These tests should be carried out comparatively on rabbits weighing 1,500 to 1,600 grams and on white mice weighing 15 to 16 grams.

2. The substances to be compared are liquid toxin, solid toxin (Wellcome), and microbes killed by heat. (a) Liquid toxin will be prepared by each laboratory with a culture of toxic Shiga which will be supplied by the Pasteur Institute—namely, the filtrate of a twenty days' old culture on peptone broth (Chapoutaut's peptone) grown in litre flasks containing 500 c.c.m. of liquid with an alkalinity P_{H} 7.4. (b) The solid English toxin will be supplied by the Wellcome Laboratories. (c) The microbes killed by heating at 56° for one hour and dried in vacuum will be supplied by the Pasteur Institute (agar culture emulsified in physiological salt solution). The effect of subcutaneous, intraperitoneal, and intravenous injections will be compared.

3. It is not necessary in making the tests to discriminate between the anti-neurotoxic and the anti-enterotoxin power of the serum.

4. The titration of serums will be carried out by a mixture of toxin and serum, after thirty minutes' contact at laboratory temperature.

5. It is not necessary to seek to give the serum an anti-infectious power as distinct from its antitoxic power.

6. It would be of interest to test on man the power of monovalent serums (anti-Flexner, anti-Eis, etc.) against homologous strains of dysenteric organisms.

NOTES ON SMALL-POX.

BY

W. McCONNEL WANKLYN, B.A. CANTAB.,
M.R.C.S., L.R.C.P., D.P.H.

Outlook.

At the time of writing (December 8th) small-pox in London appears, generally speaking, to be checked. The total cases to date are 62 with 20 deaths. No further cases have been reported from Lambeth, Bermondsey, or Poplar, and the rest of London is apparently free.

There is thus a welcome lull, due mainly to effective medical team work in countering the disease, so that it finds more difficulty in gaining headway than formerly was the case. That is the true explanation of the phenomenon which at first may seem puzzling—namely, that small-pox appears not to be able to "get going" in London; and it is also the reason why no cases were reported during the last fortnight in spite of the previous sharp outburst. It is not the case that small-pox is a feeble thing which dies out of its own accord; the fact is that at present it is a formidable menace; but so far the counter-work has been too good for it. Only so far—the effort needs to be kept up, if only because of the disquieting fact that five of the recent foci have their origins unaccounted for; and the infection which started them may have started other foci still latent and shortly to burst out. Danger, therefore, is far from being past.

The Poplar Outbreak.

The suggestion that the recent Poplar outbreak consisted of a few dropping cases or an insignificant group in an area remote from and unconcerned with the rest of London, and that therefore the whole occurrence was trivial, is not in accordance with the facts. It is correct to say that there was a compact institution of about 1,000 souls, in which nearly all concerned were in the freest communication with the surrounding neighbourhood and were susceptible to small-pox; the institution actually overlooks the docks, the part of Poplar in which it is situated being essentially a seaport town. In surveying the position beforehand this was

regarded as a notable danger-spot for the rest of London, and in the event of an outbreak there was strong reason to expect very little assistance from vaccination, owing to the fact that the local authorities and many of the inhabitants were strongly opposed to that prophylactic. The general position may be gauged from the fact that in respect of about 4,500 children born in that borough in 1921 returns of successful vaccination had been received for about 1,000 only. Such were the admitted facts of the position.

This being the case, in this institution on October 13th a man fell ill of small-pox; he had the rash on October 15th; it was recognized. This was the earliest case that eventually could be heard of; it is possible there was in the vicinity of the institution another undetected case with whom some of the inmates came in contact on and after October 10th. Be that as it may, till the institution had a clean bill as regards small-pox. The above-mentioned man moved freely about the institution between October 15th and 28th, with such effect that, so far from infection being the feeble thing which it has been represented to be, during the week-end October 28th to 30th the institution and its immediate neighbourhood was found to be variolously ablaze with 25 cases of small-pox.

London and its neighbourhood were most gravely menaced if only from the fact that there had been discharged from the institution, since the first case had begun to infect the area around him, a large number of the inmates; and from the fact that the various contacts comprised the following different classes of people:

(1) Other inmates remaining in the institution; (2) recently discharged inmates; (3) visitors to the inmates; (4) persons outside who had been visited by them; (5) medical and nursing staff; (6) scrubbers and other attendants; (7) porters and other manual staff; (8) occasional visitors to the wards, such as guardians and chaplains; (9) other staff, such as engineers, laundry men and others. Many of these persons had their homes within a mile or two of the institution, and there was the best reason to consider the whole of that area as potentially dangerous.

When the first five cases were discovered, on the morning of Saturday, October 28th, and it suddenly became apparent that the institution was already plentifully sown with infection; when all preventive measures had suddenly to be planned and started between 11 a.m. and 12.30 p.m. on a Saturday when normal departmental activity ceases till the following Monday, though fire and small-pox do not; it is in strict accord with the fact to say that London at that moment was threatened with a catastrophe of appalling and almost unexampled gravity, likely to rival some of the worst epidemics of the past in expenditure of human life and treasure.

No one who was present is likely to forget the scene of consternation when the actual position was realized; nor the manner in which the emergency was faced and tackled, and, in the end, after twenty-four hours of intensely strenuous work, it was completely mastered; so that then, it was definitely said that, in spite of a score of cases scattered throughout that crowded and susceptible community, and in spite of large numbers of that community having been intimately exposed to infection, no further cases would occur in the institution after Wednesday, November 8th—that the short period of eleven days after the first discovery of the small-pox cases. Such in fact was the actual result, due to the preventive measures which had been taken. These were effected with remarkable promptitude—a triumph of combined team work on the part of all concerned; which, while everyone did his utmost and no one seemed to lead, it should be said that the actual orders were given by the chairman of the House Committee, who was constant on the spot—an English working man, formerly a steeplehouse sagacity and courage, guided and fortified by medical advice and support, were primarily responsible for retrieving a desperate situation. Formerly convinced antivaccinator, he now took fairly into account phenomena of which he had had no previous experience; he witnessed the condition of the small-pox patients both at the institution and at the Small-pox Hospital, where he specially visited them; as a result he himself was vaccinated and influenced many others to adopt the same remedy. Like other antivaccinators whom the true facts have never reached, he honestly revised his attitude in regard to this question as soon as the facts came home to him.

These are some of the reasons why, to the surprise of many good judges, the Poplar outbreak "fizzled out." Why was it possible to achieve this result? The answer is, because the position had been well studied beforehand; because the previous quiet period had been fully and unceasingly occupied with advance preparation to meet any such emergency as did in fact arise. When, therefore, the crisis came, it was possible promptly and decisively to meet it.

British Medical Journal.

SATURDAY, DECEMBER 16TH, 1922.

THE PROGRESS OF PSYCHIATRY.

WE are glad to be able to report another piece of evidence showing the progress which is being made in the study of psychiatry and in its teaching. Sir Frederick Mott, M.D., F.R.S., has been appointed Honorary Director of the Pathological Laboratories of the Birmingham City Mental Hospitals, and lecturer in the University of Birmingham on morbid psychology. Sir Frederick Mott has undertaken to pay frequent visits to Birmingham in order to superintend the work of the laboratories and to give the necessary lectures. A whole-time assistant director will be appointed, and the necessary laboratory attendants will be provided. The laboratories will at first be at Hollymoor, one of the city mental hospitals, but it is anticipated that eventually the University will be able to find space for them in the university buildings. This is considered very desirable, in order that the staff of the psychiatric laboratory shall have the advantage of working side by side with other pathologists. It is hoped to associate with the scheme in Birmingham the various mental hospitals in the Midlands, and thus to establish scientific investigation of mental disorders on a firm basis in that important part of England. The University, we understand, contemplates the establishment of a diploma in psychology which it will be open to medical members of the staffs of the mental hospitals in the Midlands to take. The Birmingham scheme will be managed by a board consisting of five representatives of the University, five persons nominated by the committees of the mental hospitals (two medical superintendents and three lay members), with Sir Gilbert Barling, Vice-Chancellor of the University of Birmingham, as chairman.

In a recent essay¹ Dr. Damaye, a French physician, has suggested that the ideal to be aimed at is to bring every mental hospital into close relation with a general hospital. Fortunately, in this country several schemes, besides that at Birmingham, have been framed to attain the ideal. So recently as November 18th (p. 995) we were able to describe a scheme for a co-operative clinic in connexion with the Middlesex Hospital and St. Luke's Hospital. Under it two new wards, for male and female patients, will be provided at the Middlesex Hospital, and the cases will be treated by the members of the medical staff of St. Luke's Hospital and nursed by its trained mental nurses. In addition, there will be a special out-patient clinic dealing with borderland cases. Such a scheme as this, when in full working order, should exert a far-reaching influence and do much to further the study of psychiatry.

Of late a great deal of progress has actually been made, especially in regard to the teaching of psychiatry. A few years ago, save at a small number of asylums, the medical officers received no instruction and received no encouragement to take a scientific interest in their cases. At the present time, however, there are a number of centres where instruction in psychiatry and allied subjects can be obtained, and the majority of universities grant diplomas in psychological medicine. A teaching centre such as has been

established at Birmingham acts as a constant stimulus to the group of asylums with which it is connected, and will have the effect of provoking that lack of life and vigour liable to be observed in an institution deprived of external sources of inspiration. It will send out medical officers thoroughly equipped with specialized knowledge, and alive to the medical interest of the work they will undertake; it will organize and encourage research work; and it will enable the medical staffs of the asylums to keep in constant touch with the latest developments in psychiatry. In these ways an atmosphere of enthusiasm will be maintained, and the strictly medical aspects of asylum work will be kept constantly in the foreground. Those teaching centres which are now in existence have already exerted a perceptible influence, but more are necessary, and at the very least there should be one in every university town in the country.

Psychiatrists of all countries are faced with similar problems and difficulties to those which exist in our own, and in some cases the facilities abroad for the treatment of mental disorder are less favourable than those found at home. Dr. Henri Damaye, who is an asylum physician, sets forth in his frank essay the state of psychiatry in France and the actual provision made for the treatment of mental disorder. The author writes as a psychiatrist and addresses the medical profession as a whole, because he feels that the latter should be aware of the defects which exist in the asylum system. He considers that psychiatry is in its infancy, that it is scarcely recognized as a specialty, and has little to offer its disciples but a career in asylums which are badly adapted for scientific research, and do not provide the intellectual stimulus which a doctor requires to prevent stagnation and inertia. He feels that a common effort is necessary to remedy the defects which exist and to procure the facilities for treatment and teaching which are at present lacking. A somewhat depressing picture of the asylum world is drawn, and we gain the impression that psychiatry in France is almost completely isolated from other branches of medicine. There is, of course, a strong impulse in the direction of reform, just as in this country, which has found expression in the formation of La Ligue d'hygiène mentale, and, no doubt, much that Dr. Damaye at present deprecates will soon be remedied. His essay will probably be a factor in hastening reform, and with his main thesis we are in complete agreement.

Dr. Damaye insists that the reason why psychiatry is in a backward and stagnant state is that it is too isolated. It should not be the exclusive domain of asylum doctors, for the whole body of medical knowledge needs to be applied to mental disorder. In support of this view the author quotes the dictum of Séglas, "que de tous les spécialistes le psychiatre est celui qui doit être le moins spécialisé." At present he finds psychiatry almost entirely divorced from contact with medicine as a whole, and he makes some constructive suggestions for bringing it into organic union with general medicine and its biological methods of investigation. The views of most psychiatrists would be in harmony with this doctrine, though they realize, perhaps better than others, that much has yet to be done before the ideal can be reached. In particular they will, we believe, as a body accept the view that special arrangements should be made for the treatment of cases of mental disorder in their earliest stages. Sir Frederick Mott has suggested that a mental hospital should have outside its precincts a separate house or villa where patients could be treated on ordinary hospital lines without certification, and where the physicians would have the advantage of adequate laboratory assistance. The scheme would also include a convalescent home somewhere else, to which patients could go when approaching recovery.

¹ *Le Médecin devant l'assistance et l'enseignement psychiatriques.* By Henri Damaye. Paris: A. Maloine et Fils. 1922. (Cr. 8vo, pp. 125. Fr. 5.)

Although much remains to be done, it may, we think, be said that on the whole definite progress is being made in this country on thoroughly sound lines. The isolation of psychiatry from medicine, of which Dr. Damayo complains, is gradually becoming a thing of the past, and the career of the young psychiatrist should in the future afford him much greater opportunities for definite medical work than it has in the past. He will tend to become far less of an "officer" and much more of a doctor. As Dr. Damayo observes, however important administrative functions may be, nothing should be allowed to deflect the interest of the asylum physician from his primary function—namely, the medical treatment of his patients.

TREATMENT OF TRYPANOSOMIASIS.

A SERIES of papers have been published during the last few years in the *Journal of Experimental Medicine* describing a search for an efficient chemotherapeutic agent for the treatment of sleeping sickness. The inquiry, begun in the laboratory, was afterwards applied, with encouraging results, in the treatment of patients. The first paper to which we refer was that by Jacobs and Heidelberger, published in 1919; in it they described a new trypanocidal remedy, N-phenylglycinamide-p-arsonic acid—

This substance, which is a pentavalent arsenic compound and a derivative of atoxyl, has been termed for convenience "tryparsamide." Its toxic and trypanocidal actions were investigated by Brown and Pearce in laboratory animals. They found that it had a very low toxicity for animals; for example, the minimal lethal dose for mice on intravenous injection was over 2 grams per kilo, which is about one-twentieth the toxicity of salvarsan. Toxic symptoms occurred only when doses near to the minimal lethal dose were given; the recovery of animals from sublethal doses was rapid and complete, and repeated administration produced little cumulative action. Tryparsamide proved to be only slightly irritant and could be given intravenously, intramuscularly, intraperitoneally, or subcutaneously.

It was found to have a satisfactory trypanocidal action—for example, the minimal curative dose given intravenously to mice infected with *Trypanosoma brucei* was 0.2 gram per kilo, which gives a ratio between curative and lethal doses of 1 to 10. This ratio compares favourably with that of atoxyl, where a ratio of 1 to 4 has been obtained (with *T. equiperdum* in rats). On the other hand, salvarsan (also with *T. equiperdum* in rats) gives a ratio as high as 1 to 37.

The action of tryparsamide in causing the death of various trypanosomes in mice, rats, rabbits, guinea-pigs, and monkeys was determined; favourable results were obtained; the drug was found to have a strong curative effect upon infections of *T. gambiense* (the sleeping sickness parasite) in rabbits. Less favourable results were obtained with *T. rhodesiense* (the parasite of Rhodesian sleeping sickness). Tryparsamide had no very marked curative effect upon spirochaetal infections in rabbits.

These experimental results suggested that the drug would be a valuable remedy for sleeping sickness, and Dr. Louise Pearce continued the research in Leopoldville, Central Africa. Ninety cases of sleeping sickness were treated with tryparsamide—55 were early cases, with no involvement of the central nervous system, and 35 were late cases in which the central nervous system was

involved. About 2 grams of tryparsamide were found to be an efficient and safe intravenous dose, although doses as high as 7 grams (0.112 gram per kilo) were given without ill effects. A single dose caused the trypanosomes to disappear from the glands and from the blood stream within twenty-four hours in every case. Twenty-one cases were followed up: 12 of these were found to relapse within fifty-eight days; in one case, however, no relapse occurred during as long a period as 111 days. These results were considered to show that the drug had a powerful curative action upon early cases of trypanosomiasis, but that repeated doses of the drug were necessary to prevent relapses. In advanced cases treatment with repeated injections of tryparsamide caused a rapid diminution in the number of cells in the cerebro-spinal fluid, and this was accompanied by marked mental and physical improvement. In seven out of ten advanced cases, previously treated unsuccessfully with atoxyl and tartar emetic, there was marked improvement.

The investigations are too recent to permit any prediction to be made as to the ultimate therapeutic value of tryparsamide, but the results recorded suggest that the drug is an advance in the treatment of sleeping sickness, and may prove useful. Tryparsamide injections caused no untoward effects in the early cases of sleeping sickness; in nine of the advanced cases, however, the injections were followed by marked impairment of vision, but in six of these the effect was only temporary.

The strong trypanocidal action of tryparsamide is interesting, since the pentavalent arsenic compounds were the first organic arsenicals to be used as trypanocidal agents. Ehrlich's search for an agent to produce therapia sterilisans magna led to the pentavalent compounds being neglected in favour of the more potent trivalent arsenic compounds; it now appears very doubtful whether therapia sterilisans magna is a possible ideal, and it is well that the effects of the less active pentavalent compounds should be once more explored. The whole series of papers form a record of a finely conceived and organized research, commencing in a chemical laboratory in New York and carried right through to the final clinical tests in Central Africa. The execution of such a series of investigations has only been made possible by the support of the Rockefeller Institute.

The trypanocidal dye, Bayer 205, was recently mentioned in these columns, and it will be interesting to see whether Bayer 205 or tryparsamide will prove the more efficient agent for combating sleeping sickness. It is a curious accident, shall we say, that the two most important recent trypanocidal agents should come, one from Germany and the other from the United States, though neither possesses African colonies. Yet such remedies are of vital importance to countries with African possessions.

EPIDEMIC MALARIA.

THE epidemic of malarial fever in central and southern Russia, to which brief reference was made last week, should be cleared of one fallacy at least: the present Bolshevik administration of the country cannot be held responsible for its outbreak or its spreading, for exactly the same phenomena occurred in the same Russian provinces in 1897, and accounts were telegraphed to the same newspapers in almost the same words. Great epidemics and pandemics of malaria are indeed a large part of its history, and have furnished most of the experiences of the profession on intermittents in general. For example, all Sydenham's cases came from the London epidemics, which occurred as episodes in his practice at intervals of as long as a dozen years; and Talbot, the great ague curer of the time, candidly admits that he studied the disease at a village in the Essex marshes, and came to London to practise on it in Chancery Lane. Perhaps the best of many.

¹ Jacobs and Heidelberger, vol. 30 (1919), p. 411. Brown and Pearce, vol. 30 (1919), pp. 47, 437, 455, 483; and vol. 33 (1921), p. 193. Pearce, vol. 34 (1921), Supplement No. 1.

good chapters in Hirsch's great work is the hundred or more pages on malaria. Hirsch delighted in a complex problem, with ever so many factors in it, which he was in duty bound to set forth with scrupulous fairness, with something of the large tolerance of his celebrated co-religionist, Nathan the Wise. Those who possess the New Sydenham Society's edition of the handbook, in the fluent English of Dr. Creighton, will be surprised, on turning to the malaria chapter, at the enormous mass of well-authenticated facts which Hirsch has brought together from his vast library of 30,000 volumes, at his power of marshalling his authorities and of bringing them to bear upon the several points, and at his systematic digest of so various data. On the great epidemics and pandemics his conclusion is, "They correspond always in time with a considerable increase in the amount of sickness at the endemic malarious foci, whether near or distant." But the assumed endemic increase cannot, of course, be proved by figures, and it is not easy to imagine how its momentum is transformed into an epidemic wave. There was a remarkable instance in India in 1902 in the United Provinces. In that year bubo-plague was almost in abeyance, but the mortality from intermittent fevers more than filled the gap; when the figures were examined it was found that the weekly tales of deaths came from the very same villages as the plague deaths in the years before. The diagnosis was accepted as correct by the authorities at Lucknow, and the Governor, Sir John Prescott Hewitt, drew attention to it in his annual review of the public health. The fevers in Agra and Oudh that year caused the enormous total of over a million deaths, so that they were truly epidemic in all places, without anything to account for them, so far as appears, save the correlation with plague. The endemic malarious foci were, of course, there; and they had become steadily worse. At a village not far from Agra there is a small pond; near it is a hut in which is kept a notebook, with pen and ink, for remarks; the Sanitary Commissioner, at a recent visit, had written in it: "Mosquitos do not seem to breed on the surface of this pond." Meanwhile the level of the water had risen several feet, owing to the too liberal libations on the ground from the irrigation canals of half a century before. Some forty or fifty years ago the progressive water-logging of the soil, with the corresponding increase of malarial disease, was a common subject of complaint in the reports of sanitary inspectors. Now, the United Provinces seem to have got used to it, but open treaches have been cut for surface drainage through the rush-grown flats. In this country there have been several great epidemics of intermittent fever at long intervals. One of these, which lasted two years, 1557-58, has left many traces in history which are perfectly definite and authentic. Another, exactly a century after, 1658-59, is equally well authenticated. Among its victims was the Lord Protector, Cromwell, at Hampton Court; Dr. Richard Morton, who was ill with the fever for three months, says the whole of England was "one vast hospital." At another interval of more than a century, the epidemic agues came again, in 1780-82, and were described by so cool and dispassionate a hand as Sir George Baker. Hirsch gives great epidemics of intermittents in other parts of Europe on several occasions down to 1866-72. For information as to these we may refer readers to the replete pages of Hirsch; and as this is the second week in Advent, let us by all means have the collect for the day: "That we may in such wise hear them, read, mark, learn, and inwardly digest them, that by patience we may embrace, and ever hold fast," the great treasure of observations which hundreds of competent authors have left.

ELECTROCARDIOGRAPHIC INTERPRETATIONS.

In the seventh Mellon lecture, delivered at the University of Pittsburgh in May last under the auspices of the Society for Biological Research, Sir Thomas Lewis set himself the task of clearing up some points in his theory of "limited potential differences" in its relation

to the interpretation of the initial phases of the electrocardiogram. The statement of the case is more fully discussed and the hypothesis more clearly stated than when it first appeared in *The Mechanism and Graphic Registration of the Heart Beat*, published in 1920. The main argument with which the lecture deals is really between two views on the relationship of the active part of cardiac muscle to the cardiographic deflections. According to one hypothesis, called by the lecturer that of "distributed potential differences," the active part of the muscle is considered to be relatively negative to the remainder of the muscle mass; in the other, that of "limited potential differences," the active part is considered to be relatively negative to the inactive muscle in union with it or in its immediate vicinity. In the former case the direction of flow of the excitation wave is considered to be in the direction of the line joining the centre of the active mass to the centre of the remaining and inactive mass; in the latter case it is considered to be from the active muscle to the part that is next becoming active. The point at issue can be better understood if we imagine a part of the ventricular muscle, say one inch from the base, first becoming active and then a part still nearer the base. In a lead from the right arm and left leg, according to the former view, the arm would show negativity relative to the leg, because the active part is near the base and the large mass of inactive muscle is in the direction of the apex. According to the theory of "limited potential differences," the current will set in the direction in which the excitation wave is travelling—in this supposed case toward the base—and consequently the lead nearer the active part, and incidentally in this case nearer the apex, will show relative negativity. In other words, the position of the active part near the base does not in itself determine the direction of the deflection, but it is associated rather with the direction that the excitation wave will take in passing from active to inactive muscle in the immediate vicinity. The author is convinced that this latter theory is the only one which can explain in this connexion all the present observations on heart muscle, though he is not committed to it as a full and final explanation. In his lecture the argument begins with a reference to actual and hypothetical experiments to illustrate the principles, and then passes to actual findings in the hearts of the toad and the dog. The deflections in the electrocardiogram from the toad are shown to be in accordance with this theory, while the downward deflection corresponding to activation of the bulbus arteriosus and indicating relative negativity of the apical contact can only be explained on this view. While the bulbus lies nearer the base than the apex of the ventricle, the excitation wave begins at the base of the bulbus—that is, the part nearest the apex—and travels to the part above it—that is, nearer the basal contact; hence the apical contact shows relative negativity. Again, in experimental stimulation of the endocardial and epicardial surfaces of the ventricle of the dog the electrocardiograms differ in a way that is only to be explained on this hypothesis. In the human electrocardiogram, while R represents negativity of the basal contact and S negativity of the apical contact, it can readily be seen that we are not therefore justified in concluding that R is essentially a basal effect and S an apical effect. The arguments throughout seem conclusive, and the hypothesis of "limited potential differences" must be accepted as the best that offers in the present state of knowledge.

THE GOVERNMENT AND THE OPIUM CONVENTION.

THE Home Office has issued a ten-page pamphlet relating to the action taken by the British Government towards putting into force the International Opium Convention signed at the Hague in 1912. Readers of the BRITISH MEDICAL JOURNAL have been advised from time to time of the steps taken, first by the Dutch Foreign Office and later by the League of Nations, to secure ratification and effectuation of the Convention by all the Powers, and the need for such general co-operation has been emphasized in these columns ever

since the Convention was drafted. The Home Office pamphlet cites the action taken before, during, and after the war to deal with the traffic in dangerous drugs. Prior to the war there was little or no check beyond the not very stringent provisions of the Poisons and Pharmacy Acts, while export and import trade and the manufacture of these drugs were uncontrolled. During the war the spread of the cocaine habit among soldiers and of opium smuggling led to a licensing system under D.O.R.A. in respect of those drugs. Attention was called in 1916-17 to the "large quantities of morphia exported to Japan and that there were grounds for believing that much of this British-made morphia was being smuggled from Japan into China," from which Indian opium was being excluded. Japanese authorities were then required to certify that such imports of British morphine were for medicinal purposes and Japanese consumption only. It is claimed that this system resulted in a gratifying reduction of British exports of morphine to Japan from 550,000 oz. in 1917 to 6½ oz. in 1920. The figures obtained by the Advisory Committee on opium at Geneva have, however, directed attention to the "serious discrepancies between the export of drugs from Great Britain to Japan as shown in the British returns and the imports to Japan from Great Britain as shown in the Japanese returns." Thus while the figures for exports of morphine and heroin from Great Britain to Japan, as given in the British returns, were, for the years 1917 to 1920, 1,825 lb., 0, 0, and 1 lb. respectively, the total imports of morphine and heroin from England to Japan, as given in the Japanese returns, were for the same years 41,509 lb., 7,749 lb., 2,715 lb., and 11,714 lb. respectively. In 1918 and 1919 significant increases in the export of British morphine to the United States occurred, also to Switzerland and other countries. Attempts have accordingly been made, with limited and tardy success, to extend the system of import certification. It would appear that the system has not as yet been adopted by more than half of the States which are members of the League of Nations. An effort has also been made, with the assistance of the provisional Health Committee of the League, to arrive at an estimate of the amount of the drugs in question which can be regarded as the medical or legitimate requirements of each country. A rough and ready "rationing," in the case of morphine, on the basis of 1/4 grain per head per annum, has been suggested until a more accurate determination is arrived at. By Chapter II of the Opium Convention the signatories bind themselves to take measures for the gradual and effective suppression of the manufacture, internal trade in, and use of opium "prepared" for smoking, and to prohibit its import or export either "immediately" or "as soon as possible." "Opium smoking," according to *The Truth about Indian Opium*, recently issued officially, "is essentially a social vice," and the Home Office pamphlet vouchsafes some explanation why opium smoking still continues in British Colonies. Complete suppression is said to be impracticable so long as production of opium goes on unchecked in neighboring countries. This conclusion serves once again to enforce the policy, advocated by this JOURNAL for the last decade, and now reproduced in the resolution passed at the recent meeting of the third assembly of the League of Nations, in these words—namely, "the control of production, so as to limit it to the amount required for medical and legitimate purposes, is the most effective method of putting a stop to the illicit traffic."

SURGEONS IN CAMERA.

WHEN the Council of the Surgical Section of the Royal Society of Medicine suggested that an evening should be devoted to a recital of "Surgical mistakes and the lessons to be learned from them," and explained that arrangements had been made to exclude press, public, and coroner's officers, volunteers for the confessional sent in their names in surprising abundance, and on Wednesday, December 6th, in the presence of a large and sympathetic audience, related their experiences. The rule of the evening was "one surgeon—one mistake," and no questions to be asked by any of the

other surgeons in the room who had made no mistakes, or, at any rate, none suitable for publication. A chairman of conspicuous fairness and ability presided over the meeting and he had very little difficulty in controlling those enthusiasts who attempted to unbosom themselves of all or nearly all their mistakes. To those who came expecting thrills the opening rounds must have seemed tame indeed—mere venial errors of diagnosis from which an elastic conscience might recover in a night. However, it proved that these earlier mistakes were more affairs of outposts, for as the more ordinary misdeeds became exhausted and the spirit of emulation manifested itself, our flesh really did begin to creep as we listened to the real thing—surgical adventures worthy of Lewis Carroll or Heath Robinson. They all occurred some years ago, of course, and in several instances there were extenuating circumstances (or should we say co-defendants?) in the shape of physicians or radiographers upon the strength of whose diagnosis the operation in question had been carried out. It is interesting to speculate on this aspect of the matter a little further. If an eminent physician says, "This patient has a cokernut which ought to be removed," and an equally eminent surgeon proceeds to remove what in fact turns out to be a lemon, is this a surgical mistake? and, if so, is it a valid defence for the surgeon to say that he cut without looking, as the physician in the case was the dominant partner and he merely the guileless guinea-pig? Perhaps, if the Medical Section ever has its own evening of self-exposure, we may hear more upon these interesting problems; in the meantime we await with the greatest interest the suggested discussion at the Section of Radiography on the twin subjects, "What happens when the surgeon interprets his own plates?" and "When is a stone not a calculus?"

MEDICAL RESEARCH IN SOUTH AFRICA.

In his report for 1921 of the South African Institute for Medical Research, Johannesburg, Dr. W. Watkins-Pitchford, the director, shows that excellent work continues to be done in research, and that in addition an increasing number of routine investigations are carried out and a large amount of vaccines and serums prepared. The initial cost of the buildings and equipment of the Institute, amounting to over £41,000, was provided by the Witwatersrand Native Labour Association, and the land on which the Institute was built was set aside for the use of the Institute by the Government of the Union of South Africa. The work of the Institute is divided into a research division and a routine division; and the income of the research division, to the amount of £10,000 a year, is derived in equal proportions from the Native Labour Association and the Government. During the past financial year the cost of maintenance of the Institute as a whole was £28,038; of this total the cost of the research division accounted for £11,993, and the balance of £16,045 represented the cost of the routine division. The revenue of the routine division, earned from services rendered for payment, amounted to £17,450, showing a surplus over expenditure of £1,405. Dr. Watkins-Pitchford states that there is need for increased laboratory accommodation and greater financial support for research work; the question of appointing additional workers on the research side of the Institute has again had to be held over for financial reasons. The subjects upon which experimental investigations have been carried out during the year include scurvy, tuberculosis, the Weil-Felix reaction, cerebro-spinal meningitis, pneumococcal meningitis, influenzal pneumonia and lobar pneumonia, tropical ulcer, bilharzial diseases, and infective silicosis. In regard to tuberculosis, the value of sodium morrhuate was investigated, and 47 cases of pulmonary tuberculosis were treated; in 19 cases the disease was apparently arrested and a definite resistance established, and in 7 there was what might be termed "remarkable improvement," but no very definite opinion could yet be expressed upon the value of this drug. In the routine division of the Institute, of which Dr. J. H. Harvey Pirie is superintendent, the total number of investigations carried out during the year was 23,192, an increase of 4,845; much of the increase is stated to have been

due to greater use having been made of the facilities offered to medical practitioners for having laboratory examinations carried out. Autogenous vaccines to the number of 698 were prepared, nearly half of them for the treatment of respiratory affections; 591,119 c.cm. of stock vaccines were issued to stores, nearly four-fifths of this quantity being Lister's pneumococcal vaccine. The quantity of serums prepared during the year, chiefly antimeningococcal serum, was 24,625 c.cm.

SMALL-POX IN SOME NEWSPAPERS.

DR. WANKLYN, whose services are retained by the Medical Department of the London County Council to advise as to the diagnosis of suspected cases of small-pox, is able also where in this issue (p. 1181) to say that the outbreak in London appears to have been checked. The possibility of undiscovered cases cannot be excluded, so that there should be no relaxation of vigilance on the part either of local health authorities or of the medical profession in their duty of intimating the occurrence of vesicular or pustular eruptions in any way suspicious of variola. It would be interesting to know approximately what has been the effect of the outbreak in leading the public to resort to vaccination or revaccination as a protection against infection. The effect has not been confined to London and its neighbourhood. Paragraphs in newspapers show that the need for protection has been appreciated by the public in many parts of the country. Most of the guidance given by the newspapers has been thoroughly sound. There has been the usual propaganda by antivaccinationists, but their sophistries have little effect in presence of threatened small-pox. A Richmond newspaper contains the unusual statement that a medical man was in the chair at an antivivisection and antivaccination meeting there; he is reported to have said that students and medical men were never instructed on the subject as on other medical matters, that lectures were not given there, and that "all they had to do was to learn what came within the subjects on which they obtained their degrees, and vaccination was not one of these subjects." Whether the report is correct we do not know, but if it is, why then the profession is wide enough to include eccentrics and eccentricities. The lay lecturer told his audience of the huge salaries paid to vivisectioners; one at New York, he alleged, received £15,000 a year. It was matter of complaint by this lecturer that Jenner himself received a gift of £30,000. He alleged that "many firms were engaged in the manufacture of lymph and serums, and there were statistics to show that an old horse, not worth more than £5, had been treated and made to produce typhoid or diphtheria serum worth £800." He said also that the public were "being vaccinated with a lymph that had not got the culture of small-pox." Indeed, "they had proof that cow-pox was not only not allied to small-pox, but that it had also the possibilities of another unpleasant and dangerous and distasteful disease." After this "At Home" lecture, tea was served and music rendered. A Nottingham newspaper recently published an article on some alternatives to vaccination. It is said to have been written by a London physician. In this article it was asserted that vaccination is dangerous and often harmful, even it may be "for the remainder of the life time," but fortunately "these bad effects can be antidoted even after the lapse of years." One of the most efficacious of these alleged antidotes is *Thuja occidentalis*, which is used in dilution, "the strength known as 30 being one of the best-acting"; it is, the writer states, to be obtained from most homoeopathic chemists and is both preventive and curative of small-pox. Another remedy with similar claims is *Hydrastis canadensis*. Further, the North American Indians discovered that *Sarracenia purpurea* is a remedy for small-pox, and its value both for prevention and treatment has been confirmed "by doctors in America"; but of all the "remedies" mentioned probably the most satisfactory for general use is *Thuja*, though the London physician has recently heard "that the production on the arm by Spanish

fly cantharides) of blisters of the same number and area as in vaccination is used in America as prophylaxis of small-pox." The writer concludes by averring that in the article "enough has been said to show that for prevention of small-pox there are other measures that are more sure and infinitely safer" than vaccination. We trust our readers feel indebted to us for passing on to them this notice of the remedies.

THE PHYSICAL TRAINING OF THE SOLDIER.

THE physical training of the soldier was the subject of an address by Colonel R. B. Campbell, D.S.O., inspector of physical training in the army, at a largely attended meeting of the War Section of the Royal Society of Medicine on December 11th. Colonel Campbell made it plain that physical training, which consists of certain exercises, games, and tests, has but a modest place in the education of the recruit; it occupies only five hours of the week, whereas ordinary drill, bombing exercises, and the like occupy many hours a day. He said that physical training was of value, because it helped to build up the physical efficiency of the recruit, and it enabled him to be graded for the position which he might be called upon to occupy in the battlefield. The art of war required many kinds of mental ability and temperament; a good infantryman, "full of devil," would be wasted as an artilleryman, and a cool, self-possessed gunner might be a poor bayonet fighter. Physical training brought out not only the physical qualities, but the qualities of character, which enabled each man to be assigned his place. The exercises chosen were such as would enable a man better to play his part with whatever technical weapon might be entrusted to him, and the battlefield had to be associated constantly with the form of exercise chosen, just as the circumstances of the ring had to be related to the exercises of the boxer. In the first physical exercises of the raw recruit it was customary for the squad instructor to test by simple and natural movements for nerve, agility, physical strength, and quickness of mental apprehension. The most useful forms of exercise were found to be boxing, swimming, obstacle racing, gymnastics, and some kind of game, such as basket ball. Gymnastics inculcated daring and pluck, while the game quickened the team spirit. He showed a number of curves representing the results obtained over a certain period of weeks, with daily tests on recent recruits. These tests were for speed (the 100-yards race), endurance (the three-mile run), agility (the high jump), dash (leaping over a horse or other quick movement), nerve (balancing exercises), and strength (heaving exercises). For some weeks there was in each of these cases a continuous upward curve denoting improvement in efficiency, but in very many cases a downward drop took place at the end of a certain number of weeks, possibly indicating a reaction period, or some fault in the training, though the error might lie in the ordinary drill which the recruit was receiving at the same time. Colonel Campbell concluded with a description of the organization of the physical training staff in the army. He mentioned that the army was about to adopt the Board of Education's terminology with regard to physical training, and he pleaded for the adoption of a system of universal physical training with better co-ordination between the civil schools and the services. One or two officers of the Royal Navy joined in the discussion, pointing out that naval conditions required some modifications of the army programme, or a difference in emphasis; while a member of the Royal Air Force said that that service also required some special tests, and that the military system of developing the respiratory organs was not at all suitable for the flying man. An interesting point brought out in the discussion was the relation of physical training to convalescence. In answer to one speaker who had remarked that at a convalescent depot in France he found it difficult to get the physical training instructors to take sufficient interest in debilitated men, Colonel Campbell remarked that he did not like his instructors to take part in remedial or orthopaedic work, which properly belonged to medical

officers or to a special staff trained under them. The instructor in physical training was better fitted to deal with the healthy individual, and it would be as fatal to relate physical training to the hospital as to relate it to the cemetery. Sir John Goodwin, who presided over the meeting, heartily endorsed the suggestion that medical officers and the physical training staff should be more closely interlinked.

SILICOSIS AND MINERS' PHTHISIS.

Various theories have been advanced at different times to explain why those who work habitually in atmospheres which are laden with silica dust become so sensitive to tuberculosis. The silica inspired induces a fibrosis of the lungs; there is a general increase in bulk of the connective tissue trabeculae, and nodules of dense fibrous tissue often surround visible particles of silica. It was thought at one time that this fibrosis was dependent on the physical properties of silica—its gritty character, its hardness and insolubility; but more recent work seems to have established that this proliferation of fibrous tissue must be attributed to the chemical action of colloidal silica on the tissues. Why this silicotic fibrosis aids the establishment of tuberculosis has never been explained in a completely satisfactory fashion. Dr. W. E. Gyo and Dr. W. J. Purdy¹ have lately brought forward convincing proof that colloidal silica is a toxic substance, and, armed with this knowledge, Dr. Gyo and Dr. E. H. Kettle² have, with the help of a grant from the Medical Research Council, examined by the experimental method the effect of silica on the development of tubercle bacilli in living tissues. Their observations may throw light upon the problem of why individuals who are resistant to tuberculosis become susceptible after the development of silicotic fibrosis. The injection of 2 mg. of silica into the subcutaneous tissue of a mouse produces a granular coagulation necrosis, which at first does not affect the cells except at the periphery; later the coagulum gradually shrinks, becomes invaded by large mononuclear cells, and active proliferation of connective tissue with the formation of numerous capillaries occurs. The tubercle bacillus is only very slightly pathogenic for the mouse; when injected subcutaneously the organisms survive and proliferate in the tissues, but cause very little reaction; no cell necrosis or tissue destruction results, and, though the bacilli may be transported by phagocytes to lymphatic glands and the viscera, in these secondary foci very little tissue reaction is seen. On the other hand, Gyo and Kettle found that "an injection of tubercle bacilli accompanied by silica into the subcutaneous tissues gives rise to a much greater local reaction than an injection of tubercle bacilli alone, and, further, that general dissemination is earlier and more active." The bacilli multiply in the central coagulum caused by the silica and here form large colonies of organisms which are subsequently taken up by phagocytes during the resolution of the silica lesion. One important effect of the simultaneous injection of silica with the tubercle bacilli is therefore that the organisms can proliferate abundantly in the coagulum, temporarily protected from the cellular defences of the body, so that a small dose of bacilli becomes equal to a dose of considerable magnitude. This multiplication of the bacteria provides an explanation of the effects observed by the authors of the action of silica on mice. How far, it may be asked, does this help us to understand the connexion between silicosis and miners' phthisis? The silica when introduced into the lungs acts as a cell poison, but with its gradual removal by phagocytes and tissue fluids the normal processes of repair ensue, and finally nothing remains but a dense scar. Such fibrotic lungs may be peculiarly liable to tuberculosis, either because the scar tissue itself is actually less resistant and therefore more vulnerable than normal tissues, or because the successful invasion of the tubercle bacillus depends on the disorganization of the circulation of the tissue fluids brought about by lymphatic obstruction.

Further experiments are to be made to determine which these factors is responsible for the development of tuberculosis secondary to pulmonary silicosis.

BACTERIOLYTIC PROPERTIES OF TISSUES.

THE capacity of inducing the disintegration of bacteria technically referred to as bacteriolysis, would seem to be much commoner property of organic substances than was formerly believed. The remarkable phenomena described by Twort and d'Horelle have stimulated research in this branch of bacterial ecology, so that new manifestations of bacteriolysis are constantly being described. Dr. Fleming and Dr. Allison, who have been studying the bacteriolytic properties of different tissues and secretions, find that they vary in the capacity to dissolve different bacteria; certain well-known pathogenic bacteria are, however, easily disintegrated in some tissue extracts. Dr. Fleming has previously described a coccus which is singularly susceptible to the bacteriolytic properties of animal tissues, and this has been named *Micrococcus lysodeikticus*. In a communication to the Royal Society on November 9th Fleming and Allison describe how by various means strains of this coccus resistant to the lytic action of the tissues can readily be developed. Strains more resistant to one tissue or secretion are equally resistant to tissues, whether derived from man, the lower animals, or from vegetables. The resistance of these specially prepared strains is therefore not specific. After a culture of *M. lysodeikticus* has been dissolved by some lytic agent the power of the fluid to induce this change in other cultures is found to be greater than that of the original tissue extract or secretion, and this increase affects wholly or mainly the homologous organism.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

The Committee of Medical Members.

DR. F. E. FREMANTLE has been elected chairman, and Dr. Elliot secretary, of the group of medical members of Parliament. At the meeting on Monday further consideration was given to the new regulation proposed by the Nurses' Council under which nurses on nursing home staffs would be precluded from registration, except such as had had one year's hospital training. The framing of regulations for the operation of the charter rests with the Nurses' Council; the Minister of Health therefore has no direct authority in the matter. Draft orders, however, have to be laid on the table, and must be approved by both Houses. The committee felt that the rule would cause hardship in a number of cases. Notice of objection it has been given in the House of Commons, so that progress has for a time been stayed.

Small-pox and Vaccination.

On inquiry by Mr. Gilbert as to the cost of vaccination and how it was met and as to the services of public vaccinators, Mr. Boyd-Carpenter said that the latest year for which complete figures were available was that ended March 31st, 1921. In that year the total expenditure on public vaccination was £183,423, which £174,000 was paid by boards of guardians out of rates, £8,473 was defrayed out of money voted by Parliament. Public vaccinators were employed by boards of guardians under contracts which might be terminated by either party giving twenty-eight days' notice. As a general rule the method of payment was by the amounts of which were specified in the contract, but in a few cases an annual salary was paid. The fee for vaccination at home was invariably higher than for vaccination elsewhere. No payment was made from public funds for the vaccination by private doctors of their own patients. In answer to Mr. R. Young, Mr. Boyd-Carpenter said he was advised that the high rate of mortality amongst the recent London small-pox cases was probably due to the importations from Eastern Europe of a particular virulent type of infection.

Dr. Watts asked, on December 6th, if, in view of the serious epidemic of small-pox, the Minister of Health would take steps to enforce the provision of the Vaccination Acts; and having regard to the fact that there are upwards of three million unvaccinated children in the country, would he consider the advisability of repealing the conscientious objection brought into that Act by Major Boyd-Carpenter replied that the Minister of Health was keeping continuously before him the question of the necessity otherwise of amending the Vaccination Acts, but he was not prepared at this stage of the outbreak to introduce legislation.

In reply to Mr. Sorymgeour, who asked for statistics about Dundee, Major Boyd-Carpenter said that three unvaccinated children in the borough had recently contracted small-pox, two of them had died. The total number of cases of small-pox

¹Brit. Journ. Exper. Path., 1922, iii, 75.

²Ibid., 141.

incurred in the other duties of the Island Revenue Department.
The total number of regular officers, R.A.M.C., now serving in Great Britain is 413. Of these 13 are with Territorial Army units and 31 are quartermasters. By an arrangement between the Ministry of Pensions and the War Office, under which the Ministry treats soldiers in its hospitals where no military hospital is available and pensioners are treated in military hospitals where no pensioners are being treated in 14 receiving outdoor treatment in pensions hospitals.

England and Wales.

LIVERPOOL MEDICAL INSTITUTION: DR. HENRY HARVEY'S JUBILEE.

A SPECIAL general meeting of the Liverpool Medical Institution was held on December 6th to tender the congratulations of the members to Dr. Henry Harvey, who has completed his fiftieth year of membership. Ladies were invited, and the President, Dr. Abram, and his sister Miss Abram, received the members and visitors. After tea the President took the chair and read the resolution of the Council and letters of apology for absence from Drs. E. W. Hopo and T. Stack. Dr. Caton, past president of the institution, proposed the resolution of congratulation in terms of high praise of the jubilee member. He recorded his first meeting with Dr. Henry Harvey as a fellow student at the University of Edinburgh. Dr. Caton was two and a half years his senior, but both lived through those spacious times distinguished by men who held a European reputation in medicine—Sir James Simpson, Symes, Goolyear, Matthews Duncan. It was also then that Lister was elaborating his antiseptic method amid considerable opposition. Dr. Harvey as a student impressed Dr. Caton by his ardour in his studies and his literary attainments; not only was he well informed in the classics, but as a result of his education abroad was versed in European languages. After graduating Dr. Harvey was appointed resident surgeon at the Hospital and Dispensary, Darlington, and two years later out of fifty candidates obtained the post of senior house-surgeon at the Royal Southern Hospital, Liverpool. In 1872 he became a member of the Medical Institution, and in 1873 settled down in private practice in Wavertree, then a rural township on the outskirts of Liverpool. His ability was soon recognized in his being appointed as M.O.H. Wavertree, which post he relinquished on the absorption of Wavertree by Liverpool. The accuracy and trustworthiness of his reports was especially emphasized in the letter of regret Dr. Hopo had written. Dr. Caton touched upon the importance of a medical man having a hobby: Dr. Harvey recreated his mind by gardening and literature; he was an ardent student of Dante, and a member of the Liverpool Literary and Philosophical Society. Dr. Caton concluded his remarks by graceful allusion to the sterling character, the courteous disposition, and the human interest that were typical of Dr. Henry Harvey, whom they all delighted to honour on this occasion. Mr. Charles Larkin, in seconding the resolution, alluded to the high esteem in which Dr. Harvey was held by the members of the British Medical Association; so secure was their confidence in him that he had always been a member of the Ethical Committee of the Liverpool Division. Dr. Harvey had filled various offices in the Medical Institution, and was a most regular attendant at its meetings. Mr. Rushton Parker followed, and the President, Dr. Abram, in putting the resolution to the meeting, endorsed all that the proposer and seconder had expressed in such felicitous phrases, and referred to Dr. Harvey's youthfulness and activity. Dr. Murray Cairns said in order to show how highly the Edinburgh graduates in medicine esteemed him, those in practice in Liverpool and surroundings had unanimously elected Dr. Harvey as president of the local Medical Branch of the Edinburgh University Club.

The resolution was carried by acclamation, which was intensified when Dr. Harvey rose to respond. He disclaimed all the kind phrases that had been used to describe his personality, but expressed the great satisfaction he felt in receiving their congratulations, and thanked them from the bottom of his heart. He then rapidly surveyed the great changes that had taken place in the Medical Institution during the past fifty years. He mentioned an amusing discussion about diagnosis. Some 80 per cent. of children in some national schools were afflicted with a skin trouble which was at first thought to be purpura haemorrhagica but afterwards turned out to be due to flea bites. Dr. Harvey thought the mental atmosphere of the Medical Institution was in itself a great tonic; the informal conversations that took place between members before the meetings were of incalculable benefit. They kept a man young, and as now members came in the sympathy of the older ones was quickened. In conclusion, Dr. Harvey said he hoped that when others were celebrating their jubilee year of membership they would have as much pleasure in looking back upon their fifty years of membership as he had.

GRADUATE DEMONSTRATIONS AT BATH.

A series of post-graduate demonstrations have been held recently at the Royal United Hospital, Bath. They began at 2.30 p.m. on six successive Saturdays, tea being provided at the conclusion of each. They comprised demonstrations of clinical cases, lantern slides, pathological tests, and short operations bearing on the special subjects chosen for each afternoon, so that all aspects of the subject might be illustrated. The first demonstration was on common diseases of the blood, and this was followed by demonstrations dealing with chronic dyspnoea, renal incompetence and infection, cardiac affections, common nervous diseases, and finally orthopaedic principles. The attendance was well maintained, and varied between twenty-six and thirty-four practitioners not on the staff of the hospital. To show their appreciation of the teaching, which was given without fee, the class entertained those who had given the demonstrations to a lunch on the last Saturday, and afterwards presented them with a cheque for £50 towards the museum fund of the hospital. The additions to the museum which such a generous gift will make possible are sure to enhance the value of future courses, which it is hoped will be held annually.

THE STATE AND MEDICAL SCIENCE.

On November 29th Sir Alfred Mond, Bt., M.P., lectured to the Cambridge University Medical Society on the relation of the State to medical science. He began by pointing out that from very early times evidence might be found of State interest in and partial control of the health of the race; as examples he mentioned the Mosaic laws and Greek legislation. Nowadays great importance was attached to public hygiene. Bad environment and conditions of living led to low racial vitality and decreased resistance to disease; a very striking example of the result of such conditions was afforded by Russia since the revolution; so great an epidemic flood was started that at one time it threatened to overwhelm all Europe. Had not the science of hygiene made such great advances the armies in the great war would have been destroyed by the devastating effects of epidemics, which down to comparatively modern times took a far greater toll of lives, in war, than the fighting itself. Great Britain in some ways was protected by the fact that it was an island, but nevertheless there was a vast amount of work to be done in improving national health and hygiene. The Ministry of Health was doing a great service, but the only too prevalent lack of scientific knowledge was a great drawback to its activities. When it was realized that money spent on research was money saved, while that spent on treating patients was money spent once and for all, a great step would have been taken towards the best possible conditions of national health.

Scotland.

DR. BYROM BRAMWELL.

SOME of the many friends and admirers of Dr. Byrom Bramwell are arranging to celebrate his 75th birthday by presenting to him some mark of the high esteem, respect, and admiration in which he is held by so many members of the medical profession, and particularly his old house-physicians, clerks, and students. It is thought that a portrait painted by some well-known artist would be the most suitable form the presentation could take, but nothing has yet been decided. A provisional committee has been formed, which includes Sir Clifford Allbutt, Sir Thomas Barlow, Sir James Crichton-Browne, Sir Dyce Duckworth, Sir Frederick Mott, Sir Robert Philip, Professor David Drummond, Professor Lovell Gulland, and Dr. Robert Hutchison. The subscriptions, which are limited to a maximum of £5, may be sent to Dr. F. N. Kay Menzies, 37, Egerton Gardens, London, S.W.3, who is acting as honorary secretary and treasurer.

GLASGOW UNIVERSITY IN THE SIXTIES.

Dr. W. L. Reid presided over a well-attended meeting of the Glasgow Medical Lunch Club which was held on December 7th, when Sir Hector C. Cameron, C.B.E., M.D., LL.D., was present as the guest of honour. Sir Hector Cameron's address took the form of reminiscences of his student days in Glasgow University, 1862-66, and of his various teachers and their characteristics. In the course of his remarks he

made interesting comparison of the medical curriculum and teaching of his day with that of to-day. Later he made special reference to the early work of Lister in the Glasgow Royal Infirmary, where he developed his antiseptic system of surgery. The address was richly interspersed with humorous anecdote, and was greatly enjoyed. Dr. R. M. Buchanan, Bacteriologist to Glasgow Corporation, expressed the thanks of the members to Sir Hector Cameron for his very interesting address.

CENSUS OF DUMFRIESSHIRE, 1921.

The border county of Dumfries,¹ the southern boundary of which marches with Cumberland towards the east, and which lies along the Solway Firth towards the west, had a census population of 75,370, being an intercensal increase of 3.5 per cent. In 1801 the population was 54,957, in 1831 it was 73,770, and since then there has been little change. The urban population at the Census was 39.5 per cent. of the total, the largest of seven burghs being the county town of Dumfries with 15,728 inhabitants, and the smallest Lochmaben with 989. Moffat and Sanquhar have increased in population; the others have rather decreased. The increase of Moffat (a holiday resort) may be partly due to the Census being in June. There are in the county 110,4 females to every 100 males. The average male age is 30, and female 32.3; of 21,400 children under 15, 1,553 have lost their father, 819 their mother, and 151 both parents. Of the male population aged 15 and upwards, 42.9 per cent. were unmarried, 51.3 married, and 5.7 widowers or divorced; the corresponding figures for females were 44.2, 44.5, and 11.3. Gaelic speakers numbered 160, all bilingual. The number of persons per occupied house was 4.4, and every 100 windowed rooms had 107 occupants, against 164 in 1861, since when there has been a steady improvement. Of the total population, 2.4 per cent. lived in one-roomed, 27.3 in two-roomed, 21.7 in three-roomed, and 14.7 in four-roomed houses. Of the total population aged 12 and upwards, 57.4 per cent. have remunerative occupation, and of the total persons so occupied, 24.5 per cent. are engaged in agriculture, 12.6 in personal service, 8.3 in commerce, 7.8 in transport and communication, and 6 in textiles.

Ireland.

HOSPITALS AS SANCTUARIES.

ARISING out of an attempt by members of the rebel forces to rescue one of their body who was undergoing treatment at Mercer's Hospital, Dublin, when the military policeman in charge was shot, Surgeon McArdle, St. Vincent's Hospital, has sent a protest to the press. He writes:

"The occurrence at Mercer's Hospital to-day has obsessed me. The Irish people have the credit the world over of being a sporting lot. Everyone who has taken part in big-game shooting or in the minor shooting of these countries recognizes that there is a haven of refuge for game which is sacred. Until now we surgeons thought our hospitals were refuges sacred from interference.

"During the Black and Tan régime Irish surgeons were commanded, under serious penalties, to notify the authorities of the reception of the wounded who came under their care, the conditions under which they were injured, and the locality from which they were brought. I am happy to say Irish surgeons accepted the responsibility and gave no report. During all this time there was no instance of an attack made in hospitals by any member of the army of occupation. It is with extreme regret I learned this morning that an unprecedented occurrence at Mercer's Hospital demonstrated that parties, unthinking of the well-being of Ireland, discredited one of the sanctuaries of the people of Ireland by an attempted murder. In the long and weary and strenuous times when the Black and Tans provided us with many grave and complicated cases the sanctuaries represented by the great hospitals were never invaded. I desire to enter a protest against the invasion of these sanctuaries, which have always afforded a willing, beneficent, and unselfish devotion to all, regardless of status, who required their aid."

THE ULSTER BRANCH.

At the last meeting of the Ulster Branch of the British Medical Association an opening address was given by the President, Mr. Andrew Fullerton, surgeon to the Royal Victoria Hospital, Belfast, on "Aches and pains of renal origin." We hope to publish the address in an early issue. At the conclusion of the address Mr. Mitchell, in proposing a vote of thanks, said that Mr. Fullerton had specialized in the surgical treatment of renal affections and that his experience and technical skill were always at the service of his pro-

fessional brethren, who were deeply indebted to him. Dr. R. Reid, ex-president of the Branch, in seconding the motion, referred to cases lately under his care which had been explained by Mr. Fullerton's paper. The resolution was passed with acclamation and Mr. Fullerton made a suitable reply.

ULSTER MEDICAL SOCIETY.

The annual dinner of the Ulster Medical Society was held on December 8th in the Medical Institute, Belfast, and about one hundred guests, Fellows, and Members were present. After dinner the President, Professor R. J. Johnstone, M.P., who occupied the chair, gave the toast of "The King," which was duly honoured, and then that of "Prosperity to Ireland," to which the Marquess of Dufferin and Ava, D.S.O., Speaker of the Senate of Northern Ireland, and Major the Right Hon. Hugh O'Neill, D.L., M.P., Speaker of the House of Commons of Northern Ireland, responded. The toast of "The Legal Profession," proposed by Professor Lowry, was acknowledged by the Right Hon. Lord Justice Moore, by the Right Hon. Lord Justice Andrews, and by Mr. S. R. Crymbo, LL.B., President of the Incorporated Law Society of Northern Ireland. The health of "The Guests" was given by Dr. Morrow; Mr. A. G. Walby, President of the Association of Dentists of Ireland, and Mr. Fullerton, C.B., C.M.G., President of the Ulster Branch of the British Medical Association, responded. The President then, on behalf of the Society, presented Mr. Fullerton with a copy of the resolution of congratulation on his election to the honorary fellowship of the American College of Surgeons, which had been passed at the previous meeting, engrossed on vellum, with water-colour paintings of the Medical Institute, of the Belfast University, and of the shields of the U.S.A. and of Ulster. Professor Symmers gave the health of "The President," who replied, and then proposed a toast to the Honorary Secretary, to whom, he said, was due the success of the dinner, in arranging which he had taken infinite trouble. Dr. Marshall replied.

Correspondence.

THE TREATMENT OF NON-MALIGNANT AFFECTIONS OF THE COLON.

SIR,—In one of the opening papers on this subject reported in the JOURNAL of November 25th Sir Arbuthnot Lane divides intestinal stagnation into two groups: (1) those characterized by the formation of bands; (2) those characterized by the absence of bands. He goes on to say that in the first group the band not only kinks the colon, but rotates it on its long axis, and causes obstruction of such a degree that it places the life of the patient in serious peril. In the second group there is also obstruction, in this instance by abrupt angles, etc. The paper is dealing with chronic intestinal stasis.

Now it is a well-established pathological fact that chronic obstruction to a muscle causes hypertrophy, so one would expect hypertrophy in chronic intestinal stasis if these views were correct. But this is just what is not found; on the contrary, there is invariably atrophy of the colonic muscle. Any thickening of the wall which may appear will be found to be inflammatory—a colitis, which is not at all uncommon in the proximal half of the colon in these cases.

Waugh, in his paper, evidently anticipates that this may be raised as an objection to his view of stasis—namely, a colon with loose supports trying to raise its load against gravity—for he says:

"That atony and atrophy of its fatigued musculature should ensue over the areas where the strain is greatest is no matter for surprise in accordance with the physiological law of the effect of continuous stimulation. Not only would hypertrophy be utterly impossible under these conditions, but its occurrence would be so inexplicable as to need revision of these laws."

Yet, surely, one would expect hypertrophy in the first place even under these conditions; but is he justified in speaking of continuous stimulation in this connexion? The colon is not lifting against gravity when the individual is recumbent even though its attachments may be loose, and at least eight hours of the twenty-four are normally spent in the reclining attitude.

Moreover, I think he is wrong in assuming that a loose ascending colon is an abnormality. According to my own observations it is the rule to find a considerable degree of mobility in this part of the colon, sufficient, at any rate, to bring it well up into the abdominal wound—with the exception of the hepatic flexure; and even this part never

¹Vol. 1, part 14 of Census of Scotland. H.M. Stationery Office, London, or 23, Fortin Street, Edinburgh. (7s. net.)

receives the ligamentous attachment which one finds at the splenic flexure, as one would expect were it necessary for the ascending colon to pull against something for the efficient discharge of its function. And why, arguing from his hypotaxis, should the splenic flexure be so fixed, since it is propelling downhill?

As regards treatment—undoubtedly both hemi colectomy and colopexy give a percentage of good results, especially colectomy in that soggy type of caecum, which is the stasis case *plus* colitis. I venture to say, however, that most surgeons will agree that the majority of cases give poor or indifferent results with either method of treatment, and for this reason, that stasis is primarily a muscular weakness due to some medical as opposed to a mechanical cause.

It would be interesting to know for how long a fixed colon remains as fixed as it is made at operation. Judging by the frequency of recurrence after other forms of "pexy" operations one would be prepared to find much the same thing happen here. For after all a colopexy is the establishment of artificial adhesions, and all adhesions (even inflammatory, though these are the toughest) stretch under tension.—I am, etc.,

Leeds, D.C. 4th.

E. R. FLINT.

SIR,—In the BRITISH MEDICAL JOURNAL of November 25th is published the paper read at the Annual Meeting of the Association at Glasgow by Sir Arbuthnot Lane. He refers to Colonel McCarrison's experience in the Himalayas, and states that in nine years Colonel McCarrison did not see one case of atrophic dyspepsia, of gastric or duodenal ulcer, of appendicitis, of mucous colitis, or of cancer, and further states that he has obtained similar evidence from other medical men who have been engaged in practice for many years amongst the primitive races.

I am not in a position to express any opinion on the presence or absence of such diseases amongst the people of the extreme north of India, but venture to record my experience in Burma, lest it be assumed that freedom from those diseases is common to all Eastern races, some of which, by the way, I do not regard as "primitive."

My experience has been gained as a civil surgeon in various parts of Burma, and for the last two years before coming home on leave in the General Hospital, Rangoon, where about two hundred laparotomies are done every year by the various members of the staff. The patients of Eastern races treated in that hospital are Burmese, Indians, and Chinese, and the Indians, who are much more numerous than the Burmese, come from all parts of India.

My opinion is that gastric and duodenal ulcer and all the other diseases mentioned by Sir Arbuthnot Lane in the quotation given above are not at all uncommon amongst the patients we see. One very frequently sees cases of chronic dyspepsia which have lasted for years, and in which the history is typically that associated with a gastric or duodenal ulcer. One also sees in some of these cases well-marked evidence of pyloric obstruction.

Cases of this sort would generally submit to operation at home, and the presence of such pathological conditions would be revealed by operation. But it is not easy to induce such patients in the East to submit to operation. In a considerable number, however, coming within my own experience, and operated upon by my colleagues or myself, diseased appendices, gastric and duodenal ulcers, and malignant disease of the intestinal tract have been definitely proved to exist in Burmese and Indian patients.

Further, many cases of general peritonitis, admitted to the Rangoon General Hospital during the two years that came within my own knowledge, have been proved at operation to be due to acute appendicitis or to perforation of a duodenal ulcer.

I am not sure whether Sir Arbuthnot Lane, in mentioning "cancer" in the quotation given above, is referring only to cancer of the digestive tract or is speaking of cancer generally. I can personally recall very many cases of cancer in Burmese and Indian patients, in practically all parts of the body—tongue, floor of mouth, fauces, breast, liver, intestinal tract, rectum, and uterus. Indeed, malignant disease, in these races, is not at all uncommon, and I believe that, if more of the patients with very chronic dyspepsia that one meets with were willing to submit to operation, we should find that the pathological conditions revealed would be very like those met with at home.

I should not like to say that such conditions are as common amongst Eastern races as among European: I do not think

that they are; but I am convinced that they are very much commoner than is generally supposed, and that this opinion would be supported by medical men with experience in large hospitals in the East.—I am, etc.,

R. KELSALL,
Major I.M.S.

London, Dec. 5th.

PENAL DISCIPLINE.

SIR,—Your review of Dr. Mary Gordon's *Penal Discipline*, at page 929 (November 11th), refers to a statement made by her that one in every eight of the girls at the Borstal Institution at Aylesbury had to be put in irons. This statement, unless qualified, is likely to mislead the general reader.

There were indeed thirty-three occasions in the year 1920-21 on which a leather belt with swivel handcuffs (not irons) was used to prevent an inmate from injuring herself or others during a period of excitement; but of these thirty-three occasions one inmate (who afterwards committed suicide at Rampton) accounted for eight, and seven others accounted for fifteen, the remaining ten occasions being spread over ten inmates.

The eight inmates who accounted for twenty-three of the thirty-three occasions were all certified mentally deficient while at Aylesbury, and subsequently removed to Rampton as being of dangerous or violent propensities; and the number of restraints found necessary in their cases was partly due to the fact that some time elapsed after their certification before they could be removed. Thus only eighteen inmates in all were restrained out of the 269 girls who were inmates of the institution during the year. When it is remembered that all but a few of the inmates of this institution have led irregular lives and are frequently in a highly excitable condition, the necessity for these restraints is hardly remarkable.

Whilst no one will champion repression for its own sake, it must be admitted that unless these girls learn at Aylesbury to repress what are to them "normal instincts," on occasion, they are very unlikely to succeed when, on discharge, they have again to try to live at peace with the rest of us.—I am, etc.,

WEMYSS GRANT-WILSON.

The Borstal Association, 15, Buckingham Street,
Strand, W.C.2, Dec. 5th.

PSYCHO-ANALYSIS.

SIR,—In the JOURNAL of December 9th Dr. P. McBride virtually asks your readers, with reference to his recent correspondence with Dr. Steen, for replies to the questions: (1) What does Dr. Steen seem to believe and to have said? (2) Where is Dr. McBride's mistake? As a reply to (1), I suggest that Dr. Steen seems to believe devoutly and steadfastly in the doctrines of psycho-analysis, which, as expressed in his own words (JOURNAL, November 25th), "concerns itself only with mental processes," and, when formulating laws, employs "psychological terms only." He also "seems to believe" that the conception of mental activity being accompanied by corresponding nervous changes is an assumption of no value in psychological study, and to imply that this physiological conception is demoralizing. As to question (2), I do not find that Dr. McBride has made any material mistake in the course of this correspondence. Further, it seems that Dr. Steen is not striving to establish any claim for psycho-analysis to be "scientific," and is desirous of retiring from the controversy by declaring that "wild horses will not drag him into a discussion of the relationship between mind and matter."

In your issue of December 9th there is a very valuable letter from Professor R. J. A. Berry of Melbourne University, which strongly supports Dr. McBride's views, and another from Dr. Henry Rayner, which is greatly to the point in this discussion.

May I refer Dr. McBride to the review by myself of a recent work on *The Psychology of the Criminal*, which was published in the JOURNAL of December 2nd, and deals to some extent with the matter of the principles and practice of psycho-analysis? I may add to these remarks that I agree with Dr. Steen in recommending such as may be interested in Freud's theories to read Freud's *Introductory Lectures on Psycho-analysis*, of which an English translation was published last year. A careful perusal of the first part only (63 pages) on "The psychology of errors" may throw much light on the mental trend and dialectical method of the psycho-analyst.—I am, etc.,

December 10th.

H. BRYAN DONKIN.

SIR,—The quotation from Hart in Dr. Steen's letter of November 25th is a good example of what I referred to in my previous letter. I there tried to show that in order to put psycho-analysis on a true scientific basis it was necessary to ascertain the physiological activities on which the methods depend, and now we have Dr. Steen apparently supporting the directly opposite view that the physiological conception of mental disorders should be kept quite apart from the psychological conception. In the words of the quotation, "Nothing but hopeless confusion can result from the mixture of 'brain cells' and 'ideas.'"

Whilst admitting that the word "mixture" is hardly a well-chosen one in this connexion, we all can form an idea of what is meant, and it is not surprising that we have hopeless confusion when we have advocates of psycho-analytical methods endeavouring to support the contention that physiology and psychology can be kept in two watertight compartments as far as one's conception of them is concerned.

I have difficulty in making out exactly what conception Dr. Steen has of mental processes and disorders. In one of his previous letters he seemed to imply that mind can show itself without physiological nerve and brain activity; now he assures your readers that he believes nothing of the sort. I am afraid that nothing but hopeless confusion can arise unless students of disorders of mind keep clearly before them the fact that there is a physiological basis for all the psychological terms they use, and until psycho-analysts recognize this, and are able to produce a feasible working hypothesis based on it, they will fail to put their practice on a sure scientific basis.

Believing as I do in the limited use of psycho-analysis as a method of treatment, as apart from many of the theories, etc., on which it is based, I believe this is not impossible. To study the subject on the principle of the sentence from Hart is as if one went to investigate the products of a factory where defects in the articles produced had been discovered and left outside the scope of the investigation the machinery through which the articles passed from the raw material to the finished product.

The whole argument can be shortly put thus: Can mental disorders exist without disease of or irregularities or alterations or modifications of the normal physiological action of nerve and brain cells? If not, then, instead of keeping "brain cells and ideas" in two watertight compartments it is more scientific, and would be more fruitful of results, if the relationships of the one to the other were never lost sight of in the study and discussion of all neurological and psychological questions. We would then see much fewer purely metaphysical terms used in the discussions on psycho-analysis, suggestion and auto-suggestion, hypnosis, and faith healing. Dr. McBride has given a quotation from Stewart Paton; let me quote to the same effect from Ferrier, who has done so much to place the study of cerebral action on a scientific basis:

"We have no proof of subjectivity or modifications of consciousness apart from the action of the cerebral hemispheres, but we have no reason to believe that anything is superadded, or that the action of the cortical centres is of a different order from that of the most simple nervous apparatus, but rather that between the simplest reflex action and the most complex cerebral process there is a continuous unbroken gradation."

—I am, etc.,
Leith, Dec. 3rd.

WILLIAM ELDER, M.D., F.R.C.P.E.

PSYCHIATRIC CLINICS.

SIR,—Having had experience of the great value of out-patient treatment of the neuroses, psychoneuroses, and early psychoses, I desire to support very strongly the appeal which Dr. R. H. Steen makes so forcibly in your issue of November 18th for the establishment of a special institution for psychotherapy. That there is need for such an institution for the civilian population is only too clear, and the present position of almost complete inaction is probably only the expression of a feeling of despair at the magnitude of the task to be undertaken. Nevertheless, the time has certainly arrived when something should be done in this matter, and there can be little doubt that never has the opportunity for pressing the need for such treatment been so favourable as now, when so large a proportion of the general public are evincing such unmistakable interest in psychological problems.

It will hardly be denied that the patient suffering from a minor mental disorder (generally erroneously called a "functional nervous disease") is the bugbear of the practitioner

who has no knowledge of modern psychological methods, and who neither knows how to deal with the case personally nor how to obtain the treatment which he knows is required, unless indeed the patient is in a position to pay substantial fees to a specialist in psychological medicine. The result is disastrous. The huge majority of cases receive no treatment worth the name, and therefore go from bad to worse, and this only because they cannot obtain the help which ought to be placed within their reach, and which indeed is now at hand.

Experience goes to show that in the vast majority of instances the ideal method of treatment is at an out-patient clinic, for it is eminently desirable that wherever possible the patient shall continue his employment and remain in his ordinary environment while under treatment. Only in these cases where the home conditions are insupportable, or close observation is necessary, or where out-patient treatment cannot be provided within a reasonable distance from the patient's home, is in-patient treatment in a hospital either necessary or desirable. Indeed there is a positive danger in many cases that admission to hospital may produce the condition of "hospitalization" and make the patient unwilling to face the ordinary cares of life. Nevertheless, a clinic should be linked up with a hospital where selected cases may be admitted, and preferably both should be staffed by the same personnel.

The staff, as Dr. Steen suggests, should be comparatively numerous, to permit of wide choice of physician for individual cases, and to allow also for transfer from one physician to another when the element of personality, either in the physician or the patient, is interfering with progress. The staff should also include specialists in the treatment of speech defects, as stammering is so common in the cases requiring treatment, and a gymnasium for re-educational exercises is definitely of benefit in those cases where there is a want of muscular co-ordination and in cases of functional paralyses and pareses. For those who are unemployed or whose form of employment is unsuitable it is well to provide workshops where occupational therapy can be carried out, and the patients trained either in the habit of working, which many have lost, or in new spheres of greater usefulness.

It is, of course, only in the larger centres of population that such a scheme could be carried out fully; but even in the smallest town something in the nature of a psychotherapeutic clinic could readily be provided with inestimable advantages to the community as a whole, and there is no doubt that this would be welcomed by the civilian population. In these days of high taxation and of high rates it is unlikely that public bodies will be able to afford financial assistance for the establishment of an institution for psychotherapy. It is therefore earnestly to be hoped that some open-handed philanthropist of broad outlook will make the same provision for patients needing out-patient treatment as did the late Sir Ernest Cassel, shortly before his recent death, for those requiring in-patient treatment.—I am, etc.,

London, N.W., Dec. 9th.

H. E. DAVISON, M.D.

"THE DAWN OF THE HEALTH AGE."

SIR,—The late Professor Benjamin Moore of Oxford in his book, *The Dawn of the Health Age*, wrote:

"At the present moment we possess sufficient knowledge of medical science to enable us to save at least three hundred thousand lives every year in this country alone. Anything more futile, less scientific, more hopelessly absurd than the present method of dealing with disease can scarcely be conceived."

I think most of us will agree with these statements. At present prevention is left mainly to medical officers of health, a small minority of the profession, whose sphere is narrow, who are hampered with ancient statutes and hindered by the trammels of present conditions. When we turn our general practitioners on to prevention, when we give to each, let us say, three hundred families to keep well, then we may hope for progress. Already we have medical inspection of school children, and therefore men who have gained experience in this new and promising field. Why not extend this system to the whole population?

The record cards of the school children would be handed to the medical men, whose business it would be to continue the inspection and the records, right through life. Some day these records, when tabulated and correlated, would add immensely to our knowledge of the causes of disease and to our ability to prevent disease. General medical inspection would make us familiar with the early stages of disease, and also with the still earlier departures from strict health, before

these become manifest to the ordinary observer. Medical services of to-day are largely a thing of patches and inequalities, calling for unification under the Ministry of Health.

The subject is a wide one, and I do not wish to wander far afield. As a nation we may not be quite ready financially and otherwise to embark on this undertaking, but I wish to suggest that the subject should receive attention, as it may soon come within the range of practical politics.—I am, etc.,
J. A. WILSON.
Cambuslang, near Glasgow, Nov. 2nd.

POSITION OF INSANITY IN CRIMINAL LAW.

SIR,—I had the good fortune to be present at the recent meeting of the Hunterian Society when the psychological aspect of crime was discussed by alienists and legal luminaries. As an onlooker may I venture to say what the discussion appeared to me to indicate?

The medical standpoint is the aspect of crime as seen by the psychological expert. That of the eminent barristers present is the inability of a jury to grasp psychological issues. The jury has to accept the judge's ruling on legal points; it should similarly accept ruling on far more difficult psychological questions.

Medical experts are not satisfied that the rulings on psychological issues are in accordance with modern medical knowledge. A gap occurs between the alienists' knowledge and its reception by the jury. In the Admiralty Court, in certain cases, the judge is assisted by expert assessors. Might not the gap between the intelligence of the jury and the knowledge of the expert, alienist witnesses be similarly bridged over? As an alternative might not a small jury of alienists take the place in such cases of the decadent grand jury? The whole issue is that there is a gap, and that this is against a fair and proper hearing. Incidentally, may I note that the protection of a convicted person by the existing safeguards seems to lead to an ignoring of the penal effect of the conviction.

I should like to be informed whether psychology is one of the compulsory subjects taken by students preparing for the Bar? And how far the study of this subject is carried before and after being called?—I am, etc.,

F. R. HUMPHREYS.

Winchester, Nov. 28th.

INSULIN.

SIR,—So much prominence has been given to the "insulin" treatment of diabetes that it is perhaps not out of place to review the steps which have led up to the production of this

do, in the blood sugar of depancreatized of pancreatic extract had frequently been observed, notably by Mulin, Kleiner, and Paulesco, yet no results of any value had been obtained by this method in the treatment of human diabetes. On the contrary, it has been said that the administration of such extracts to human beings is not unattended with danger.

It occurred to Drs. Banting and Best that the cause of this failure probably lay in the fact that in the course of preparation of the extract the hormone supplied by the islets was destroyed by the proteolytic enzyme liberated from the acini. They therefore set about to find a method by which the pancreas could be obtained relatively free from active acinous tissue. Now it is one of the best established facts in physiology that the proteolytic enzyme exists in the pancreas in an inactive form—trypsinogen—which is activated normally only on contact with another ferment, enterokinase, secreted by the small intestine. It is indeed activated on autolysis of the pancreas whole or macerated at body temperature, but only slowly. If this is true rapid maceration in a half-frozen condition is hardly likely to cause any appreciable activation. On the other hand the establishment of the thesis of Banting and Best carries with it implicitly a proof that trypsin is active even when in the pancreas. This question, therefore, is important to the subject of digestion as well as to that of diabetes. Moreover, it is clear from reading the recent correspondence on the subject that many who have engaged in it are under the impression that Banting and Best have completely established this important point.

At first Banting and Best¹ caused the acinous tissue to atrophy by ligaturing the ducts. Ten weeks later extracts were made from the degenerated gland by rapid maceration

in a partially frozen condition and given to depancreatized dogs. In the first experiment, which is described as "not conclusive," the dog was abnormal in that practically no sugar was excreted except when sugar was orally given. Administration of 25 grams of sugar raised the blood sugar from 0.18 to 0.33, and 15.88 grams were recovered from the urine in five hours. Three days later, the blood sugar being 0.20 and the urinary sugar nil, degenerated pancreas was given. (The dose is not clear, for the text says 4 c.cm. but the chart 5 c.cm.) Blood sugar fell to 0.12. Two further injections were given, the blood sugar being 0.11 per cent. 20 grams of sugar were then given—the text says at 12 a.m., the chart says at 2 p.m. The discrepancy here is important, for if the chart is correct the sugar had begun to return to its previous level before the sugar was given; if the text is correct the rise in blood sugar is at least partly due to the sugar given. With three subsequent injections of degenerated pancreas the blood sugar remained at about 0.20. Of the 20 grains injected only 0.21 was recovered in the urine. But there was practically no urine and the animal was dead next day. Truly, as the authors admit, no conclusions can be drawn from a moribund animal. The experiment only indicates that the degenerated pancreas lowered the blood sugar temporarily.

The second experiment was conducted on similar lines. The first fact which strikes one is that on August 12th, although six doses were given, amounting in all to 46 c.cm., the blood sugar actually rose until the last dose was given, when it began to fall. On the next day, under the influence of huge doses (72 c.cm. in all), blood sugar was reduced to a normal level. On August 14th 30 c.cm. of extract drove the blood sugar from 0.18 to 0.06, with, however, recovery in five hours. So far, then, this experiment shows that with very large and frequent doses blood sugar falls temporarily, but that with moderately large doses the blood sugar is not reduced.

The authors then attempt to show the superiority of the degenerated over the normal gland. The following table, taken from their chart, shows the result.

Date.	Extract.	Blood Sugar.		Duration of Suppressed Blood Sugar.*
		Before.	After.	
Aug. 15 ...	10 c.cm. degenerated gland with HCl	0.30	0.17	Six hours approximately.
Aug. 15 ...	10 c.cm. degenerated gland with NaOH	0.28	0.24	One hour.
Aug. 16 ...	10 c.cm. degenerated gland, neutral	0.30	0.18	Two and a half hours.
Aug. 17 ...	10 c.cm. whole gland, fresh, cold	0.30	0.16	More than 7 hours, but prevented by next injection.
Aug. 17 ...	10 c.cm. whole gland with HCl	0.21	0.15	More than 6 hours, but prevented by next injection.
Aug. 18 ...	10 c.cm. whole gland with NaOH	0.16	0.14	Ten hours.

* That is, time taken to return to about 0.30.

From these facts the authors draw the astonishing conclusion that the whole gland is much weaker than the degenerated. But a glance at the chart is sufficient to convince anyone that the only reasonable conclusions that can be drawn are:

1. That the whole gland extract is more effective than the degenerated.
2. That the extract from the whole gland causes a much more lasting effect than does that from the degenerated gland. Had the two injections on August 17th been given a fair chance the superiority of the normal would doubtless have been still more striking.

We may now pass to the third part of the experiment. This is intended to show that instead of tying the ducts the acini can be exhausted by continued injections of secretin and prolonged stimulation of the vagus. Now it is well known that all attempts to show histological changes in the pancreas indicative of exhaustion have failed. The authors' criterion of exhaustion—namely, the large amount already secreted—is therefore quite unjustified. To establish their point Banting and Best have to show that the gland which they say is exhausted really is exhausted. This can only be done by demonstrating the absence of the three ferments by the ordinary methods. This they have neglected to do.

They found that the "exhausted" gland incubated with saline was still potent. This fact they quite unjustifiably

¹ Banting and Best: *Journ. Lab. Clin. Med.*, vol. vii, 1922, No. 5, p. 1.

take to show that there is no proteolytic ferment left. But in the absence of direct proof of exhaustion this experiment shows clearly that the hormone is not destroyed by anything in the acini on two hours' autolysis. Thus their main contention falls to pieces.

On August 20th 24 c.c.m. of the "exhausted" gland lowered blood sugar from 0.33 to 0.071, and with subsequent injections it was maintained at this level. On the following day 10 c.c.m. "exhausted" extract incubated two hours with pancreatic juice were injected. The effect was trifling. The conclusion which they draw is that the active principle had been destroyed by the ferment. It may be remarked, however, first, that this last dose was much smaller than the first; and secondly, we are not told whether the pancreatic juice was active or not. Presumably it was active, for "active" pancreatic juice is mentioned in a similar experiment performed later.

The third experiment shows that large doses of degenerated pancreas lower the blood sugar for a time, and that the active principle is destroyed on boiling. The experiment was performed on an animal dying of a "widespread abdominal infection."

The fourth experiment deals again and in a similar manner with an "exhausted gland." The criticisms made above apply here. *The authors have neglected to perform the one crucial experiment. They have not shown that the active principle in the normal active gland is destroyed on self-incubation—that is, in the absence of activated pancreatic juice.*

Finally, in this experiment, an extract from the "partially" exhausted gland of the cat was given. It provoked a general reaction. From this the remarkable conclusion is drawn that extracts from "more or less exhausted glands" produce symptoms of toxicity.

The fifth experiment is apparently to show that a part of the pancreas in which degeneration has occurred is more effective than the processus uncinatus, which is not degenerated. On referring to the chart, however, it appears that the first dose (10 c.c.m.) from the undegenerated part is more effective than the first dose (20 c.c.m.) from the degenerated part. True the second dose from the normal part failed, but then it took four strong doses from the degenerated part to push the blood sugar down to its normal level.

The facts which may therefore be learnt from these experiments are:

1. That both the normal and degenerated glands cause a temporary fall in blood-sugar.
2. That the normal gland is actually superior to the degenerated gland.
3. That the active principle is destroyed *in vitro* by active pancreatic juice.

On the other hand the experiments do not prove—

1. That the degenerated is superior to the normal gland.
2. That the active principle is destroyed by unactivated pancreatic juice.
3. That the acini can be exhausted by prolonged secretion.

Two things are to be regretted: first, the inequality of the dose—frequently a larger dose was given for the test than for the control; secondly, the absence of any record of the fluctuations in blood sugar after removal of the pancreas but before administration of the extract.

Having therefore failed to establish their main thesis, but encouraged by a complete misreading of their results (I challenge any unbiased person to read the paper carefully and come to any other conclusion), Banting and Best² then proceeded to investigate further methods of preparing a hormone free from the destructive action of ferments. They tried foetal pancreas, in which, according to Ibrahim, the acinous tissue is not developed. The first experiment is illustrated by a chart which is difficult to follow, inasmuch as the blood was withdrawn for sugar determination usually at the same time as the injections were given. It appears, however, that injection of foetal extract in several doses on November 17th and 18th reduced the blood sugar from 0.30 to 0.08, but that injections from November 20th to 22nd had no effect. Later injections caused toxic symptoms which proved fatal. The second experiment shows that foetal pancreas is as potent as the degenerated. It is important to observe that no comparison has been made between foetal and normal adult pancreas.

At this stage in the proceedings Banting and Best completely change their method, for they now make an alcoholic

extract after the manner first adopted by E. L. Scott: an alcoholic extract first of foetal then of normal adult pancreas. Reduction of blood sugar again occurs, but here again there is no comparison made between the effects of the alcoholic and those of a watery extract in the same animal. The superiority of the alcoholic extract therefore remains unproved. Still with an alcoholic extract the danger of producing toxic symptoms is present, so that clearly the problem is not a question of removing the proteolytic enzyme.

From this point the research takes on quite a different aspect, the problem being to produce a non-toxic rather than a not inactive substance. As Collip, one of the collaborators, remarks:

"The problem was to remove most of the protein and salts and all of the lipid material from the extracts without destroying the active principle."

At the moment a modification of Scott's method seems to be used: extraction with 80 per cent. alcohol and subsequent purification. What Banting and Best have failed to realize is that in so radically changing their method they have abandoned the principle from which they started and which they never proved.

The conclusion we come to, therefore, is this: the production of insulin originated in a wrongly conceived, wrongly conducted, and wrongly interpreted series of experiments. Through gross misreading of these experiments interest in the pancreatic carbohydrate function has been revived, with the result that apparently beneficial results have been obtained in certain cases of human diabetes. Whether insulin will fulfil its promise time alone will show; but I venture to believe that whatever success the remedy will have will be found to be due to the fact that the hormone has been obtained free from anaphylaxis-producing and other toxic substances. The experiments of Banting and Best show conclusively that trypsin *qua* ferment has nothing whatever to do with it.—I am, etc.,

THE ROYAL COLLEGE OF SURGEONS OF ENGLAND: MEMBERS AND THE COUNCIL.

SIR,—Will you favour me with space in your JOURNAL to refer to the recent proceedings at the annual meeting of the Royal College of Surgeons of England, and particularly to the President's remarks at its close?

For over twenty years a claim has been advanced by Members, frequently supported by distinguished Fellows, for representation by Members of their point of view, as general practitioners, at the Council board. The position in our College is unique. The Members originally constituted the College. A "new order of Members," called "Follows," were self-elected (without examination) in 1848, and became the functioning authority, and obtained a Charter which decreed that only Fellows should vote for the election of the Council. That is to say, a graft of 1,700 Fellows alone have the franchise and power in the parent body of 18,000 Members. This obvious injustice has never been defended. So strongly did the late Timothy Holmes feel on this matter that when Vice-President he declined the President's chair, being unwilling to preside over a Council of whose mode of election he did not approve. Last year no annual meeting took place, as the President declared there was not the necessary quorum of thirty, although there were in the theatre twenty-nine male Members and one female Member, and in the adjoining room many members of Council, whom the President admitted were there but did not attend so that a quorum could not be formed. To increase the difficulty of forming a quorum in future a new by-law has been introduced—contrary to all precedent in similar bodies—declaring that the Council and President shall not count towards a quorum. This attempt to deprive Fellows and Members of their one and only opportunity in the year for expressing their views is not worthy of the President and Council of this great College. At the end of the meeting, when no reply was allowed, the President advanced for the first time in this controversy, without alluding even remotely to the merits of the question, the Council's reasons for refusing the claim of the Members under three heads.

The first declares

"that the present electorate of 1,700 Fellows is a thoroughly representative one, that a very large number of the Fellows are in general practice, and that it was wrong to assume that the Fellows were all engaged in work as consulting surgeons."

² Banting and Best: *Ibid.*, vol. vii, 1922, No. 8, p. 3.

In reply I would point out that this electorate is less than a tenth of the total constituency of the Collegio; that it has never been asserted that all the Fellows are consulting surgeons, but it is true that all the Council are. There never has been a general practitioner, Fellow or Member, on the Council, and it is not likely that there ever will be, on the present franchise, as the majority of the Fellows are consultants. So, most certainly, the Council cannot be said to be a representative one, when, of 18,000 Members 16,000 have no direct representation at the Council.

The second point states

"that the Council are not prepared to advocate measures in opposition to the opinions of a large number of the present electorate."

That is to say, the Council encroaches itself behind its own privileges, and refuses to surrender any of them in the interest of fair and just representation, which undoubtedly would improve the relations existing between the Members and the Council and be for the mutual advantage of Fellows and Members. Moreover, the President ignores the fact that some years ago the Association of Fellows passed a resolution in favour of the Council granting Members a share in the management of Collegio affairs.

The third point was

"that there was no evidence before the Council of a widespread demand by the Members for an amended charter, and very few Members came to the meeting to support the motions of the Society of Members of the Collegio."

For a quarter of a century Members have argued hard, and fought hard, for this change, and with marvellous patience and perseverance, at each annual meeting—their only opportunity. Rarely was there a single Member present who was out of sympathy with this request. The Members may well reply that all the evidence is in the reverse direction. At no time during this agitation has there been any indication that the main body of Members are not desirous of the reform asked for in their name.—I am, etc.,

REDMOND ROCHER,

President of the Society of Members of the
College of Surgeons of England.

1, Eccleston Square, S.W.
Dec. 9th.

INDIRECT ADVERTISING.

Sir,—On reading the account of the discussion on the above topic at the meeting of the General Medical Council on December 1st I was astonished to find a total ignorance of the part played by the ordinary journalist writing in the lay press. It seems to be supposed that every paragraph complained of is inspired by, and even sometimes paid for by, the medical man named. I venture to say, both as a journalist and as a medical man, that such is certainly not the case. The public interest in medicine and in medical men is so great nowadays that the "news" editor of the daily press seeks such paragraphs as being of public interest. If a prominent man is operated upon the man in the street likes to know who did it, and the wise journalist tells him. If the big politician consults Sir X. Y. about his health he does not always conceal the fact from his friends, and the astute paragraph writer does not miss the item for his column in the "Daily Inkipot." The press has a right to record the work and doings of all public men—irrespective of their wishes—and prominent medical men are interesting public men. This of course has nothing to do with the obviously paid paragraphs of "moves" and "addresses." The public do not care for such items of news, but the public do care to know who cut off Lady So-and-so's leg or the name of the "famous surgeon" who is attending a popular actress for appendicitis. No reporter worth his salt would fail to find out such information. And are the surgeons in question to be put in Dr. Bolam's pillory because the penny-a-liner has earned his pennies? What have they had to do with it? Again, a prominent doctor reads a paper at a popular congress. It is widely discussed. His remarks are of public interest, and being so constitute a big advertisement for the doctor. Why not? The answer is, because some unknown members of the profession never get the same chance. The idea is contemptible. It springs from the lowest form of emotion—jealousy. It has no other basis, and it constitutes a very common failing in our profession. One sees it constantly in medical life—"my opponent," "the opposition," applied to those who should be regarded as colleagues in the noblest of all professions. One could multiply instances of professional

irritation at success in others, but it hardly seems worth while. The point I wish to emphasize is, that whatever rules and regulations may emanate from Dr. Bolam as a sort of medical sin-smeller, are likely to be utterly disregarded by those who uphold the liberty of the press and the right of the public to be informed about men and matters, medical or otherwise. I have no personal interest in this matter of advertisement as a doctor.—I am, etc.,

December 11th.

A JOURNALIST AND DOCTOR.

THE SMALL-POX OUTBREAK AT POPLAR WORKHOUSE.

Sir,—The following note regarding an outbreak of small-pox that occurred in the burgh of Kirkintilloch in November, 1920, may not be without interest. There were 33 cases, 32 of which were infected directly or indirectly by the first case; this was a child, 12 years of age, unvaccinated, whose symptoms were comparatively mild, and whose illness was diagnosed as chicken-pox (this occurred before chicken-pox was compulsorily notifiable); after a few days in bed she was able to be up and about; she infected in the first place her five brothers and sisters (all unvaccinated) and her parents (vaccinated in infancy only); these first 8 cases of the outbreak all made complete recoveries; of the succeeding 25 cases 11 died. In all, 19 cases were unvaccinated, of whom 7 died, a mortality of 37 per cent.; but if we exclude the comparatively mild cases occurring in the 6 unvaccinated children of the family where the outbreak originated, there remain 13 cases (of whom, as stated above, 7 died) with the high mortality of 54 per cent.; it should be further added that the ages at death were from 5 to 11 years, a period of life when mortality is fairly low and resistance to disease good.

The numbers involved in this epidemic are of course too small to permit the making of any general inference; but they show that at least one outbreak originated in a mild case where the symptoms were not masked by vaccination, and though commencing with a mild type of the disease (among the unvaccinated) it rapidly became virulent.—I am, etc.,

Bishopbriggs, Dec. 10th.

JAS. B. MILLER.

Sir,—Dr. Millard will not admit that an unmodified case of small-pox can walk about, but states that the man would be too ill and would send for his doctor. In the Milroy lectures for 1919 Dr. McVail mentions the case of a man with a fully developed and abundant eruption who was discovered seated in a place of public resort (George Square) in Glasgow. In the BRITISH MEDICAL JOURNAL for April 19th, 1919, Dr. Millard said that—

"Infantile vaccination as a State institution aiming at the universal vaccination of infants has been living on a reputation largely based on prophecies now proved to have been erroneous; it is already discredited by the large masses of the population, and is rapidly becoming obsolete. I submit that the time is ripe for a reconsideration of the question whether it is any longer really necessary."

If Dr. Millard's suggestion were followed, then we would witness a repetition of the Gloucester disaster wherever small-pox commenced. Gloucester, like Leicester, neglected vaccination. As Dr. McVail said, "Its representatives told the Royal Commission about the cleanliness of their fine old city, and called attention to the freedom from small-pox"—and then the deluge in 1895-96. The type of infection was severe, and the 48 beds grew to 318. Vaccination and re-vaccination became the rage, and Gloucester became the best vaccinated town in the British Empire. As I write, I have before me a photograph of a portion of the Gloucester cemetery showing the graves of 279 unvaccinated children under 10 years of age who died in the 1895-96 epidemic, together with one child out of more than 8,000 who were vaccinated before or during the epidemic. And Dr. Millard's reply to the weeping mothers is that "the premium to be paid (in the form of so much vaccination) is out of all proportion to the risk to be insured against."

Unvaccinated children, attacked by small-pox, tend to die. What a price to pay for a theory! We have no guarantee that the first case of unmodified small-pox occurring in Dr. Millard's unvaccinated city in the clouds would be diagnosed in time. Very many doctors have not seen a case of small-pox.

Though surely unlikely nowadays, there is, too, the point mentioned by Dr. Spencer Low in his report on the Dewaury epidemic of 1904—"Non-notification of cases in many instances meant concealment of cases." What about tramps? A sick tramp, with the amelioration of symptoms not known when the rash appears, might wend his way to a lodging-house. Dr. Wanklyn mentions a case where a sanitary inspector recognized the disease through observing the soles of a tramp's feet projecting from the end of the bed.

Will Dr. Millard, who is one of the most respected and hard-working medical officers of health in England, kindly answer a question? Suppose that small-pox came to Leicester and killed some unvaccinated children of 7 years of age, and the fathers came to Dr. Millard's office and said: "We are but labourers; we took your advice that vaccination in infancy was 'discredited' and 'obsoleted,' so we did not vaccinate our children. The disease has killed our bairns, but the vaccinated children are alive. What is your reason or your belief?" What would Dr. Millard say to those bereaved parents?

Dr. Millard's way is the easy way, the popular way, until the day of reckoning comes. My way—vaccination, re-vaccination, and a third course—is the hard way, the unpopular way, made more hard and unpopular by the propagation of a theory not held by one doctor in a thousand.—I am, etc.,

CHARLES S. THOMSON,
Medical Officer of Health.

Town Hall, Deptford, S.E.14, Dec. 5th.

THE RADICAL PREVENTION OF VENEREAL DISEASE.

SIR,—The purpose of my letter of October 7th was to call attention to the historical fact that the highest ideals are in reality the most practical and fruitful of results in the long run.

In reply, correspondents have reiterated the familiar statements that "high moral ideals are impracticable," that there is "too much human nature about humanity" for their success. One correspondent seems to say we have made no advance on Moses' system. Consistently with this view, he argues that a morality of selfish discretion, based on fear as a motive, is the only practical one available for us. Do those who make these statements realize their position? It implies reverting to the moral system of 1,900 years ago. It is simply relinquishing the moral gain of the Christian era.

As evolutionists—to take no higher ground—we are bound, surely, to protest against this attitude. The history of the Christian era has exposed the fallacy of the statement that "high moral ideals are impracticable." It is made so commonly as to be almost regarded as an axiom, instead of the fallacy that it is. It is an atavistic, degenerate, retrograde statement! It reveals the desorter from the cause of evolution and progress. It is unchristian—obviously. It is the first step on the slippery slope of Bolshevik morality.—I am, etc.,

Sheffield, Dec. 5th.

HERBERT CAIGER.

SIR,—The periodical discussions on this subject have become very wearisome. We are continually reminded by the same disputants of their specific prophylactic measures supported by the same stereotyped "arguments." But what does it all amount to? Nothing. At the beginning of the war, when venereal diseases were raging in Egypt, I was requested to superintend the European Lock Hospital, and did so for some time. The conditions existing in the "hospital" were found to be appalling; as instances, specula were never sterilized after use in each individual case, after inspection or treatment; douche nozzles the same; and, most incredible of all, the matrons and staff were compelled (there was no other alternative) to use the same lavatories and baths as diseased patients.

Notwithstanding the faulty system of administration, etc., after considerable experience the conclusion is irresistible that there is but one way of dealing with such diseases, and that is by isolation in conjunction with segregation. Treat the victims as if they were suffering from small-pox or other contagious diseases, and we will be spared the reiteration of shibboleths and moral platitudes. Although such a system—which according to the moralists "legalizes vice"—has been tried in various countries it cannot be admitted that it has been attended with any great measure of success, but this because, except in some parts of Germany, it has never been

properly carried out. Take, for instance, the conditions briefly outlined as existing in Cairo: is it fair to condemn a system of prophylaxis carried out under such ghastly circumstances, more calculated to spread disease than to prevent it?

The fact is that this peculiar branch of medical practice has never been divorced—as it should be—from its moral aspects, and appears to be only too frequently associated with incompetence and callousness and to rest on a corrupt basis. Perhaps not the least regrettable fact in connexion with this unsavoury controversy is the prominent part taken in it by women. It may be that they are overtaxed by our social system of to-day; if such is the case the standard of civilization which exacts so much from their biological requirements cannot survive indefinitely.—I am, etc.,

Cairo, Nov. 23rd.

T. GERALD GARRY.

HOSPITAL POLICY: THE REPORT OF THE COUNCIL.

SIR,—As the Council have not accepted the amendment of Dr. Brackenbury, although it gained a majority of votes at Glasgow, and undoubtedly reflects lay opinion, I would review their policy once again. It had origin in a few hospitals of great industrial centres, whose staffs, during the early post-war boom in trade and wages, had been grievously exploited by well-paid workmen, who declined any inquiry into their financial state. For such areas the Leicester motion is entirely suitable, but they are a small minority. Nevertheless certain of the Council and Hospitals Committee, with all the ardour of proselytes, initiated a campaign to enforce this policy upon all. On December 18th, 1920, an immense agenda list, whereon the Leicester was but No. 26 of twenty-eight motions, was posted for a meeting actually to be held within two days of its receipt. Although by far the most important and contentious motion, its discussion was postponed to the last hour, and we were strongly urged to pass it *nem. con.* as another meeting was due shortly in the same room. Of course the promoters of this motion and their converts held the field. Moreover, Mr. Eccles succeeded in conveying the impression, which exerted great influence, that the staff of St. Bartholomew's Hospital favoured this policy, which they have since condemned. This was what Mr. Harman described afterwards as a "keen debate"! Scarcely more valuable was the vote at Newcastle. The all-important motion occupied nine lines in fifty-four double-column pages of the report of the Council; it was never alluded to again, and was absent from the agenda. Naturally few Divisions had given it a thought, and once more the full weight of Council and Committee was brought to bear on an audience mostly unprepared. Mr. Harman, indeed, stigmatized sound amendments as "weakly, sickly, and sentimental," having himself in December put forward sentiment as the main excuse for the survival of that voluntary system for which, as so "lovable," he pleaded with much eloquence. Moreover, while vigorously exploiting that hasty vote of December, the value of which I have indicated, he ignored entirely that in February of Scottish staffs, who, after two months for consideration, had condemned his policy—a graceful compliment to the President-elect. Dr. Brackenbury's amendment, if thereto be added the rider of Dr. Fothergill, entirely meets the case, for "maintenance and accommodation," as distinct from treatment, are lay functions, and have not, like the latter, greatly increased in cost, nor is there difficulty in providing them at home. The cost of maintenance, excluding all treatment and nursing, is, in our hospital, but 30s. a week, and should not greatly exceed this sum elsewhere. Those patients who can be certified by a hospital official as able to pay only 2s. 6d. to 30s. weekly are the thrifty poor, and none other. It will be an ill day for our reputation, and a deadly blow to the voluntary system, when the "honorary" staffs of "voluntary" hospitals, while retaining their title and prestige, and all those indirect emoluments well known to laymen; attempt, quite certainly in vain, under any species of camouflage by the use of titles such as "peppercorn" and the like, to deny their free service in these institutions to the thrifty poor. As for the risk of "manipulation," let us invite representatives of approved societies to a conference, and come to some agreement with them, as has already been done with county councils and other bodies, and this transparent bogey will for ever disappear. Again, if some day a Labour Government abolishes "charity" for the poor, surely it were infinitely better to start the new régime unhampered by the precedent of a quite inadequate payment for this class.

The policy of the Council can be accepted only on the lines of the amendment of Dr. Brackenbury and Dr. Fothergill, which is practically the West Sussex amendment of Section VI, para. 19 at the second Hospital Conference in London, and at Glasgow. This policy was provisionally accepted, at my suggestion, by the lay board of our hospital before that Conference. Rather than accept the full policy they, and I believe the vast majority of lay boards, would reject the staff fund altogether. I have yet to learn that any member of the Council or Hospitals Committee, with the exception of Dr. Clarke, has so far dared even to approach his own board with a policy more advanced than this. If they have, let them say so, and state the result, and we shall know how we stand.—I am, etc.,

Chichester, Dec. 2nd.

G. C. GARRETT.

TREATMENT OF GENERAL PARALYSIS BY MALARIA.

SIR,—The omission of a few sentences in your account of my paper on this subject before the Medico-Psychological Association may cause a misapprehension. The full statement is that of the last 116 cases treated, 42 were completely cured, 22 so nearly completely cured that signs could be detected only by careful examination, 14 partially cured and at work, and, finally, 38 in which no improvement was found. Professor Wagner-Jauregg believes that all early cases can be completely cured.—I am, etc.,

London, W., Dec. 8th.

E. W. SCRIPTURE.

Obituary.

W. B. RUSSELL, B.A., LL.B., M.B.,
Colwyn Bay.

THE death of Dr. W. B. Russell occurred on December 4th at his residence in Colwyn Bay. William Barker Russell was born on July 28th, 1858, at Southolme, near Scarborough. He was educated at Old Malton Grammar School, and Trinity Hall, Cambridge, where he graduated B.A. and LL.B. At the close of a brilliant career at Cambridge he won a scholarship of £100 per annum for three years to enable him to pursue further his legal studies; but after a period of experience with a well-known firm of solicitors in Leeds he resigned the last year of his Cambridge scholarship and turned to the study of medicine. At Leeds University he was a fellow student with Sir Berkeley Moynihan, and after passing the M.B. examination he spent two years at Scarborough Hospital as house-surgeon. This was followed by a further two years at Malton, in Yorkshire. In 1892 he went to Colwyn Bay, where he spent the most important years of his life. Colwyn Bay and its surroundings made an excellent centre for his studies in birds and flowers; and during his early years much of his spare time was spent in acquiring an extensive knowledge of the flora of North Wales. His knowledge of birds—their habits and calls—was very intimate, and the keenest pleasure of his life was to study these in their native haunts. He would wax enthusiastic over the presence of a flying beetle, at an unusual time of the year, and even in the last few days of his life he would constantly talk of the sounds of the birds as he heard them in the confinement of his room. The hooting of owls at night was to him a source of pleasure. He was a recognized authority on natural study, and contributed articles on bird and flower life to a book which was published on the history of Colwyn Bay some years ago. He was extremely fond of animals, and for nearly ten years was constantly accompanied by his little dog, both on professional visits and on his long country tramps. Dr. Russell was a great walker, and would never ride to any patients if he could walk; he was also a keen fisherman, and until a few years ago a very regular sea-bather. During the war he was a keen volunteer, and took his place as medical officer to the Colwyn Bay Company. He was one of the initiators of the Colwyn Bay and District Cottage Hospital, and served for many years as honorary physician. His practice included patients of every class, and he was able to inspire in rich and poor alike affection and esteem.

"A. N. L." writes: Dr. Russell was greatly beloved by the poor, and to a class of people who have been recently described as the "new poor" he was most generous in giving his services. While his kind thoughtfulness for others was a predominating feature, his knowledge of the art of medicine and skill in diagnosis were much respected by his colleagues

in the profession. Only his intimates knew what a fine nature was hidden by an armour of reserve. His main characteristic was that he would take the greatest pains to avoid giving others a small amount of trouble. He carried out in actual life what most others are content to talk about. Another side to his character was his determination, and his final illness was faced with a calm serenity which had its reward in a quiet and peaceful end.

Dr. S. L. BUTTERWORTH WILKS writes: The outstanding features of his character were sincerity and generosity. He was a scholar, a gentleman, and a Christian in the best sense of all three. His knowledge and culture were well digested and wide, yet he was diffident and self-depreciatory. His courtesy was charming. His religion was unobtrusive and humble. His generosity was as secret as he could make it, and it was not a mere easy pecuniary generosity—it was a real generosity of soul. He would eagerly push credit on to another rather than take it himself. A sensitive man, he was almost morbidly fearful of hurting the feelings of others; but he could form a severe opinion and express it, on anything that struck him as unfair or unkind. He was diligent to avoid the giving of trouble or any cause of annoyance, and he was unstinting in his devotion to his patients, rich or poor.

THE LATE SIR NORMAN MOORE.

A REQUIEM MASS for Sir Norman Moore was sung on December 9th at St. James's, Spanish Place. In the large congregation were many members of the medical profession, including Sir Humphry Rolleston, President of the Royal College of Physicians, Dr. Raymond Crawford, Dr. H. G. Turney, and Dr. H. Morley Fletcher (Censors), Dr. J. A. Ormerod (Registrar), Dr. Arnold Chaplin (Harveian Librarian), and two former Presidents, Sir William Church and Sir R. Douglas Powell; Sir Anthony Bowlby, President of the Royal College of Surgeons, Sir D'Arcy Power, Vice-President, and Sir Henry Morris and Sir George Makins, former Presidents; Sir William Hale-White, President of the Royal Society of Medicine; Sir Dyce Duckworth, representing the Order of St. John of Jerusalem; Mr. E. J. Layton, representing the Governors of St. Bartholomew's Hospital; Sir Archibald Garrod, Regius Professor of Medicine at Oxford; Mr. H. J. Waring, Vice-Chancellor of the University of London; Sir Dawson Williams, Editor of the *BRITISH MEDICAL JOURNAL*; Sir St. Clair Thomson, Sir Percival Hartley, Sir George D. Thane, Dr. F. J. Waldo, Sir Henry Gauvain; and Mr. Reginald Vick, Warden of the College, and representatives of the resident medical staff and nurses of St. Bartholomew's Hospital.

Dr. EDWIN GEORGE BULL died at Weatheroak House, Spark-hill, Birmingham, on November 29th. He was born in London in 1857 and received his early education at Warmminster, Edgbaston, and George Watson's School, Edinburgh. Proceeding to the University of Edinburgh he graduated M.B., C.M. in 1878 and obtained also the diploma of M.R.C.S. Eng. Though not physically strong he took throughout his life a keen interest in sport of all kinds, and while at the university became a member of the University Company at that time attached to the Black Watch. His university career was followed by a period of post-graduate work at Paris and Vienna, whence he returned to England and ultimately settled in Birmingham as a general practitioner. In addition to his medical practice he found time to devote himself to the public life and interests of the district in which he lived. He was for many years chairman of the Yardley School Board, a position for which he was entirely fitted by his literary, linguistic, and artistic talents, of which the latter alone would have secured as wide a recognition as he obtained in the profession of his choice. Dr. Bull was a member of the Central Division of the Birmingham Branch of the British Medical Association. His health, never very good, had prevented the full development of his powers, and he was of late years entirely confined to his house. He was greatly esteemed alike by his patients and fellow practitioners, whose visits were always welcome even within a fortnight of his death. The interment took place at Witton, near Birmingham, on Saturday, December 2nd.

We regret to record the death, on September 16th, of Dr. ALEXANDER LEWERS, who was one of the best known physicians in Melbourne. Dr. Lewers was born at Creswick, Victoria,

and received his medical education at Charing Cross Hospital, London; he took the diplomas of M.R.C.S.Eng. and L.R.C.P. Lond. in 1890, and on his return to Australia went into practice at Creswick. In 1898 he again visited London for post-graduate study, and worked chiefly under Sir James Galloway at Charing Cross Hospital; he took the D.P.H. in 1899. In 1903 he was appointed physician to out-patients at St. Vincent's Hospital, Melbourne, and at the time of his death was senior physician to the hospital. When a clinical school was established at St. Vincent's Hospital in 1910, he was appointed a lecturer, and soon afterwards became an examiner in clinical medicine at the University of Melbourne. Dr. Lewers was for many years a member of Council of the Victorian Branch of the British Medical Association. He was a voluminous writer on medical and other subjects, and from 1903 to 1914 was editor of the *Australian Medical Journal*, formerly the official organ of the Victorian Branch of the British Medical Association; it ceased to exist on the foundation of the *Medical Journal of Australia*. Among his published works is a volume of essays entitled *Medicine and Meditation*.

Dr. PERCY ROBERTS ASH, whose death took place at Hesses, Yorkshire, after a long illness traceable to his active service in France, was formerly engaged in general practice in Hull, and was at one time visiting surgeon to the Hull and Sculcoates Dispensary. He received his medical education at Leeds, and took the diplomas of M.R.C.S.Eng. and L.R.C.P. Lond. in 1895. Dr. Ash had a distinguished career in the Territorial Army and its predecessors. He first obtained a commission as lieutenant R.A.M.C. (Vol.) in the Brigade Bearer Company of the 1st Volunteer Battalion East Yorks Regiment, and on the organization of the Territorial Force was transferred to the 3rd Northumbrian Field Ambulance R.A.M.C.T., with which unit he served until he was invalided home from France. He commanded that field ambulance in France, with the rank of lieutenant-colonel, and was mentioned in despatches. On the formation of the Territorial Army he was responsible for the organization and recruiting of the 151st (3rd Northumbrian) Field Ambulance. His funeral took place with full military honours at Hesses, the officers who had served under him acting as pall-bearers. He is survived by his widow, with whom much sympathy has been widely expressed.

We regret to record the death of Dr. CHRISTOPHER WESLEY NARBETH, which took place on September 17th, at Grenoble, France, after a delayed operation for appendicitis, at the early age of 24. Dr. Narbeth was educated at Christ's Hospital and St. Bartholomew's Hospital, and took the diplomas of M.R.C.S.Eng. and L.R.C.P. Lond., and the degrees of M.B., B.S. Lond., in 1920. He had held the appointments of house-physician to Sir Percival Hartley, and house-surgeon to the skin and venereal disease department at St. Bartholomew's. During the war he served as surgeon sublieutenant in H.M.S. *Saracen*. While holding his house appointments he took the D.P.H., and had recently been appointed assistant medical officer of health for Surrey. The ability which Dr. Narbeth had already shown, and his pleasant and unassuming manner angured a successful career in public health, and his untimely death on holiday abroad is lamented by all who knew him.

Dr. ALFRED YALE MASSEY, who died on August 22nd at Irebu, Coquilhatville, Belgian Congo, was born at Hastings, Canada, in 1871, and graduated B.A. and M.D., C.M. at Toronto University; at a later period he studied at University College Hospital, London, and took the diploma of L.M.S.S.A. Lond. in 1913. After being engaged in medical work for a short time in Labrador, Dr. Massey went to Angola, South Africa, where he spent three years as a medical missionary, resigning in order to pursue research work in tropical diseases. He spent some years in Katanga, South Africa, and at Tanganyika, and eventually joined the Belgian Congo Medical Service; at the time of his death he was chief medical officer at Coquilhatville. Dr. Massey made valuable investigations in different tropical diseases, especially in sleeping sickness, and was a contributor to the *Transactions of the Royal Society of Tropical Medicine and Hygiene*. He received the honour of Chevalier de l'Ordre Royal du Lion from the King of the Belgians.

Dr. ST. GEORGE GRAY, late of the Colonial Medical Service, died in London on December 2nd, aged 59. He was educated at Trinity College, Dublin, where he graduated M.B. and B.Ch. in 1887, and M.D. in 1910. He served as assistant medical officer of St. Lucia, in the West Indies, where he was in charge of the Yaws Hospital. He was afterwards house-physician of the San Francisco Polyclinic, and subsequently in the West African Medical Staff, where he rose to be a senior medical officer. During the war he served in the Southwark Military Hospital.

Universities and Colleges.

UNIVERSITY OF OXFORD.

Dr. ALEXANDER G. GIBSON has been reappointed University Lecturer in Morbid Anatomy for a period of three years.

Examiners in Medicine.—The following have been appointed Examiners for the B.M. Examinations: In Organic Chemistry, F. D. Chattaway, M.A., F.R.S.; In Human Anatomy, F. G. Parsons, F.R.C.S.; In Histology, J. Priestley, D.M.; In Materia Medica and Pharmacology, J. Dixon, M.D. Lond.; In Pathology, J. S.; In Forensic Medicine and Public Health, B.M., M.A.; In Medicine, A. G. Gibson, D.M., F.R.C.P.; In Surgery, H. S. Souttar, B.M., M.A., M.Ch., F.R.C.S.; In Obstetrics, A. Donald, M.D. Edin.

Francis Gotch Memorial Prize.—The prize for 1922 has been awarded after examination to Murray McCheyne Baird, B.A., New College and Guy's Hospital.

Board of Electors to the Professorship of Pathology.—The Board of the Faculty of Medicine has re-elected to this Board Professor R. Muir (M.D. Edin.) for five years, as from the first day of Michaelmas term, 1922.

Board of the Faculty of Medicine.—The Board has co-opted A. P. Dodds-Parker, B.M., M.A., F.R.C.S., a member of the Board for the statutory period of two years, as from the first day of Michaelmas term, 1922; and Sir F. W. Keeble, M.A., B. Lambert, M.A., E. Hope, M.A., have been nominated to it for the same period by the Board of the Faculty of Natural Science.

Radcliffe Travelling Fellowship, 1923.—An examination for a Fellowship of the annual value of £300, and tenable for two years, will be held during Hilary term, 1923, commencing on Tuesday, February 20th, at 10 a.m. All intending candidates should send their names, addresses, and qualifications, etc., to the Regius Professor of Medicine, University Museum, on or before Wednesday, February 7th. Candidates, who must have passed all the examinations for the degrees of B.A. and B.M. Oxon., can obtain further particulars by applying to the Dean, Department of Medicine, Museum, Oxford.

Degree Days.—The degree days in next term are the following: Thursday, January 25th; Saturday, February 17th; Thursday, March 8th; Saturday, March 24th.

UNIVERSITY OF CAMBRIDGE.

The General Board of Studies will shortly appoint a University Lecturer in Embryology; applications must reach the Registry on or before December 19th. The Raymond Horton-Smith prize has been awarded to A. B. Appleton and H. W. C. Vines, adjudged equal for theses for the degree of Doctor of Medicine. The Board of Archaeology and Anthropological Studies has elected K. P. Chatterji to the Anthony Wilson studentship in ethnology and archaeology. The Gordon Wigan prize in Chemistry has been awarded to R. G. W. Norrish.

The following candidates have passed both parts of the examination for the Diploma in Psychological Medicine and are entitled to receive the diploma: P. C. P. Cloake, G. H. FitzGerald, D. N. Hardcastle, T. D. Power.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

At the annual meeting of the Royal College of Physicians of Edinburgh, held on November 30th, Sir Robert Philip, M.D., was re-elected President. The following were elected as the Council for the ensuing year: Dr. J. W. Ballantyne, Dr. G. Lovell Gulland, C.M.G., Dr. J. C. Dunlop, Dr. G. M. Robertson, Dr. Robert Thin, and Dr. J. Lamond Lackie. The other office-bearers are as follows: *Vice-President*: Dr. G. Lovell Gulland, C.M.G. *Treasurer*: Dr. Norman Walker. *Secretary*: Dr. J. S. Fowler. *Honorary Librarian*: Dr. J. W. Ballantyne. *Curator of the Laboratory*: Dr. J. J. Graham Brown. The Council appointed Dr. W. T. Ritchie as the Gibson Memorial Lecturer for 1923.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

At the monthly business meeting of the President and Fellows, held on December 1st, 1922, the following, having passed the Final Conjoint Examination of the Irish Royal Colleges, were duly admitted Licentiates in Medicine and Midwifery of the College:

Miss Enid Baile, V. V. Brown, C. Cohen, M. Coleman, J. J. Cosgrove, W. J. Crawford, D. Eppel, A. T. Gallagher, H. J. Gillett, A. Goldfoot, T. J. McCarthy, J. J. Mackey, M. J. Mallon, C. G. O'Connell, M. D. O'Connor, P. W. O'Connor, M. Price, I. Richmond, M. A. Walsh.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.

At the monthly meeting of the Faculty, held on December 4th, the following were admitted (after examination) as Fellows: I. J. Block, D. Cameron, J. N. Ghosh, P. Gupta, R. P. Jarrett, D. M. Lindsay, F. C. Logan, A. M. McCutcheon, G. M. Mehta.

Medical News.

THE Registrar of the Dental Board of the United Kingdom desires to remind those persons who are liable to pay the fee for the retention of their names on the *Dentists Register*, and have not yet done so, that, unless the remittance is received on or before December 31st, their names will not appear in the *Dentists Register* for 1923, and that, if they practise after December 31st, they will render themselves liable to prosecution, and, on conviction, to a heavy fine.

THE annual lively dinner of the Society of Apothecaries of London was held in the hall of the Society at Blackfriars on Tuesday, December 12th. The Master, Surgeon General W. B. Slaughter, presided over a large and distinguished company. After the King's health had been honoured the Master proposed the toast of the Navy, Army, and Air Force, and Vice-Admiral Sir Robert Hill, Medical Director, R.N., responded. The toast of the Royal Colleges and the Universities was proposed by the Senior Warden, Dr. Thomas Wakefield, and was replied to by Sir Anthony Bowlby, President of the Royal College of Surgeons of England, and Mr. H. J. Waring, F.R.C.S., Vice-Chancellor of the University of London. In proposing prosperity to the Society of Apothecaries of London, Sir Sydney Russell-Wells, M.D., M.P., gave a brief historical sketch of the various qualifying bodies in England, in the course of which he paid several compliments to his hosts and their predecessors. Dr. F. Gordon Brown, Senior Past Master of the Society, made an appreciative reply. The health of the guests was proposed by Dr. A. D. Bretheloy, Junior Warden, and acknowledged by Mr. James Berry, F.R.C.S., President of the Medical Society of London. Between the speeches a charming programme of music was rendered, and at their close the company adjourned for coffee and conversation.

AT the beginning of the war the German professors were mobilized to justify the German aggression. They now appear to be organizing with the object of appealing to foreign nations as well as to their own countrymen to recognize that, owing to the recent economic catastrophe, the strain on the German people is reaching breaking point. A meeting was to be held on Friday, December 15th, in the hall of the University of Berlin, under the presidency of Professor Ruhner, at which addresses were to be given by Professor W. Hls, on the decline in the standard of life among the German people; by Dr. Dippe, chairman of a German practitioners' union, on the German doctor at the sick bed of the German people; and by Professor Krautwig of Cologne, on the German child in danger.

THE chairman's bell, offered under circumstances already related to the Massachusetts General Hospital by Dr. F. William Cock, who has given a similar bell to University College Hospital, was formally presented at a dinner of the alumni of the hospital on Ether Day by Dr. Washburn, director. The president of the Alumni Association, Dr. H. F. Vickery, expressed the hope that the bell might be rung from year to year at the gatherings of the alumni, and that it might always cause the members to think of the great, friendly country across the seas, the distant mother of most of them, whose ideals for the progress of medicine and world happiness were the same as their own.

A BRONZE statue of the Prince of Wales in his robes as Chancellor of the University of Wales was unveiled on December 7th by Sir John Williams. It is the gift of Mr. T. D. Jenkins of Aberystwyth, and has been placed in front of the University College of Wales, Aberystwyth.

THE inaugural dinner in connexion with the Edinburgh Medical Schools' and Graduates' Club took place at the Grand Hotel, Bournemouth, on December 5th, the President, Dr. Hyla Greves, in the chair. The members of the club reside within a radius of twenty-five miles of Bournemouth. Over fifty members and their friends attended; amongst the latter were the Mayor of Bournemouth, Sir Daniel Morris, and General Sir Harry Brooking. The usual loyal toasts and that of Alma Mater were duly honoured, a very successful musical evening followed, and the first meeting of the club came to an end before midnight, after a very hearty vote of thanks to the chairman for presiding.

THE Friday evening discourse before the Royal Institution on January 26th, 1923, will be given by Sir Almoth Wright on the machinery of antibacterial defence.

THE house and library of the Royal Society of Medicine 1, Wimpole Street, W., will be closed from Saturday, December 23rd, to Wednesday, December 27th, both days inclusive.

WE are informed that the Executive Committee of the National Baby Week Council has recently sent a resolution to the Ministry of Health to the effect "that the matter of vaccination in relation to infant welfare is sufficiently urgent to merit the careful attention of the Ministry of Health, and that the Ministry should take all possible steps to promote more universal vaccination of children."

AS was announced in our issue of December 2nd (p. 1089), the out-patient department of the Maudsley Hospital is now open to receive cases of nervous and mental disorder; patients with neuroses or early and recoverable types of psychosis who are desirous of treatment will be specially suitable. All forms of treatment necessary for both their bodily and mental disorders will be available to them. Medical practitioners having cases of this kind may communicate with the Medical Superintendent, Dr. Edward Mapother, at the Maudsley Hospital, Denmark Hill, S.E.5. Men patients attend on Mondays and Thursdays, and women on Tuesdays and Fridays, at 2 p.m. on each day.

AT the annual meeting of the Royal Surgical Aid Society, held at the Mansion House on December 8th, it was stated that the society was now celebrating its diamond jubilee, and that since its commencement more than 1,110,800 surgical appliances had been supplied. The treasurer announced that the society spent over £30,000 a year in supplying and fitting these appliances.

DR. F. E. FREMANTLE, M.P., has been appointed a member of the Rent Act Committee which is instructed to advise on the future of the Rent Restriction Act.

THE Board of Control has added to the committee which is inquiring into the dietaries in mental hospitals Dr. P. T. Hughes, medical superintendent of the Worcester County Mental Hospital, Barusloy Hall, near Bromsgrove, and Mr. W. J. Gibbs, clerk and steward of the Tooting Bee Mental Hospital.

SINCE 1893 Livingstone College, Leyton, has given medical courses, varying in length from nine months to one, to missionaries going abroad; it has as its object to train in medicine and surgery and tropical hygiene the missionaries of the churches before they go to the foreign field. It clearly disclaims any suggestion that the persons so trained go out as "medical missionaries"; of the 698 students who have passed through its courses many have testified to the advantage such training has given them, situated as many of them came to be in outlying spots where anything approaching medical advice, treatment, or care (as these things are understood with us) is lacking. If any further credential is needed it is furnished by the fact that the late Sir Patrick Manson was a friend to the college and a lecturer within it, and by the names well known in the medical profession which appear in the list of the teachers.

A COMMUNICATION from the Secrétariat du docteur Nansen pour le secours à la Russie, dated Geneva, November, 1922, states that Dr. Haigh, a member of the Epidemics Commission of the League of Nations, who visited the provinces of Nikolaïeff, Kherson, and Odessa in September, describes the serious situation of the medical and health institutions in a report addressed to Dr. Nansen. The hospitals lack everything for their good working. Drugs, linen, soap, and disinfectants are all wanting; even clinical thermometers are very scarce. Dr. Haigh fears that the lack of preventive equipment will result in a grave extension of the epidemics of typhoid, typhus, and relapsing fever during the coming winter. The medical staff, badly equipped, and even suffering from hunger, is making a desperate struggle with the situation.

ARTICLE 15 of the Dangerous Drugs Regulations authorizes the master of a ship not carrying a duly qualified medical practitioner to obtain supplies of the drugs required by the Merchant Shipping Acts. This provision does not apply to foreign ships. It is now suggested that port medical officers of health should be authorized by the Secretary of State to grant certificates for the supply to foreign ships of a quantity of the drugs sufficient for the period of the voyage to the home port. The Minister of Health has addressed to port sanitary authorities a circular (357 of December 1st, 1922) inquiring whether they would be willing to allow their medical officers to give the necessary certificates.

A COURSE on "orthopaedics indispensable to all practitioners" will be given by Dr. Calot at 59, Quai d'Orsay, Paris, from January 22nd to 28th, 1923. The demonstrations, which will be accompanied by English explanations, will begin at 2 and terminate at 7 p.m. each day.

THE University of Paris has recently conferred honorary degrees on Professor Bordet of Brussels and Professor Ehlers of Copenhagen.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

ANYONE desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Atiology, Westrand, London*; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate, Westrand, London*; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Mediscera, Westrand, London*; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

QUERIES AND ANSWERS.

MORSLEY'S WAX.

"C." asks (1) whether Morsley's wax is used hot for engrafting purposes, (2) how it is sterilized before use, and (3) what means are used for keeping it soft in the operation room.

*. We are indebted to Mr. Percy Sargeant for the following replies to these questions: (1) It is used warm, at such a temperature that its consistence is just sufficiently soft for easy manipulation. (2) It is heated in a suitable vessel at the temperature of boiling water for five minutes, and then poured into saline or weak mercuric perchloride solution at 105° F., from which (3) it is used as required during the operation.

INCOME TAX.

"T. M. H." had "dry rot" in his premises—used solely for professional purposes—and had to expend £180 on repairs. The inspector of taxes has allowed a deduction of one-half only.

*. Our correspondent does not quote the Inspector's ground of objection to the full allowance. The only objection to allowance of the whole which occurs to us as having some validity is that if there was "dry rot" in the premises when "T. M. H." acquired them a portion of the total cost may have to be regarded as part of the capital expenditure necessary to obtain the premises in a proper condition for use. *Prima facie* the whole amount would seem to be allowable.

"H." bought a car in 1915 for £200 and sold it in 1922 for £130, buying a high powered car for £495; a car of the same make and power would then have cost £350.

*. The amount of allowable renewal cost is £350 - £130 = £220; we assume that the original car was not purchased at second hand.

LETTERS, NOTES, ETC.

PREVENTION OF PUERPERAL INFECTION.

DR. EDGAR R. IVATTS writes: I think the fact that the death rate from puerperal fever is "higher" in the county of Lancashire than other English counties admits of a fairly simple explanation. It is due to the uncleanly habits, more particularly in the rural districts. The folded counterpane or old sacking placed under the woman's hips, which only partly protects the bed, is as often as not under the sheet and not infrequently is placed between the bed and the mattress, so that the woman is left lying in a circle of soaked soiled bedding until it dries underneath her. In some houses old clothes and dirty rags are thought quite good enough to absorb the after-secretions, and often these are not very frequently changed. Further, it is, or used to be, a very prevalent notion that a woman should not have any of her personal clothing changed until a day or two after parturition or else she will "catch her death cold"; cold, it is supposed, being the cause of most of the mishaps occurring after child-birth. I have myself more than once changed a woman's soiled clothes on visiting her again, as I knew it would not be done otherwise. I am not a pathologist but would imagine that soiled bedding, soiled night-shirt, and possibly dirty clothes on vulva, plus warmth and moisture under the bedclothes, would encourage the growth of pathogenic organisms in a comparatively short time. The apparent transmission of the complaint from one to another is probably due to the same causes operating among people of the same habits. The comparative absence of puerperal sepsis in lying-in hospitals I should attribute to the wholesome surroundings and the scrupulous cleanliness observed in such places.

LEFT-HANDEDNESS AND STAMMERING.

THE inquiry by Dr. C. L. Lapper (November 18th, p. 1004) has led Dr. J. A. FRETTON (Chacewater, Cornwall) to send the following note: A girl aged about 6 years was left-handed from birth; her mother had been taught by her mother that if a child who was left-handed from birth and had been taught to write with the left hand was changed over and taught to write with the right hand that child would stammer. She had sent her own little girl to school and the child then wrote with the left hand. She gave instructions at the school that no attempt was to be made to get the child to write with her right hand. The teacher thinking, however, that she knew better, insisted on changing the bad habit, and during the mother's absence from home actually taught the child, successfully, to write with her right hand. The child soon developed a distinct stammer in speech. On the mother's return she at once had the child put back to the old habit to use the left hand when writing, and the stammering soon after disappeared. When seen by me the child at the mother's request wrote her name first with the left hand and then with the right. The stammering is now gone.

DR. W. INMAN (Petersmouth) has also sent some notes, founded on an investigation in connexion with the relation of left-handedness to squint and stammering in many hundreds of left-handed persons. He considers that compulsion should not be used, having observed that, among other nervous symptoms, many left-handed children, he says, "is a rebel." The study of his characteristics lies in determining whether he is a rebel because he resents interference with his inborn aptitude and right to use his left hand, or whether his left-handedness is intended to be a clear sign to the parent that something has gone wrong with the child. The evidence is in favour of the latter view. It has been proved that a member of society as the right-hander. Even then the proper course to pursue will be to find and deal with the cause of the habit. . . . If Dr. Lapper cares to refer to my letter on alpecia and squint in the JOURNAL of November 4th (p. 893), he will see that there are other associations of interest in connexion with left-handed activities."

UNSUSPECTED PREGNANCY.

DR. R. BROOM (Douglas, South Africa) sends us the following note to add to the cases published recently in our columns: About twenty years ago I was called to see a lady who had just given birth to a child. It was her second child, and I had attended her first confinement. She lived about one hundred yards from my own house, and I must have seen her at least every month, though not professionally, as she was exceptionally healthy. She was a large, fat Jewess, and she explained to me that she had never once suspected that she was pregnant. Menstruation had occurred every month, and on this occasion, having a little more pain than usual, she lay down and her husband gave her two glasses of brandy. I have not the baby was least doubtful. Her husband was a well-to-do man and nothing. Yet she had not a stit. the arrival.

TINNED FOOD.

A CORRESPONDENT in Kashmir, after stating that in the bazaars there tins are sold which have changed hands many times, and must be from eight to ten years old if tins were stamped and labelled, or some protection would be afforded. The jury at the inquest on the Loch Maree victims added a rider to their verdict to the effect that every vessel containing preserved meat, fish, fruit, or vegetables intended for human consumption should bear a distinctive mark by which, if necessary, details of manufacture might be traced.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 27, 30, 31, 32, 33, and 34 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 28 and 29. A short summary of vacant posts notified in this advertisement column appears in the Supplement at page 220.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£ s. d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by reference. It is against the rules of the Post Office to receive post-restant letters addressed either in intitle or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

355. Sensitiveness to Non-bacterial Toxins and Proteins.

A. WHITFIELD (*Brit. Journ. Dermatol. and Syph.*, November, 1922, p. 331). In discussing the question of sensitiveness to non-bacterial toxins and proteins, considers that sensitiveness to external irritants should not be confused with the anaphylaxis of protein sensitization, because, while in the former first contact usually causes some reaction, and further contacts cause reactions varying in inverse proportion to the interval between them, and the sensitiveness is exalted rather than destroyed thereby, in the latter no disturbance results from first contact, and reactions follow further contacts only after a considerable interval, and the sensitiveness is destroyed by the reaction. That some patients react to the extravasation of blood into their tissues with the production of an erythematous eruption was shown by four cases in which erythematous-urticarial eruptions occurred on the tenth day after severe traumatic ecchymoses unaccompanied by any breach of surface, recovery taking place in a few days. Auto-sensitization of the patient's skin to the serum of his own blisters was shown in a case of acute bullous eczema in which the trickling of serum from the bullae produced, in rapid succession, an erythematous streak, or wheal, and finally a row of vesicles. No such effects occur in *Rhus toxicodendron* poisoning, thus supporting the contention that there is a difference in kind between plant sensitiveness and serum sensitiveness (anaphylaxis). Attention is called to the phenomenon observed in some cases associated with muscular rheumatism where a patchy eczematous eruption frequently occurs on the outer sides of the limbs, notably above the external malleolus and over the great trochanter and subcutaneous border of the ulna. If these patches are rubbed briskly erection of the hair follicles, followed by redness and swelling of the part owing to serous effusion, takes place, and shortly after the subsidence of this urticarial reaction itching may be complained of in various asymmetrical regions widely separated from the original site. While this may be due to absorption of bacteria or to a reflex nervous irritation, its possible etiology from absorption of exuded lymph producing a toxic urticaria is suggested. Two other cases are recorded—one in which an insect bite on the leg was followed fourteen days later by the development of a herpetiform group of vesicles at the site, and an acute vesicular eczema all over the face. The other case was one of severe hay fever, accompanied in each attack by marked pityriasis of the scalp and falling out of the hair; this patient was also a chronic dyspeptic in whom strawberries always produced indigestion and all the symptoms of hay fever.

456. Paroxysmal Tachycardia due to Digitalis and Strophanthus.

D. DANIELOPOLU (*Arch. des Mal. du Cœur, des Vaisseaux et du Sang*, August, 1922, p. 537) observes that the very complex action of digitalis and drugs belonging to the same group on the normal myocardium becomes still more difficult of comprehension in myocardial failure. While in one direction these drugs diminish automatism and conductivity, in another they increase excitability and contractility. Thus in some cases of cardiac failure digitalis relieves, while in others it aggravates, the condition. The author refers to recent researches by Cushing and others which show that in an advanced stage of digitalis poisoning the ventricle may begin to contract automatically, with an acceleration of auricular pulsations. Other observers have found that strophanthin produces an intense stimulation of the normal and heterotrophic centres, characterized by tachycardia and extra-systolic arrhythmia, leading to ventricular fibrillation. Numerous clinical observations are cited, which show that digitalis and strophanthin may produce (in addition to "coupled rhythm") paroxysmal tachycardia. Details are given of two cases, women aged 30 and 25 years respectively, both having enormously dilated hearts following polyarticular rheumatism. In the first case large and repeated doses of digitalin (Nativelle) failed to relieve the condition. In the second case the same drug improved the myocardial action and promoted diuresis, followed, however, by vomiting; all drugs were stopped, and after forty-eight hours the rhythm became normal at 120; but a slight recurrence of

acute polyarticular rheumatism was followed by "coupled rhythm" and paroxysmal tachycardia lasting three days. A third (fatal) case was that of a man, aged 88, suffering from chronic nephritis with much hypertrophy of the left side of the heart and dilatation of the right; transient improvement followed two intravenous injections of 0.25 mg. strophanthin daily for three days, followed by daily injections of the same amount. The dilatation then increased and digitalin was given, but the heart continued to enlarge and the pulse rose to 112; digitalin, strophanthin, and quinine were given alternately or in combination, and transient improvement occurred at intervals but was not maintained, and the patient died in six days. Danileopolu concludes: (1) The chief phenomenon of myocardial failure is diminution of contractility accompanied by increase of excitability. In chronic dilatation where the myocardium is still capable of responding to cardiac tonics these substances act typically—they increase contractility, restore coronary nutrition, which itself lessens excitability. (2) In unrelieved dilatation, where contractility is seriously lessened, digitalis has no effect, as in the "oserinized" heart (Frölich and Pick) it lessens contractility. The vagus is often hyperexcitable in asystolic cases. If the myocardial excitability is not very great (this is rare) the vagotropic action of digitalis slows the pulse rate (direct negative chronotropic action of digitalis). This is P. Mordlen's dissociated action, where the aggravation of myocardial failure is not due solely to lengthening of diastole but above all to its negative inotropic action. Then, almost always, myocardial hyperexcitability is greatly increased. Negative chronotropic action does not follow, for it cannot overcome the greatly increased myocardial hyperexcitability. By its negative inotropic action digitalis lessens contractility, while, either directly or indirectly, it increases excitability, producing either normotropic or heterotropic tachycardia or pulsus bigeminus. This is the "inverse action" of digitalis, the commonest of its typical effects. (3) Dissociated or inverse effects are rarer with strophanthus than with digitalis; when they appear after administration of strophanthus in the ultimate phases of cardiac failure we may consider the patient doomed.

457. Infections of the Gastro-Intestinal Tract.

G. R. SATERLEE, J. W. DRAPER, and H. A. COTTON (*Amer. Journ. Med. Sci.*, September, 1922, p. 313) discuss respectively the medical, surgical, and neurological aspects of infection of the gastro-intestinal tract. The medical treatment (G. R. SATERLEE) of chronic intestinal toxæmia consists of diet, massage, hydrotherapy, and vaccines or serum, and the removal of all obvious foci in the mouth, rectum, or elsewhere is essential to prevent the resulting toxæmia becoming generalized and causing a lowering of resistance. From the experience of over 500 cases treated by autogenous colon vaccines, it appears that the colon bacillus is the primary cause of the lowered resistance, and that the streptococcal and other bacterial infections are secondary. The chief foci of infection are found in the tonsils, teeth, in abscesses and necrosis of the jaw, and in the nasal sinuses, rectum, seminal vesicles, and cervix uteri, and thorough investigation, followed by efficient treatment, is essential to success. From the surgical point of view (J. W. DRAPER, with pathological report by J. EWING) colon pathology in its relation to the etiology of systemic disorders requires further investigation, since there is not enough evidence as yet available to prove that any particular group of mental symptoms can with certainty be attributed thereto, and the extirpation of considerable portions of the ileum is unwarranted if based solely upon anatomical conditions. In all functional psychoses extensive colon pathology exists in 20 per cent. of the cases, and mental symptoms have been arrested or improved by operation in a large percentage, though colectomy is contraindicated until the patient has had all other foci removed and has been treated with vaccines and serums. The mortality from the operation was found to be 12 per cent. in 77 consecutive cases. From the neurological standpoint (H. A. COTTON) the special relation of the clinical symptoms of functional psychoses to regional distribution of focal infection is emphasized, the source and type of chronic infection in the psychotic patient being the same as that found in many of the systemic disorders. Infection of the teeth is the most constant focus, and the removal of all infected teeth and tonsils is imperative before treatment with autogenous vaccines and serums is commenced. The type, specificity, and severity of the infection, together with

any constitutional lack of resistance, are the factors determining whether or not a psychosis will develop, hereditarily and psychogenously rather precipitating than actually causing its occurrence.

458. Flix Mas Jaundice.

O. HANSEN (*Medicinsk Revue*, July-August, 1922, p. 304) considers that the use of flix mas as an anthelmintic is so dangerous that it ought not to be sold without a prescription. In doses of 20 grams it not infrequently causes toxic jaundice, and even in doses of 10 grams the author has found it to give rise to bilirubinaemia. Indeed, only in one out of twenty cases treated with the extract of male fern could bilirubinaemia not be demonstrated. Occasionally jaundice of the sclerae and skin was also observed, but the faeces were never discoloured. This jaundice has been regarded as haemolytic, but the author has never been able to find signs of blood destruction; the percentage of haemoglobin and the number of red cells is increased rather than diminished after the exhibition of male fern, the increase being due to the concentration of the blood caused by diarrhoea. Though no permanent ill effects were observed, larger doses are apt to cause acute yellow atrophy of the liver, as shown by Sternberg and Grawitz, and even in the slight cases of bilirubinaemia it is probable that the extract of the male fern has injured the paracymbia of the liver. The difference between the condition underlying this slight bilirubinaemia and acute yellow atrophy of the liver is only a matter of degree.

459. Significance of Chronic Jaundice.

S. LAACHE (*Norsk Mag. f. Lægevidenskaben*, October, 1922, p. 745) has made a study of chronic non-haemolytic jaundice in 16 men and 15 women between the ages of 19 and 76. Most of them were middle-aged or elderly; 19 came to necropsy and 3 others to biopsy (operation). In as many as 14 of these 22 cases cancer was diagnosed. The importance of gall stones as a cause of chronic jaundice proved to be comparatively slight, and they were found only in 7 cases, in 3 of which they were associated with malignant disease. As in these 3 cases the gall stones may have developed as the result of the cancer, the importance of cancer as compared with gall stones in the genesis of chronic jaundice is seen to be very great. Cirrhosis of the liver was found in two cases, the disease probably being syphilitic in one of these cases. A remarkable feature of the other case of cirrhosis was the definite improvement that followed the exploratory laparotomy at which the diagnosis was made; this improvement was, however, not maintained. This material shows how essential it is to arrive at an exact diagnosis before treatment is attempted.

460. Sedatives and Hypnotics in Diseases of Children.

E. ROMINGER (*Klinische Wochenschrift*, September 23rd, 1922, p. 1949) discusses the importance of sedatives and hypnotics in the treatment of certain diseases of children. Drugs should be avoided which are liable to produce cumulative effects, and also those liable to act injuriously on the respiratory and circulatory centres in the medulla. Many hypnotics suitable for adults are unsuitable for children. Chloral hydrate is a powerful hypnotic. It may be given by the rectum, but risk of toxic action must be kept in mind; it is especially dangerous in marasmic and badly nourished children. Paraldehyde and amylen hydrate are uncertain and not free from risk, and may produce, in older children, symptoms resembling alcoholic intoxication. Urethan is uncertain in its action and liable to cause toxic symptoms; but bedonal is a very useful drug, and almost free from bad effects (dose in infants 0.5 to 1 gram in 20 to 40 c.cm. of mucilage by rectum). Sulphonal and trional are unsuitable owing to cumulative action. Veronal and medual have also a cumulative action, and sometimes produce toxic and cutaneous symptoms. Luminal is a motor sedative, used with good results in epilepsy in adults, but cumulative action and injurious influence on the respiratory centre are objections. Sodium luminal is the most satisfactory preparation; it is useful in the convulsions of infants and in epilepsy, but as a hypnotic is uncertain. As a general rule morphine should not be given to children. Opium and pantopon are less dangerous when relief of pain is desirable. Great caution as to the dose is necessary. It is estimated that three-quarters of the cases of poisoning by morphine and opium occur in children under 5 years of age. Certain antipyretics have a sedative action on the nervous symptoms and act as hypnotics—antipyrin, pyramidon, phenacetin, and lactophenin. Caution is necessary in deciding the dose of antipyrin and phenacetin, but with pyramidon and lactophenin the risk is less. Bromural and adalin are useful as sedatives in cases of disturbance of sleep through motor unrest. Adalin is the more powerful. Bromides and valerian tea may lead to sleep by diminishing motor unrest.

SURGERY.

461. Palliative Trephining for Pressure on the Brain.

ANSCHÜTZ (*Dent. med. Woch.*, October 20th, 1922, p. 1405) reviews the results achieved in the 50 cases in which he trephined for the relief of pressure symptoms. He admits that the diagnosis of cerebral tumour is far from easy, and in one of his cases, in which cerebellar trephining was performed for the relief of pressure (cerebro-spinal fluid under a pressure of 700 mm.) and for severe congestion papillitis, the necropsy failed to show any pathological change in the brain. The author classifies his material according to the height of the pressure of the cerebro-spinal fluid: in 7 cases it was up to 300 mm., and at the other extreme there were 7 cases in which it was over 600 mm. The latter class represented hopeless cases. Among the remaining 43 cases there were 6 deaths, one from meningitis. In addition to these 6 operative fatalities and 6 cases which could not be traced, there were 10 cases in which the operation gave relief, but death occurred within a year. The author concludes that, though palliative trephining is almost invariably useless when high pressure and coma have lasted some time, it may be strikingly successful in averting blindness and prolonging life when the symptoms are due to slowly growing malignant disease. The results are still better when new growths are of a stationary character, and the author records the case of a man suffering from a glioma the size of a plum in the optic thalamus and a malignant adenoma of the pituitary body. Palliative trephining not only reduced the intracerebral pressure, but restored his eyesight and general working capacity, and it was not till nearly eleven years after the operation that he died from influenza pneumonia, and the diagnosis of tumour of the brain was confirmed. The author's technique is practically identical with that followed by Cushing for subtemporal trephining.

462. Traumatic Hydronephrosis.

A. STRÄUL (*Schweiz. med. Woch.*, October 12th and 19th, 1922, pp. 937 and 1033) records in detail the case of a man, aged 25, whose hydronephrosis was traced to a fall on his back. The author's discussion of the accident insurance aspect of such cases shows how difficult it is to trace the genesis of a hydronephrosis to an accident, and though about 50 cases of traumatic hydronephrosis have been recorded, all do not bear close scrutiny. In distinguishing between traumatic and non-traumatic hydronephrosis the three following points should be considered: (1) absence or presence of renal symptoms before the accident; (2) absence or presence of other causes of hydronephrosis, such as congenital anomalies of the urinary system, disease of the uterine appendages, chronic perityphlitis and peritonitis, tumours of the abdomen and bladder, and gonorrhoeal stricture of the urethra; (3) proof that the accident directly affected the kidney or led to changes which could be regarded as responsible for obstruction to the flow of urine.

463. Essential Haematuria.

ACCORDING TO G. P. VAN NES (*Nederl. Tijdschr. v. Geneesk.*, August 26th, 1922, p. 919), in addition to the ordinary causes of renal haemorrhage (such as tuberculosis, stone or tumour, and acute nephritis), general or local renal congestion (so-called renal varix) may be responsible for haematuria. Chronic nephritis or acute glomerulo-nephritis may be the cause of the bleeding. Haemorrhage from the kidney without cause of the bleeding. Essential haematuria, if it any anatomical lesion, or so-called essential haematuria, occurs at all, is very rare. The diagnosis of haemorrhage from a healthy kidney can even be made clinically, but is only possible after careful naked-eye and microscopical examination of the kidney in question. Unilateral haemorrhagic nephritis has been repeatedly observed, although the absolute proof, consisting of comparative examination of both kidneys, is still wanting. Nephrectomy in these cases is only indicated in the event of dangerous haemorrhage. Nephrotomy or removal of portion of the kidney for examination is, according to the literature, a good operation, since it is only by this means that other causes can be excluded, and the operation may have a favourable effect upon the haemorrhage.

Hypernephroma.

JEAN DE SMETH (*Le Scalpel*, October 7th, 1922, p. 957) points out that there are two varieties of epithelial tumour corresponding in structure to the suprarenal: (1) the benign hypernephroma or adenoma, which does not differ from other adenomata, often very small and under the capsule; (2) the malignant hypernephroma, the type more usually met with, a nodular tumour of yellowish or red colour, perhaps soft, or it may be hard in places; this often lies in the upper pole of the kidney or surrounds the organ. These tumours, sometimes called after Grawitz, are found in young subjects

and in either sex, frequently at the upper pole of the kidney. Israel finds that a rise of temperature is present more often with this than with other renal growths. The predominant symptoms are swelling, haematuria, and pain; a diagnosis, however, may be impossible without a microscopic examination or perhaps before metastases are found. Analysis of the urine in the absence of haematuria gives no indication. The weakness of the patient, sometimes cachexia, may give evidence of a malignant tumour. Bimanual palpation shows the size of the growth, or perhaps radiography will give a picture of the tumour without the necessity of pneumoperitoneum. The author, after describing four cases, draws attention to the frequency of hyponephroma and the means of approach for renal tumours. He advises the incision of Grégoire, which allows good exposure of the kidney and ureter, and enables the glands to be removed along with the kidney.

465. X-Ray Treatment of Cancer of the Breast.

S. NORDENTORF (*Ugeskrift for Læger*, October 5th, 1922, p. 1300) publishes the results of x-ray treatment of 42 cases of cancer of the breast under his care in the period 1915-19. Of operable cases not operated on or treated by such a limited operation as excision of the tumour without amputation of the breast, there were 8 cases, 7 of which were still alive at least three years after treatment. Of 11 inoperable cases treated by the x-rays alone all were dead. Of the 23 cases of recurrence following operative treatment all but two were dead. The author admits that these figures are discouraging, but by themselves they are misleading. It must be remembered that the number of cases of cancer of the breast which five years ago were given x-ray treatment which can be regarded as adequate according to modern standards is exceedingly small. It is obviously unfair to judge of the present efficacy of x-ray treatment by the results obtained with the methods employed several years ago. The present statistics would therefore hardly be worth publishing were it not for the encouraging results obtained among the operable cases. The author deprecates the tendency to dilettantism exhibited by practitioners who imagine that to provide themselves with an x-ray outfit is the most essential move towards becoming an x-ray specialist. To stress this point the author refers to a series of x-ray disasters and to cases in which the x-ray dosage was absurdly small, and he looks forward to the time when x-ray treatment may be forbidden everyone but the fully qualified radiologist. Till then the dilettante radiologist will not only directly injure his patients, but will degrade the good name of a procedure possessed of great and growing possibilities.

466. Naso-pharyngeal Lesions in Children Predisposed to Tubercle.

CROPPA (*Rif. Med.*, September 4th, 1922, p. 844) has compared the results of examining 100 children detained on account of a predisposition to tuberculosis and a series of normal children. The figures show a marked preponderance of naso-pharyngeal trouble in the former children. Pharyngeal catarrh was present in 68 per cent. of the children with tuberculous predisposition as against 36 per cent. in other children, enlarged tonsils in 54 per cent. against 20 per cent., adenoids 51 per cent. against 18 per cent., incipient middle-ear trouble 62 per cent. against 38 per cent. The membrana tympani was apparently normal in 25 per cent. of the first group as against 54 per cent. in the second, the nasal passages in 23 per cent. against 80 per cent., and the throat in 9 per cent. against 48 per cent. Since tuberculosis may be encouraged by an unhealthy condition of the nasopharynx it is important that any defects observed, especially in children who may be suspected of a tuberculous predisposition, should be treated.

467. Treatment of Tendo-vaginitis with Carrel's Method.

G. VIDFELT (*Acta Chirurgica Scandinavica*, October 11th, 1922, p. 242) has systematically used Carrel's irrigation method for the treatment of acute septic tendo-vaginitis at the Sabbatsberg Hospital in Sweden, and his report deals with 43 cases of acute tendo-vaginitis, 13 of which were complicated by carpal bursitis. Immediately after free opening of the tendon sheath and the insertion of rubber tubes, hourly irrigation with Dakin's solution was instituted and kept up day and night. To relieve the pain 1 gram of acetyl-salicylic acid was given from three to five times a day. The drug seemed to have a favourable effect on the septic process as well as relieving the pain caused by the irrigations. In 31 cases the tendons were entirely preserved, and in 12 there was partial or complete necrosis of the tendons. With regard to the wisdom of preserving the ligamentum carpi volare, the author has come to the conclusion that its preservation involves definite risks of injury from pressure on the neighbouring structures. In one case, in which he

deferred division of this ligament, gangrene of the median nerve occurred. Free division of this ligament does not, as might be expected, entail prolapse of the tendons in the volar channel or necrosis of the motor nerve supply of the muscles of the thumb.

OBSTETRICS AND GYNAECOLOGY.

468.

Glycosuria in Pregnancy.

ACCORDING to A. W. BAUER (*Zentralbl. f. Gynäk.*, September 2nd, 1922, p. 1413), pregnancy produces no alteration in the blood sugar content of about 0.08 per cent. This percentage is increased after ingestion of carbohydrates, but the amount and duration of the increase are similar whether the genital organs are normal or diseased, and whether the uterus is or is not gravid. In both the pregnant and non-pregnant states the blood sugar is similarly augmented after subcutaneous injection of 0.5 to 1 c.cm. of adrenaline. The frequency of spontaneous glycosuria in pregnancy—given by Reichenstein as 11 per cent.—was found by the writer to be less than 1 per cent. Conflicting reports have been given of the significance of glycosuria after carbohydrate ingestion as a diagnostic indication of early pregnancy; Frank and Nothmann found it in 100 and other observers in 50 per cent. of cases. Guggisberg found adrenaline glycosuria in 85 per cent. of pregnant subjects. The hyperglycaemia and glycosuria appear to take independent rather than parallel courses. In the clinical use of these tests Bauer believes that it is essential that the patient should be in bed, and fasting. In all of 170 women who were in the first three months of pregnancy he found after oral administration of 100 grams of grape sugar the glycosuria occurred without conspicuous increase in the blood sugar; the findings were similar in two-thirds of those pregnant after the third month. For the test to be reliable, blood sugar estimation is necessary in addition to examination of the urine, for in a good proportion of healthy non-pregnant subjects, and also of patients with deranged thyroid function, latent diabetes, or neurasthenia, glycosuria follows the taking of 10 grams of sugar, but is accompanied by well-marked increase of the blood sugar content. Probably the excessive renal permeability to sugar during pregnancy is due to diminished ovarian function at that time. On these lines can be explained the finding that glycosuria, unaccompanied by notable hyperglycaemia, follows carbohydrate ingestion not only during pregnancy but also in the presence of adnexal tumours and inflammations. It is of practical importance that a negative test points much more strongly to the absence of early gestation than does a positive test to the presence of pregnancy. The test is positive in extrauterine pregnancy, but for the reasons given above is of no use in differential diagnosis from adnexal disease.

469. G. PUSINICH (*Rivista d'Ostetricia e Ginecologia Pratica*, August, 1922, p. 444) found that 26 women in the first five months of pregnancy exhibited glycosuria 20 to 180 minutes after intramuscular injection of 2.5 mg. of phloridzin. The test was positive in 50 per cent. of cases during the last four months of pregnancy, in 15 per cent. of puerperal subjects, and in 10 per cent. of women apart from pregnancy. No figures are given regarding the findings in those suffering from adnexal abnormalities, but it is concluded that the absence of phloridzin glycosuria, elicited as is explained, may be taken as excluding the possibility of a gestation in the earlier months.

470.

Syphilis during Pregnancy.

H. BOAS and S. A. GAMMELTOFT (*Acta Gynecologica Scandinavica*, 1922, vol. 1, fasc. 3, p. 309) publish their conclusions concerning the incidence, treatment, and prognosis of syphilis during pregnancy, as derived from ten years' experience at the Rigshospital in Copenhagen, where the percentage of syphilis has been found to have increased from 3.7 per cent. in 1912 to 7.7 per cent. in 1921, among 1,300 to 1,900 patients annually admitted, from the fifth or sixth month of pregnancy onwards. The authors' main deduction is that it is of paramount importance, if a living and healthy child is to be born, that apart from the history with regard to previous anti-syphilitic medication, and apart from the result of the Wassermann test, treatment of the mother by salvarsan or one of its derivatives should be instituted during pregnancy. The figures published are of more than usual significance, in that almost 70 per cent. of the mothers and children have been traced during a period of at least six months (frequently much longer) after birth. Of 158 syphilitic mothers who had never received treatment, one only gave birth to a healthy child; of the remaining 157, 70 only gave birth to living children. Of these 70 children, 28 appeared healthy at birth, but gave a positive Wassermann reaction; and 26 others,

although at birth apparently healthy, with negative Wassermann reaction, showed signs of syphilis during the first four months of life. The larger proportions of apparently healthy children of syphilitic mothers which are given in other reports are ascribed to inferior opportunities of "following up." In mothers who had not received treatment during pregnancy, but had previously been given mercury or salvarsan, only 12 per cent. gave birth to healthy infants; but 31 out of 111 mothers receiving mercurial treatment, and 60 out of 79 receiving salvarsan treatment—given in each case during pregnancy—had healthy children. Roughly, one-third of these patients suffered at the commencement of treatment from secondary syphilis and two-thirds from latent syphilis. The conclusion is drawn that in the absence of signs of impairment or inadequacy of renal function every syphilitic pregnant subject should receive treatment, during pregnancy, by salvarsan or a derivative of that drug, combined—if the diagnosis is made sufficiently early during pregnancy—with courses of injections of mercury. In not a few instances a patient who had received adequate combined treatment gave birth after subsequent pregnancy to a syphilitic infant; but after a still later pregnancy, during which salvarsan had been administered, a healthy child was born. That the Wassermann test in the maternal blood may be negative does not alter the fact that in the absence of antisyphilitic treatment the infection probably terminate in the issue of a healthy child. The percentage of syphilitic infants is large whether the maternal infection be of recent date or of ten to twenty years' standing. The Wassermann test in the maternal blood at the time of labour is of prognostic significance if antisyphilitic treatment has not just been continued; 7 healthy children were born to 267 mothers giving a positive reaction at term, but 80 to 104 giving a negative reaction.

471. Pregnancy after X-Radiation of the Ovaries.

G. LINZENMEIER (*Zentralbl. f. Gynäk.*, September 30th, 1922, p. 1560) has traced in the literature eight cases, and adds notes of two personal cases, in which after application of small doses of x-rays to the ovaries, for therapeutic purposes, pregnancy has followed. In none of these cases did the child show malformation or nutritional disturbance, although injuries of the foetus appear to have followed similar treatment given during the early months of an unrecognized gestation, and in animal experiments malformations have resulted from radiation of early ova. The two cases recorded by Linzenmeier are regarded as suggesting that in certain cases x-ray treatment in small doses may be of benefit in sterility. The first patient, who had a uterine myoma, bore a living and healthy infant twelve months after radiation for menorrhagia and dysmenorrhoea; the second, who was treated for severe menorrhagia and metrorrhagia, conceived nine months later, and shortly after birth at term of a normal child again became pregnant. The menstrual disorders in both cases were ascribed to abnormally increased ovarian activity, probably in the follicles; it is only in those cases of sterility which may have a similar causation that benefit is to be expected from x-ray therapy.

PATHOLOGY.

472. The Catalytic Activity of the Tissues.

J. THOMAS (*Les Néoplasmes*, September-October, 1922, p. 145) defines catalytic ferments or "catalases" as ferments possessing the property of decomposing oxygenated water. All the tissues and fluids of the body possess similar properties in varying degree. Certain authors have thought that they could observe differences between the catalytic activity of the tissues and fluids among normal subjects and those suffering from cancer. Thomas has therefore studied the physiological and pathological variations in non-cancerous and cancerous patients. He quotes Winternitz and Meloy's statement that age does not appear to have any influence on the catalytic activity of human tissues and reviews the observations of numerous authors who have tested the catalytic activity of human and animal tissues and secretions. It has been found that renal tissue has a greater catalytic power than that of the lung, liver, or spleen, or of the blood. Thomas's investigations lead him to the following conclusion: The tissue and blood content of catalytic ferments varies normally, not only in one animal species compared with another and among individuals of the same species, but even in the same subject according to physiological conditions (sleep or wakefulness, rest or fatigue, hunger or digestion). Probably there is a physiological catalytic activity analogous to physiological leucocytosis. Experimentally, destruction of certain organs (liver or kidney parenchyma) appears to

have no influence on the catalytic content. A patient suffering from neoplasm of either of these organs may have normal catalytic power. Conversely, destruction of the thyroid, testis, or ovary produces diminution of that power.

473. Comparative Value of Sachs-Georgi and Wassermann Reactions in the Diagnosis of Syphilis.

R. A. KILDUFFE (*Amer. Journ. Med. Sci.*, October, 1922, p. 523) refers to his former communication on results of these tests in 295 serums, when he stated that "a diagnosis of syphilis or conclusions as to treatment cannot be based upon the results of a Sachs-Georgi test with safety, and the reaction is not suitable for general use for this purpose." Since that date (April, 1921) a number of reports have appeared in foreign and American literature. The former are uniformly favourable, while the latter in the main confirm the usefulness of the test. Kilduffe then describes his technique for both tests, and gives six tables illustrative of his results. The results of 430 parallel tests are reported and co-ordinated with his previous series of 290 tests. His conclusions are as follows: (1) the Sachs-Georgi test is often difficult to read; (2) the reaction is neither as delicate nor as trustworthy as the Wassermann test; (3) the Sachs-Georgi test may be positive with Wassermann-negative serums and negative with Wassermann-positive serums in a relatively high percentage of cases; (4) the number of non-specific reactions is sufficiently high to render the test unreliable as a means of diagnosis; (5) a diagnosis of syphilis, or conclusion as to results of treatment, cannot be based upon the results of a Sachs-Georgi reaction with safety, and the reaction does not seem suitable for general use for this purpose.

474. A New Method of Isolation of the Tubercle Bacillus from the Sputum.

E. BOSSAN and M. BAUDY (*C. R. Soc. de Biologie*, October 21st, 1922, p. 954) propose the following procedure for the cultivation of the tubercle bacillus from sputum. On receipt at the laboratory the sputum is placed in a sterile 10 per cent. solution of pure sulphuric acid in distilled water. The mixture is shaken frequently over a period of ten minutes. At the end of this time the sputum will either be completely homogeneous or it will be broken up into particles of greater or less size. In the former case a platinum loop is plunged into the thickest portion of the liquid and seeded directly on to tubes containing 4 per cent. glycerine potato medium; in the latter case a particle of the still solid material is used for the same purpose. The inoculum is well rubbed into the surface of the potato, which is then gently covered two or three times with the bouillon in the tube. After being fitted with rubber caps the tubes are incubated at 38°C. The authors have treated fifteen specimens of sputum in which tubercle bacilli were detectable microscopically by this method, and have obtained pure cultures in thirteen of them. Many of the sputa were badly contaminated, but in only a few instances did the cultures show evidence of impurity. How valuable this method may be it is difficult to conjecture; it is noticeable that all the sputa used contained large numbers of tubercle bacilli; whether it will be successful when these organisms cannot be demonstrated by any method of microscopical examination is somewhat doubtful.

475. The Schick Reaction in an Epidemic of Diphtheria.

On the occasion of a small epidemic of diphtheria in two primary schools in the town of Algiers, E. SERGENT, M. BÉGUET, L. PARROT, G. LÉMAIRE, and H. VÉRITÉ (*Arch. des Inst. Pasteur de l'Afrique du Nord*, 1922, No. 3, p. 349) made an investigation of the number of carriers amongst the scholars, and at the same time tested their susceptibility by means of the Schick reaction. Of 101 children, consisting of boys and girls varying between the ages of 6 and 15 years, there were 9 who were carriers of an organism morphologically and culturally indistinguishable from *B. diphtheriae*. The Schick reaction was performed by the unheated toxin on the left forearm, and controlled by the same toxin heated to 75°C. on the right forearm. Results were read on the second, third, eighth, and twelfth days. Of 101 children tested 29 gave positive reactions. Of the 9 positive carriers 4 were positive to the Schick test, while 5 were negative. In addition to the simple positive, simple negative, and pseudo-reactions usually obtained, they observed in 21 of the subjects a peculiar type of response which they name the paradoxical reaction. It consists of a definite reaction on the control arm (right arm) with little or none on the left arm. They consider it in the light of a protein reaction, and explain its greater intensity and duration on the right side by the effect of heat on the control toxin. In the same journal J. CIAVALDINI (p. 355) describes the performance of the Schick test on 45 children of 6 to 14 years of age. Of 11 Europeans 7 were positive, of 34 natives 12 were positive. He concludes that the natives show less susceptibility to diphtheria than Europeans.

Remarks

ON

HODGKIN'S DISEASE.*

BY

THE LATE SIR JAMES GALLOWAY, K.B.E., C.B., M.D.,
CONSULTING PHYSICIAN TO CHARING CROSS HOSPITAL.

[With Special Plate.]

ENLARGEMENT of visible lymphatic glands is a sign of disease quickly noticed by the sufferer and usually a cause of anxiety to him. In many cases it is also a cause of anxiety to the physician. It is true we are often able to reassure the patient—for instance, when it is recognized that the enlargement is due to septic infection within the lymphatic drainage system of the affected glands. Unless too far advanced, the cure of the original infective focus will cause the enlargement of the glands to disappear. In other cases we may be able to discover that the enlargement is due to a chronic infective process, such as tuberculosis, or to the occurrence of new growth, either primary or secondary in character. In such cases there is sufficient cause for alarm, but we have the advantage of understanding something of the nature of these enlargements and the satisfaction of knowing how much can be done and what should be avoided. But there are still other instances in which we are quite ignorant of the cause of the enlargement, but we do know the progressive nature of the disease. The most important example of this class is Hodgkin's disease. A recent writer has stated that this disease "presents the most hopeless condition in the whole domain of medicine." It cannot be denied that there is much truth in such a statement; it may, we trust, prove to be too emphatic. In this lecture I propose to draw your attention to certain manifestations of this disease in the hope of stimulating interest and investigation.

It is clear that the serious nature of the malady and the mystery of its occurrence must have made an impression on the mind of Dr. Thomas Hodgkin when he wrote his paper on "Some morbid appearances of the absorbent glands and spleen" in the year 1832. In the series of cases he describes he saw and noted the association of prolonged illness with enlargement of the lymphatic glands and the formation of new tissue resembling the lymphatic glands in the spleen. It cannot be said that his observations are presented in a very attractive form. Hodgkin apparently did not proceed with his investigation of the subject, and the record of his discovery appears to have been almost forgotten. Dr. Richard Bright² referred to Hodgkin's cases in his description of certain abdominal tumours, but with this exception Hodgkin's observation seems to have been lost sight of until Sir Samuel Wilks³ once more drew attention to the subject of "Enlargement of the lymphatic glands combined with a peculiar disease of the spleen" in 1856, and, recognizing the priority in discovery, spoke of "Hodgkin's disease." Wilks strangely had been in ignorance of Hodgkin's description during his earliest work on this subject, but at the end of his paper he writes: "It is only to be lamented that Dr. Hodgkin did not affix a distinct name to the disease, for by so doing I should not have experienced so long an ignorance—which I believe I share with many others—of a very remarkable class of cases, the recognition of which would have guided both myself and others to an explanation of some more recent cases coming under our notice." If Sir Samuel Wilks could now look back on the record of descriptions and investigations of this disease he would sympathize with the difficulty of affixing a "distinct name to the disease."

Since those days the disease has been carefully studied, using all the means at the disposal of modern investigation; its possible association with tuberculosis has been discussed—many have held that it is in reality an unusual manifestation of tuberculosis infection, an opinion probably now held by but few; the peculiar fever associated with the disease has been noted and looked upon as evidence that the disease is an unrecognized form of relapsing fever. Its relations to disorders of the blood, especially the varieties of leukaemia, have been investigated, and still we are unaware of the cause of the disease or its exact morbid relationships. The various synonyms

* Sir James Galloway, whose death on October 18th has been so great a loss to clinical medicine, left behind him notes he had prepared for a post-graduate lecture he was to have given. Medicine and Post-grad have been put in order. It is probable that Sir James had he survived.

which have been suggested are in some cases useful in laying stress on features of the malady; but it appears to me best still to adhere to the name of "Hodgkin's disease," especially as new "distinct names" do not take into account sufficiently the fact which becomes more evident—that we are dealing with a general specific disease associated with progressive infection of susceptible structures.

A very interesting chapter of medical bibliography could be written respecting Hodgkin's disease, especially if note were made of some of the distinguished writers.

The disease is so widely distributed, and its main features are now so well given in many textbooks, that it is unnecessary as well as inopportune for me to describe them in this place. I propose to illustrate points in its symptomatology, using for this purpose cases recently under my own observation. I think that the cases will support the conception of the malady which I have stated.

THE OCCURRENCE OF UNUSUAL PROTEIN IN THE URINE.

Apart from the complication produced by true nephritis, I believe that the occasional or temporary occurrence of albumin in the urine in small quantity is not uncommon in Hodgkin's disease, just as in many other chronic maladies, and is probably not of special significance; but the incident I am about to relate is in a different category. I have had recently under close observation, until the time of his death in Charing Cross Hospital, a case of the disease in a man. Early indications of the disease, such as enlargement of the cervical and inguinal glands, appear to have been noticed in the early part of 1919. He came under my close observation in 1920, and was then in fair health, although the nature of his malady was clear. In July, 1920, I examined his urine carefully; it had a specific gravity of 1.016, and contained no albumin and no sugar. I again saw him in the early part of 1921, when he told me that something unusual had happened; at night-time, he said, he was troubled by having to pass urine in large quantities, although during the day-time he was little disturbed in this way. On examining his urine on this occasion I found the specific gravity to be 1.014. On proceeding I saw the faintest possible cloud after acidulating the urine and heating. To my surprise this cloud disappeared on heating still further, and showed itself again on cooling. Treating the urine with picric acid saline I obtained a heavy flocculent precipitate estimated in an Esbach's tube to be about 14 parts per 1,000. It was now quite clear that the urine contained a protein of unusual character, and I suspected that it might be an example of "Bence-Jones albumin." Careful and repeated examinations showed that this peculiar protein was constantly present. It occurred in large quantities, varying from 1 to 2 up to 10 to 15 parts per 1,000 by Esbach's method. This peculiar protein remained present during the rest of his life; the symptom of polyuria gradually diminished, and in the later stages the amount of this protein present was considerably less than when first observed. Fortunately, when the patient had to be admitted to hospital I had the co-operation of my colleague Mr. Sydney W. Cole. The characters of the precipitate have been carefully investigated, both at Charing Cross Hospital and in the Biochemical Laboratory, Cambridge. I hope that Mr. Cole will publish shortly a full description of this unusual substance. In the meantime, by way of identification, I can give the following description sent to me by Mr. Cole:

The protein is similar to the "Bence-Jones albumin" in that it is coagulated on heating, redissolves on further heating, and reappears on cooling. It differs in several respects:

Bence-Jones Protein.
Coagulates at temperatures under 55° C.

Coagulates at 55° C. in the presence of a minimum amount of salt and acid.

Difficult to coagulate.

Even when highly diluted exhibits a white ring of precipitate when poured upon strong HCl (Bradshaw's test).

New Protein.

Under the most favourable conditions it does not coagulate under 75° C. Full coagulation at 79° to 82° C.

Only coagulates in the presence of a considerable amount of acids, and salts like sodium chloride or ammonium sulphate.

Becomes quite insoluble if kept at 80° C. (in the presence of acid and salt) for some minutes.

Not precipitated by HCl under any conditions.

The new protein is best detected by noting the precipitate in the cold with sulpho-salicylic acid—the urine itself failing to give a

TEMPERATURE CHART.

heat coagulum under optimum conditions of reaction (that is, just acid to brom-cresol-purple). The new protein often separated in flocculi as the urine cooled.

Microscopic and other investigations of the urine were frequently carried out, and gave no evidence of true nephritis. The autopsy completely confirmed the diagnosis of the case. The kidneys were unusually affected; the capsules were greatly thickened, but stripped off easily. There were cysts in both kidneys; microscopical examination showed that the cortices of the kidneys contained small areas of the characteristic overgrowth of the disease.

THE FEVER OF HODGKIN'S DISEASE.

In all cases of this disease the body temperature is raised at some time. On looking over many temperature charts the occurrence of fever seems often to be irregular and comparatively mild in degree. But in a few cases the course of the temperature is extraordinarily regular, both in its exaggerations and in its relapses. In a characteristic case the chart is one of the most remarkable within medical knowledge.

The temperature of other cases, which appears at first sight to be irregular, on closer examination gives evidence of a definitely periodic course. The peculiar character of the temperature has attracted the attention of many observers; its occurrence was emphasized by Pol¹ of Amsterdam, and by Epstein² of Göttingen, who described such cases as examples of an unusual type of relapsing fever.

I have recently had under my observation a patient whose temperature was a very perfect example of this relapsing type. I have a complete record of his body temperature during a period of five months preceding his death. After being nursed at home, and later in a private nursing home, he was admitted to Charing Cross Hospital under the care of my colleague Mr. Peter Daniel. I had therefore frequent opportunities of seeing the patient during the last two months of his life.

On examination little could be made out in the way of physical signs. None of the easily palpable lymphatic glands were enlarged, although I suspected that the retroperitoneal lymph glands might be. These, however, were not easily palpable. After death the glands extending along the whole of the left side of the lumbar vertebrae formed a large mass, the glands in the groin were also enlarged, and there were white nodules in the spleen.

During the relapses of the fever he was deeply unconscious, with low delirium, and resembled a severe case of typhoid fever about the third or fourth week. When the temperature remitted he recovered consciousness to a very marked degree and improved greatly in general appearance. But even in the afebrile periods the patient was obviously seriously ill.

On studying the temperature chart we observe that the fever is markedly relapsing in type; there are febrile periods of from five to eleven days in duration, succeeded by periods of pyrexia usually longer than the periods without fever. The pyrexial period in what may be regarded as atypical outbursts lasts for about twelve days; the cycle of the disease, reckoning from the commencement of the afebrile period to the end of the period of pyrexia, appears to be on the average about twenty days.

The rise of the body temperature is rapid, reaching an elevation from subnormal or normal to 104° or 105° in the course of forty-eight to sixty hours. This rapid rise was associated with a certain amount of shivering and other evidences of a febrile attack, especially with rapidly increasing and severe toxæmia. During the period of raised

temperature the patient was almost unconscious, as if severely poisoned; he could, however, be roused to answer simple questions, but with great difficulty.

After the period of eleven or twelve days the fall of temperature took place, usually more rapidly than the rise. Thus a fall from 104° or 105° to subnormal ranges of 96° and 97° would occur within forty-eight hours. After four or five days of subnormal temperature the curve would again rise slowly towards the normal, then suddenly the upward curve would show itself, indicating the commencement of the period of relapse.

This temperature chart also suggests that two attacks of fever might succeed each other rapidly, so that there would be an unusually long pyrexial period of about twenty-one days, but during such a prolonged febrile attack definite remission of fever occurs, indicating the usual limit of a febrile period, succeeded immediately by a new access of fever. It was remarkable how rapidly the patient recovered consciousness when the temperature fell.

I have had this prolonged record of fever reduced from the four-hourly charts to a small scale of one-tenth of an inch to each observation (see Chart). As nearly as possible I have taken the temperature record of 8 o'clock in the morning and 8 o'clock in the evening as indicating the course of the fever. The reduction has brought about the appearance of exaggeration of the variations of temperature relatively to the time. Bearing this in mind the reduced chart demonstrates very well the peculiar relapsing nature and the severity of the fever. I owe to my friend Professor Arthur J. Hall³ of Sheffield the suggestion of arranging such prolonged temperature curves in the way described. Professor Hall showed me a chart arranged in this manner in a similar case of prolonged Hodgkin's fever.

On examining such a temperature curve we get a strong impression that the disease characterized by this fever is caused by a specific poisoning; also that this poisoning is of infective and in all probability of parasitic nature; and further, that the periodicity of the temperature depends on some such event as the life cycle of a parasite. It is a facile suggestion to make—that the infective agent may be a protozoan. Unfortunately, as yet we have no definite evidence that a parasite is the cause of Hodgkin's disease.

THE CUTANEOUS SIGNS OF HODGKIN'S DISEASE.

Probably in all infections certain tissues are more susceptible to the morbid influence than others. This is very clearly the case in Hodgkin's disease. The lymph glands and allied structures are peculiarly susceptible. It might at first be thought that as the skin does not contain obvious lymphoid structures, with the exception of the all-pervading lymphatic channels, it would not usually show signs of the malady, but the observation of patients teaches that the skin not unusually gives evidence of the disease. These manifestations fall into two categories. By far the most important is the appearance of small erythematous points or macules on the skin of the body and the extremities. Sometimes these become distinctly papular, raised a little above the surface; usually they disappear, leaving a faint staining of the skin. Very rarely these papular lesions become slightly vascular. In association with the enlargement of the lymphatic glands, the cutaneous condition closely resembles the severer forms of prurigo. As the result of these lesions, aggravated by friction and scratching, wide areas of the skin may become thickened and swollen, producing an exaggeration of the natural texture of the skin, emphasizing the folds and wrinkles, and

CONTINUATION OF TEMPERATURE CHART.

giving an elephantoid appearance. This condition of the skin closely corresponds in appearance with what has been named lymphodermia. Coexisting with the above state the surface of the skin may be dry in some cases, desquamating in fine scales, and very often showing widespread pigmentation of a pale yellow-brown colour. But the most important of all the cutaneous symptoms is pruritus. I believe that the misery experienced by the itching in some cases of Hodgkin's disease is unexampled in other maladies. It seems to occur very commonly in mild degree, but in those cases in which the papular lesions develop the itching is intense and most exhausting. Nothing seems to be able to control the desire to scratch and rub the affected skin. The patients scratch open the papules, and only then will they admit that they have a certain amount of relief. Anyone who has to deal with a severe case of Hodgkin's pruritus will not fail to remember the misery of the patient and the difficulties experienced in advising treatment.

The histological examination of the skin in such cases shows two sets of lesions. In the first there are the usual changes occurring in severe non-pyogenic dermatitis. Such changes might arise from the specific poison of the disease itself or as the result of absorption from the newly formed tissues of the disease. Secondly, in some cases the formation of new cells in the neighbourhood of the blood vessels and lymphatic channels seems to be of a special character and to resemble the characteristic overgrowth of the disease.

In addition to these generalized cutaneous conditions, which are not very uncommon, there occurs much more rarely the formation of small tumours and nodules in the skin. They are often numerous, small, up to the size of a broad bean, flattened rather than definitely raised from the surface, and pale pink or brownish in colour. The histological examination of these nodules shows that they are composed of the characteristic Hodgkin's "granuloma." These nodules may occur apart from the other indications which I have mentioned.

These cutaneous lesions are not only important in themselves, but they have a close resemblance to the skin manifestations of other diseases. The most striking of these is the distressing malady known as mycosis fungoides. Just as in Hodgkin's disease, mycosis fungoides seems to be caused by a general infection of the body. The cutaneous manifestations fall into two groups: a widespread inflammatory change in the skin, and the formation of tumours. The histology of the tumours closely resembles the histology of the granuloma in Hodgkin's disease, so much so that certain very competent observers have come to the conclusion that mycosis fungoides is but a special manifestation of Hodgkin's disease, affecting mainly the skin. It is very important as well as interesting to note that the cutaneous manifestations in the varieties of leukaemia also resemble in many of their features the conditions mentioned. There may occur a widespread pruriginous dermatitis on the one hand, and the formation of nodules composed of characteristic cellular elements on the other.

TREATMENT.

As we are yet ignorant of the cause of this disease, its treatment is unsatisfactory. There is still too much truth in the opinion that there is no recorded case of cure or recovery. There are, however, methods of alleviation.

Arsenic seems to be the only drug which has any beneficial influence. A considerable amount of evidence shows that the drug is of value, at any rate in certain cases. It has been used in various ways—by the mouth, subcutaneously, and,

since the introduction of the salvarsan group of preparations, by intravenous injection. I have used the drug in a considerable series of cases, and have come to the conclusion that benefit is most conveniently obtained by its administration in the form of sodium cacodylate. The plan I usually follow is to prescribe the cacodylate in quarter-grain doses by the mouth, repeated during the day till as much as a grain or a grain and a half is administered daily. The patients bear this preparation well, with little intestinal discomfort. It is usually an indication to stop administering the drug, temporarily, when the characteristic garlic-like odour can be appreciated on approaching the patient closely. As a result of the administration of the drug, I believe that I have seen the glands diminish in size and the patients become more comfortable. A point of some interest has to be borne in mind. It appears that in some of the cases who have developed the characteristic pruritus of the disease, arsenic, at any rate after a time, seems to increase the pruritus. On stopping the drug I have known the pruritus diminish in degree.

A second method of treatment of undoubted value in certain cases of the disease is the use of x rays. The most distressing and dangerous complications of the disease occur when the glands within the thorax are affected. They may increase in size, producing at first discomfort, then symptoms of serious dyspnoea with stridor, owing to the pressure of the tumours on the trachea, bronchi, and other structures. A good many cases are now on record showing that the careful use of x rays in such cases of mediastinal Hodgkin's disease has brought about a great improvement in the symptoms and much comfort to the patient. Not only so, but repeated x-ray examination of the chest in these cases shows very clearly that, at any rate, the shadow produced by the tumour is greatly shrunken, no doubt owing to diminution in size of the glandular masses.

I have under observation at the present time a lady who was brought to me with clear evidences of Hodgkin's disease. There were enlarged glands in the axilla and in other parts of the body, but the main seat of the disease seemed to be those in the right side in the mediastinum. The patient suffered from dyspnoea with severe exacerbations and much stridor, so that her life was in immediate danger. She was treated by my late colleague Dr. Ironside Bruce, more than two years ago, with very satisfactory results. The patient improved, the dyspnoea and other discomforts almost disappeared, and she was able again to undertake her duties in her house. More than a year after a recurrence of the symptoms took place and she was once more treated by Mr. Stanley Melville. The favourable results, with relief of the symptoms, once more occurred. The patient after two and a half years still remains free of her symptoms and is able to carry on her duties. (See Figs. 1 and 2.)

In this case an enlarged gland was removed from the right axilla and shows the characteristic histological structure of the disease. I am glad to be able to demonstrate the x-ray photographs in this case, before and after treatment, and I have also had the advantage of comparing with these the x-ray photographs in a very similar case with similar results treated by my colleague Dr. Russell Reynolds.

There is one observation I should like to make with respect to x-ray treatment of this disease—the lesson was strongly impressed upon me when treating some cases with the help of my late colleague Dr. Ironside Bruce. It seems to be possible in certain cases, and apparently when too rapid resolution of the lymphoid masses takes place under x rays,

that very severe reactions with serious rise of temperature and other untoward results may follow the x-ray exposures. This phenomenon suggests that alien protein poisoning occurs as the result of the breaking down and absorption of the newly formed cells. It must, however, be stated that the tumours of Hodgkin's disease do not always diminish under x rays. In some cases the application has little or no beneficial effect; it is possible that in these cases much fibrous change has taken place in the glands, so that little beneficial effect from x rays can be expected.

President.

DISCUSSION ON

SURGICAL TREATMENT OF NON-TRAUMATIC
AFFECTIONS OF THE SPLEEN.

OPENING PAPERS.

I.—JAMES CARSLAW, M.A., M.B.,
Physician, Western Infirmary, Glasgow.

It has long been known that the spleen is not essential to life. Even in the sixteenth and seventeenth centuries there were cases of successful removal of spleens that protruded through wounds of the left side, and by the end of the seventeenth century experiments on the spleen began to be done on animals. It was gradually established that the spleen could be done without, and that after its removal certain compensatory changes occurred in the lymph tissue of the liver and in the lymphatic glands. Thus the way was paved for the deliberate removal of the spleen in man in conditions in which it was enlarged by disease. However, it has been only in the last few years that any clear indications for this operation have been established, great assistance in this matter being got from the systematic examination of the blood. At first unsuitable cases were chosen—notably some advanced cases of leukaemia—and the mortality was so alarming that the operation was reserved almost entirely for cases of injury. But the technique of splenectomy now presents no serious difficulty and in such suitable conditions as splenic anaemia and alcoholic jaundice the mortality, according to recent statistics like those of the Mayo Clinic, is less than 10 per cent., and in a large proportion of the successful cases the patients may be considered as cured.

In considering this subject generally one is straight away confronted with one's ignorance as to what the real functions of the spleen are. A large literature has grown up on this subject, and much experimental work has been done, an excellent summary and discussion of which will be found in Sir Berkeley Moynihan's book on the spleen,¹ which has a very full bibliography. This will be my excuse for making but few detailed references to the literature. A difficulty that meets one in studying all this work is the difficulty of reconciling the results of many of the experiments on animals with the clinical findings in the human subject. I shall therefore only mention some of the more outstanding and agreed upon conclusions. The spleen has no doubt some relation both to the formation and the destruction of blood cells. Blood cells are probably not formed by the spleen except in embryonic life. But it may be that some internal secretion of the spleen influences the bone marrow, which is the blood-forming tissue of the body, stimulating the formation of red cells and perhaps inhibiting that of the white

cells. On the other hand, the evidence of blood destruction in the spleen is quite strong, and no doubt it is this organ which is most concerned in the destruction of the used-up red cells and in passing on the products of these cells to the liver for the formation of bilirubin, etc. To a lesser extent the liver in health shares in this work. In certain diseased conditions this haemolysis is exaggerated, and this is what mainly explains the anaemia and in some cases the jaundice that occur. It is the removal of this destructive process that is in most cases the principal indication for splenectomy. When the spleen has been removed by operation no doubt the liver and perhaps also the lymphatic glands take over its former duties.

There is little doubt also that the spleen exercises important phagocytic functions in regard to the micro-organisms of many infectious diseases. This has something to do with the enlargement of spleen that occurs in most of the infections and in septicaemic conditions generally, also in such diseases as malaria, kala-azar, and syphilis. In this connexion the experiments of Morris and Bullock² on rats are especially interesting, showing that splenectomized rats are less resistant to various infections than the normal controls, but I do not think this has been confirmed in the human subject.

There are many diseases in which splenomegaly occurs. It is a feature in varying degrees, often of diagnostic importance, of the infective fevers and septicaemia, and also in the protozoal infections, in all of which one may say no call for surgical measures need arise. Then there are a number of blood diseases of great interest, in which the cause, probably an infective one, is not known. In some of these the splenic enlargement may be taken to be a part only of a general condition arising elsewhere, and in such cases any operation on the spleen is uncalled for or at least is a doubtful question. Pernicious anaemia may here be mentioned, and although many advocate splenectomy in this disease, even without splenic enlargement, and large numbers of successful splenectomies have been performed, it is generally agreed even by surgeons that the illness goes on and that the ultimate result is no more satisfactory than that attained by medicinal remedies.

Another obscure disease which in chronic cases gives rise often to very large spleens is leukaemia, and in spite of the advocacy of the Mayo Clinic I cannot agree that the spleen should be excised in such cases. This disease is principally one of the bone marrow, some infective agent causing great overaction of the white cell producing marrow and throwing into the circulation hosts of actively proliferating cells, which multiply in the lymph structures of the body generally and particularly in the spleen. Removal of the spleen in such cases is only dealing with a small part of the trouble, and that not causal. Erythraemia or Vaquez's disease is somewhat analogous, being the result of an overactivity of the red cell producing marrow, and although the spleen does enlarge in this disease this is probably the result of overwork of the spleen in red cell destruction and of the nature of a compensatory hypertrophy. The inference to be drawn from this would be that in Vaquez's disease the last thing to do would be to remove the spleen. I might also mention Hodgkin's disease here as one in which the enlargement of the spleen is only a part of a general hypertrophy of lymphoid tissues, usually most marked in groups of lymphatic glands.

But there are two groups of cases where the disease, probably a toxic agent of some kind, seems to be centred in the spleen, and it is in these that the successes of splenectomy are got. There are the splenic anaemias and certain cases of alcoholic jaundice (some hereditary and some acquired) that have been classified during the last twenty years or so. I may here suggest that splenic anaemia (and I would use the term "Banti's disease" as synonymous) is probably not an entity. Cases usually become grouped under that heading by a process of exclusion and are found by the pathologists to present quite a variety of changes. There is still much work, clinical and pathological, to be done before the splenomegalics of this group are satisfactorily classified.

I would like to refer to some cases which have been treated in some of the wards of the Western Infirmary, Glasgow, in the last few years and to make some observations based on these cases.

CASE I.

S. R., a young girl of 8, was admitted to the Western Infirmary on July 26th, 1912, under the care of Mr. J. S. G. Douglas, and an account of this case was published in the *British Medical Journal* (1914).³ She gave a history of ill health, and latterly haemorrhages into skin and retinae.

was nothing of note in the family history. There was no enlargement of lymphatic glands, slight enlargement of liver, and the spleen reached nearly to the umbilicus. Wassermann test was negative. Examination of the blood gave the following result:

Blood Examination.

Date.	R.B.C.	W.B.C.	Hb.	C.I.
July 27th, 1912 ...	2,550,000	7,800	25%	0.5
August 5th, 1912 ...	2,700,000	11,400	25%	0.46
August 28th, 1912 ...	Splenectomy			
August 29th, 1912 ...	4,650,000	34,800	35%	0.33
September 4th, 1912 ...	4,170,000	12,500	35%	0.4
November 12th, 1912 ...	4,890,000	12,000	70%	0.7

Blood films before operation showed more small lymphocytes than usual, but immediately after operation there was a very marked polymorphonuclear leucocytosis. As medicinal treatment was disappointing her spleen was removed by Dr. Alexander MacLennan on August 28th, the patient making an uninterrupted recovery. A small portion of a rib had been previously excised and found to be hyperplastic.

The pathological report by Dr. (now Professor) Shaw Dunn described the spleen, which weighed 4½ oz. (about twice the normal for patient's age), as of firm consistence and congested, with enlargement of the lymph nodes. The main departure from the normal in films from the spleen was the presence of normoblasts and myelocytes and an unusual number of polymorphs and eosinophilic leucocytes.

The patient left hospital well in November, 1912, and I am able to report that she is still alive and well. I had a letter from her mother this month in which she says that the girl, who is now a tall young woman of 18, has had no serious illness since her operation. She has, however, always been rather pale and has not yet begun to menstruate. This appears to be a case of splenic anaemia and resembles Case VI in many respects.

CASE II.

E. S., a poorly developed youth of 17, was admitted to the Western Infirmary on March 13th, 1915, complaining of swelling of the abdomen of three or four months' duration, and later also of swelling of the feet. He was under the care of Professor T. K. Munro, who has asked me to record this case and also Case IV. The patient was anaemic-looking, and his gums were soft and bled easily. He had slight enlargement of glands on both sides of his neck. The hepatic dullness was small, but the spleen was much enlarged and reached to 2½ inches below the level of the umbilicus. The Wassermann test was negative. Examination of the blood gave the following result:

Blood Examination.

Date.	R.B.C.	W.B.C.	Hb.	C.I.
March 19th, 1915 ...	4,440,000	3,000	62%	0.7
April 25th, 1915 ...	4,686,000	4,200	70%	0.7
April 27th, 1915 ...	Splenectomy			
May 2nd, 1915 ...	5,235,000	10,600	85%	0.8
June 25th, 1915 ...	4,310,000	7,800	80%	0.9

Blood films showed nothing abnormal. The fragility of the red cells was normal, but the coagulation time was a little slow (7 minutes). As medical treatment was disappointing, splenectomy was performed by Sir Kennedy Dalziel on April 27th. The spleen had extensive adhesions from perisplenitis, and at the operation some cystic condition of the liver was noticed, but the kidneys appeared to be normal. He recovered well from the operation and left hospital at the end of May, apparently improved. But the tendency to haemorrhage continued, and a year later, in June, 1916, he died after three days' serious illness, having apparently had an intracranial haemorrhage.

What the nature of this case was it would be difficult to say precisely. I have not been able to trace a pathological report on his spleen. Another point of interest is that although the surgeon might consider this a successful case from the operation point of view, the ultimate result was unsatisfactory. It illustrates the fallacy attached to the statistics of recovery in these cases, but I may say it is so far the only failure among the cases to which I am referring.

CASE III.

Mrs. S., aged 33, was admitted to the Western Infirmary, to Dr. Wm. MacLennan's wards, on November 26th, 1914. She had had a cystic ovary removed in January, 1913, and was noticed then to have an enlarged spleen. In 1914 she had two miscarriages. She was a sister of Case IV, but otherwise the family history was negative. The patient was thin and pale but slightly jaundiced, though no bile was present in her urine. There was no enlargement of glands or liver, but spleen reached 2½ inches across the

middle line and 3½ inches below the level of the umbilicus. Wassermann test was negative. Examination of the blood gave the following result:

Blood Examination.

Date.	R.B.C.	W.B.C.	Hb.	C.I.
February 2nd, 1915 ...	2,500,000	6,000	40%	0.8
February 10th, 1915 ...	Splenectomy			
March 2nd, 1915 ...	4,600,000	9,800	62%	0.6
May 19th, 1915 ...	6,435,000	10,400	75%	0.6

Blood films showed nothing abnormal about the white cells, but increased fragility of red cells was demonstrated, beginning in her case with 0.6 per cent. salt solution. The spleen was removed by Dr. Cutburt on February 10th, and she made a rapid recovery, leaving hospital on March 19th very well. I heard of her within the last few days and am able to say that she has enjoyed excellent health since her operation and has a child 2 or 3 years of age.

Dr. Haswell Wilson's report on the spleen is as follows: "The pulp shows general hyperplasia with great congestion of sinuses. No phagocytosis of red cells is seen, nor is there any other particular change. Some of the Malpighian bodies are rather fibrous and atrophied."

This case and that of her sister (Case IV) were clearly acholuric jaundice. Both of them had large spleens, were jaundiced, showed fragility of red cells, and in both the symptoms developed in adult life.

CASE IV.

Mrs. N., aged 36, was admitted to the Western Infirmary, under Professor T. K. Munro, on November 19th, 1914, complaining of weakness, fullness of the left side, and recurring attacks of jaundice all of one year's duration. There was a story of biliary colic, but she had had some attacks of severe pain in the left side—presumably perisplenitis. She had no children, and the family history was negative except for the illness of her sister (Case II). The patient was slightly jaundiced, though no bile was found in the urine. There were no enlarged glands and no enlargement of the liver, but spleen was easily felt reaching to the middle line and half an inch below the level of the umbilicus. Wassermann test was negative. Some of the blood counts are given here:

Blood Examination.

Date.	R.B.C.	W.B.C.	Hb.	C.I.
November 20th, 1914 ...	4,255,000	19,600	60%	0.7
January 9th, 1915 ...	2,300,000		38%	0.8
November 2nd, 1915 ...	4,000,000	18,000	62%	0.7
November 3rd, 1915 ...	Splenectomy			
November 8th, 1915 ...	4,250,000	14,000	68%	0.8
November 27th, 1915 ...	3,910,000	11,400	74%	0.9
October 11th, 1916 ...	3,800,000	10,937	72%	0.9

The fragility of the red cells was markedly increased, beginning in her case with 0.7 per cent. salt solution, but nothing abnormal was found in regard to the white cells. She was at first in hospital for seven weeks, getting arsenic and iron medicines, but seemed to get worse, and went home at her own request on January 12th. However, she returned to the same ward in October, 1915, with her blood a good deal better, but jaundice and spleen as before. She now demanded to have her spleen removed, because of the great success of her sister's operation. Sir Kennedy Dalziel operated on November 3rd, the spleen being found to be much enlarged and having many adhesions to stomach, liver, and abdominal wall. The appendix was normal, but gall stones were noticed in her gall bladder. There were signs of chronic peritonitis. She made an excellent recovery from her operation, and went home at the end of November, being reported in January, 1916, to be wonderfully better, and quite free from jaundice.

Mrs. N.'s after-history is interesting, especially in connexion with the suggestion that removal of spleen may leave the patient less resistant to other illnesses. In September, 1916, she began to complain of swelling of the abdomen, and was readmitted to the Western Infirmary in October, 1916, with ascites. On November 14th Sir Kennedy Dalziel opened her abdomen and drained the ascites, which was demonstrated to be due to tuberculous peritonitis. From this she made an excellent recovery, but her troubles were not over. In 1917 she began to have great pain, and menstruation with excessive discharge, and ultimately this was found to be due to a submucous fibroid of the uterus. In the spring of 1918 this was removed by Dr. S. G. Cameron by the vaginal route, and in 1919 a second similar fibroid had to be removed. After that she returned to good health, and is now really very well, though no quite so robust as her sister.

CASE V.

G. P., a female school teacher of 26, was admitted to the Western Infirmary, to Dr. William MacLennan's wards, on October 1st, 1918, complaining of enlargement of spleen, which had been first

noticed two months before. The family history was negative. She was sallow and anaemic and had a short dry cough, though nothing abnormal was detected in her lungs at this time. There were no enlarged glands and no enlargement of liver, but spleen was easily palpated, reaching 1 inch to the right and 2 inches below the umbilicus. Wassermann test was negative. She improved greatly under treatment with arsenic and intramuscular injections of galyol and left hospital in January, 1919. However, she was readmitted under my care in August, 1919, with the same symptoms, the spleen still reaching to the umbilicus. She again improved greatly under arsenic and galyol, though spleen remained as before, and was giving so much discomfort by its weight and interfering so much with her stomach that on dismissal in December she was recommended to wear an abdominal support. As in spite of a good holiday she was feeling quite unfit for work she returned to hospital on February 5th, 1920, and in connexion with a troublesome cough, which she still had, I detected something wrong with the apex of her right lung, although she had no spit. After a time she consented to have her spleen removed, and Sir Kennedy Dalziel operated on April 28th, 1920; there was some difficulty in the operation owing to the size of the spleen and the presence of adhesions. There was no sign of tuberculous peritonitis. However, she lost practically no blood, and made an excellent recovery from the operation, while the ultimate result has been very good. She resumed her full work as a teacher in August, 1921. Menstruation, which had been absent for a long time, returned, and when seen by me in March last she looked perfectly well.

Some of her blood counts are as follows:

Blood Examination.

Date.	R.B.C.	W.B.C.	Hb.	C.I.
October 2nd, 1918 ...	2,400,000	4,800	45%	0.9
October 19th, 1919 ...	3,576,000	4,200	60%	0.8
April 20th, 1920 ...	3,400,000	3,400	55%	0.8
April 28th, 1920 ...	Splenectomy			
June 8th, 1920 ...	4,560,000	5,000	60%	0.6
March 11th, 1922 ...	4,500,000	9,600	80%	0.9

Blood films in this case never gave nucleated red cells, but a leucopenia with slight excess of lymphocytes.

Professor Muir's report on this spleen is as follows: "The spleen is enormously enlarged, the weight being 5 lb. The surface shows numerous slight elevations, and through the capsular small irregular pale patches can be seen. The form of the organ is maintained and its consistence is firm. On section the whole organ is seen to be studded with numerous tubercle-like nodules, which stand out against a congested background. The nodules are of about the size of a large pin's head, of greyish colour, and arranged in closely packed clusters, in many places confluent. They are, on the whole, remarkably uniform in size throughout the organ, though one or two larger nodules are present. On microscopic examination the nodules have all the characters of somewhat chronic tubercle nodules. Caseation is present in the central parts and there are numerous giant cells of usual appearance. There is also a considerable amount of interstitial fibrosis. In spite of very prolonged search no tubercle bacilli could be found."

This appears to be a case of tuberculosis of the spleen, and it seems to be most remarkable that such a condition should be possible in a vascular organ like the spleen without general tuberculosis resulting. Splenectomy seems to have resulted in complete cure, and a very similar successful case is reported by H. Z. Giffen.⁴ One of the cases reported in the *Journal of Pathology and Bacteriology* by Dr. Kettle is of the same nature.⁵

CASE VI.

S. W., a young girl of 17, was admitted to my wards in the Western Infirmary on February 1st, 1922, complaining of general weakness of at least ten years' duration, with enlargement of the spleen. She had been under Dr. Frank Charteris as an outdoor patient at the Western Infirmary Dispensary in 1916, and as she did not improve on ordinary blood tonics she was admitted to hospital, to Professor Stockman's wards, in September of that year. She was treated intravenously with tartar emetic, and seemed to improve, but the improvement was not lasting, and she continued in the same anaemic and enfeebled condition until she came back to hospital this spring. She was not only anaemic-looking, but was poorly developed for her age, and had not yet begun to menstruate. The family history was negative. There was no enlargement of glands or of liver, and spleen was moderately enlarged, reaching half-way to the umbilicus. Examination of the blood gave the following result:

Blood Examination.

Date.	R.B.C.	W.B.C.	Hb.	C.I.
February 16th, 1922 ...	2,900,000	5,600	50%	0.9
March 1st, 1922 ...	Splenectomy			
March 10th, 1922 ...	3,020,000	9,400	50%	0.8
April 13th, 1922 ...	4,760,000	8,600	70%	0.7
May 16th, 1922 ...	4,950,000	7,500	90%	0.9

A blood film showed "marked variation in size and shape of the red cells, some being of megalocytic type. Polychromatophilia and punctate basophilia were well marked, more especially the former. One normoblast was seen during the whole examination. No characteristic abnormality was noted in the leucocytes."

As she was making no improvement on medicinal treatment and seemed to be in danger of becoming a chronic invalid and to be likely to be exposed to the danger of serious haemorrhage, which is common in such cases and often fatal, splenectomy was recommended, and Sir Kennedy Dalziel operated on March 1st. There were no adhesions and the operation presented no difficulties, the patient making a rapid recovery. It was interesting to watch the rapid improvement in the girl's appearance within a few days of operation. When she went home in May after a few weeks at the convalescent home she looked the picture of health. I may mention that intentionally after the operation she was given no arsenic or iron, and that makes the remarkable improvement in her blood counts all the more striking.

Professor Muir's report: "The spleen is uniformly enlarged and its surface smooth; weight 2 lb. 2 oz. Its consistence is moderately firm and on section the pulp shows a uniform dark red colour due to engorgement of blood. The Malpighian bodies are somewhat enlarged and stand out very distinctly against the congested background. Films were made from scrapings of the pulp and stained in various ways. The cells, relatively scanty in proportion to the blood, are chiefly lymphocytes and mononuclears, with a few polymorphs. No abnormal cells, no evidence of phagocytosis, and no accumulation of pigment are found. Sections show a general increase of the lymphoid tissue; the Malpighian bodies are large and the germ centres very distinct. There is marked congestion of the pulp and there is some evidence of thickening of the stroma at places, but this is at quite an early stage. Scarcely any blood pigment can be found, only a few granules of haemosiderin in the pulp on treating with HCl and potassium ferrocyanide."

Clinically and pathologically this case is very like Case I, and the result seems to be equally promising. In contrast I might mention the case of a young soldier of 20 whom I had as a patient in Stobhill (the 3rd Scottish General Hospital) in 1917. He was admitted as a gastric ulcer with haematemesis but was really splenic anaemia. He had had a serious haemorrhage from stomach at the age of 15 and he died from gastric haemorrhage seven months after my invaliding him out of the army. I have no doubt his life might have been saved if he had been operated on.

CASE VII.

Mrs. A., aged 35, was admitted to the Western Infirmary under my care on February 28th, 1922, complaining of weakness. This condition of ill health commenced about seven years ago and she had also suffered from cough and spit. In October last she got much worse and was actually admitted to the Tuberculosis Department of Ruchill Fever Hospital as a case of phthisis. Repeated examinations of sputum for tubercle bacilli, however, gave negative results, and she was found to have anaemia with splenic enlargement and was treated with arsenic. Ultimately she was discharged as non-tuberculous and came to the Western. Her family history was negative. She had had one pregnancy, the child being still-born. The Wassermann test was negative. The patient was anaemic. There were no enlarged glands. The liver was palpable and the spleen moderately enlarged. She had a cough and mucopurulent spit with some pulmonary changes not specially suggestive of tubercle. Blood examination gave the following result:

Blood Examination.

Date.	R.B.C.	W.B.C.	Hb.	C.I.
March 15th, 1922 ...	2,300,000	3,840	55%	1.2
April 4th, 1922 ...	2,160,000	4,875	58%	1.3
April 21st, 1922 ...	2,330,000	4,000	58%	1.2
May 5th, 1922 ...	Splenectomy			
May 8th, 1922 ...	2,200,000	16,000	58%	1.3
May 24th, 1922 ...	3,100,000	4,600	65%	1.0
June 15th, 1922 ...	3,400,000	7,200	68%	1.0
July 5th, 1922 ...	3,040,000	6,600	65%	1.0

The pathologist's report on blood films was: "The red blood cells show marked variation in size and shape, and megalocytic forms are numerous, nucleated reds, several of which are megablasts, are found. The red cells are deeply coloured and polychromatophilic and punctate basophilia are common. No characteristic abnormality of white cells is present. The blood picture is that of an anaemia of the pernicious type."

As her progress under arsenic was rather disappointing, and the outlook far from promising, I recommended that her spleen should be excised while her general condition was still comparatively good. The operation was performed on May 5th by Sir Kennedy Dalziel, and no peritonitis was found. She was very little upset by the operation. From the date of operation for two months she was given no arsenic or iron, and in spite of this there was a steady improvement in the blood counts. Thus the red cells improved from a little over 2,000,000 to over 3,500,000, and the haemoglobin from about 50 to 65 per cent. The colour index was always high, and after operation as before films showed characteristic alterations in the red cells. The blood chart in this case, as in some of the others, shows a marked post-operative

leucocytosis, the significance of which is doubtful. I am inclined to think that it is not more than one might expect after any operative interference of comparable magnitude. She has recently been put on arsenic and iron medicines, and is still under treatment in my wards.

Professor Muir's report on this patient's spleen is as follows: "The spleen is moderately enlarged; the weight is 14 oz. It is smooth on the surface with the exception of a few adhesions. It is of moderate consistence, contains much blood, and has a uniform appearance on section. The Malpighian bodies are not enlarged. The general appearance is that of a congested spleen. In films made directly from the pulp most of the cells are lymphocytes, small and large, but there are also a fair proportion of neutrophil myelocytes and polymorphs, also a considerable number of eosinophils, some being of the myelocyte type. Nucleated red corpuscles also are present, some of which are megaloblasts. No large phagocytic cells and no blood pigment were found. In sections there is little of an abnormal nature to be made out. ... but the proportion of cells of the leucocyte ... the previous case (Case VI). The Malpighian ... not abnormal in size. There is practically no fibrosis, and there are no signs of blood destruction; practically no haemosiderin is present."

It will be interesting to watch the progress of this case. She has stood the operation very well and has much improved both in general condition and in regard to her chest condition. Instead of any deterioration of blood after operation such as is described in the case of animals there has been a fair and steady improvement even without medicines. Whether that improvement will be maintained and whether any more permanent good will result in her case than would have come with medicinal measures alone is the question. Certainly the operation does not seem to have done her any harm, but I must say I would not have recommended it unless the spleen had been enlarged. The great variation that occurs in the size of the spleen in this disease, and the acknowledged fact that splenectomy may relieve but does not cure it, show that the cause of the disease depends only in part on excessive haemolysis of red cells by the spleen. Professor Muir's report is interesting from that point of view, no definite signs of blood destruction being found in the spleen.

CASE VIII.

J. C., a tailor, aged 36, was admitted to my wards in the Western Infirmary on June 21st, 1921, with swelling of the abdomen and general weakness. These symptoms were said to have started only six weeks before, and at that time enlargement of the spleen was detected. His previous health has been good except that he had had his left lower limb amputated high in the thigh at the age of 13 for osteomyelitis. The patient looked very anæmic. The spleen reached nearly to the umbilicus and ascites was present. The liver was not palpable and there were no enlarged glands. Wassermann test was negative. His blood examination last summer gave the following result:

Blood Examination.

Date.	R.B.C.	W.B.C.	Hb.	C.I.
June 21st, 1921	3,600,000	10,800	36%	0.5
July 4th, 1921	3,784,000	8,403	43%	0.56
July 16th, 1921	3,312,000	6,250	36%	0.5
August 2 st, 1921	4,420,000	5,650	52%	0.6

Blood films showed nothing abnormal. He was treated with arsenic and iron and his abdomen was tapped on July 22nd. He improved so much after the paracentesis that he refused operation at this time and went home, with his spleen, however, much the same. He was able to return to work after a time and kept fairly well till the end of April, when he had an attack of diarrhoea and with this the ascites returned badly. He was readmitted to hospital on June 28th, 1922, into the same ward. On readmission his anaemia was much worse than the previous summer and the ascites was very marked. On July 10th I drew off eleven pints of fluid, but it has rapidly returned. The spleen is no bigger than before, but after the paracentesis the liver was palpable at the left costal margin, the upper border of hepatic dullness being at the fifth rib. Blood examination on present admission gives the following result:

Blood Examination.

Date.	R.B.C.	W.B.C.	Hb.	C.I.
June 29th, 1922	1,635,000	8,600	28%	0.8
July 9th, 1922	2,303,003	4,600	30%	0.6
July 13th, 1922	2,848,000	15,700	30%	0.5
July 21st, 1922	2,580,000	4,200	30%	0.6

An interesting point about this patient's blood is that the fragility of his red cells is increased, commencing at 0.55 per cent. saline solution. This test was kindly done for me by Dr. Adam Patrick. It is usually stated that such fragility is a sign of acholuric jaundice and is never got in splenic anaemia (Bant's disease). But on neither of his residences in hospital has this patient had

jaundice, and his blood serum was tested by me for bilirubin by van den Bergh's method and found to be free. That suggests that the fragility test is not pathognomonic.

I regard this case as an advanced one of splenic anaemia, in which some cirrhosis of the liver has supervened, and we are at present treating the patient with arsenic and iron to improve his blood condition before submitting him to splenectomy. The patient is willing to have that operation, and Sir Kennedy Dalziel has agreed to undertake it.* A considerable number of successful cases have now been reported of splenectomy even in this advanced condition. H. B. Sweetser⁶ has reported a remarkable case, and W. J. Mayo⁷ has described a number of cases of splenic anaemia complicated by cirrhosis of the liver in which he operated, in five of which ascites completely disappeared after splenectomy.

These cases illustrate a considerable variety of pathological conditions. The mere finding of splenomegaly is not an excuse for operation. I would rule out interference in such diseases as malaria and syphilis, although trauma of the spleen in the subject of malaria may necessitate operation, and such a spleen has been repeatedly removed with success. I would discourage operation also in leukaemia and in Hodgkin's disease. In pernicious anaemia I am not convinced that operation is called for; certainly not if the spleen is small. It may be that there are various types of pernicious anaemia and that some of them are more suitable for operation than others. But in splenic anaemia, if the patient's health and development are chronically poor, if repeated attacks of splenic pain occur, if from its size the spleen is distressing, and above all if the danger of haemorrhage seems to have supervened, I have no doubt the spleen should be removed, and that without waiting too long. For if the disease is allowed to advance to the later stage when cirrhosis of liver and perhaps ascites have developed not only is the operation more difficult but the chances of ultimate success are lessened owing to the changes in the liver. The greatest successes of splenectomy seem to have been achieved in cases of acholuric jaundice, like Cases III and IV of my series. There are, however, mild cases of this disease which may not require operation. But if haemolysis is extreme and the patient's condition deteriorating the operation should be recommended, and splenectomy has been found to bring about complete and permanent cure. In all cases one must be prepared for unexpected results from the pathological examination of the spleen after operation and my most striking example of that is the case of tuberculous spleen (Case V).

I would like to thank Sir Kennedy Dalziel for his keen interest in and skilful surgical treatment of my personal cases, and Professor Muir for the trouble he has taken in reporting on the pathological findings.

II.—E. H. KETTLE, M.D.,

Pathologist, St. Mary's Hospital, London.

SPLENOMEGALY is a comparatively common condition, and is a more or less prominent feature in the pathology of a variety of diseases. Often it is merely incidental and of quite secondary importance. In typhoid fever, for example, or in infective endocarditis, the enlargement of the spleen rarely calls for any special notice; and even in such conditions as spleno-medullary leukaemia, when the massive spleen forms an integral part of the pathological picture, it still remains only a part. But when all such forms of splenomegaly are excluded there remains a residue of cases in which enlargement of the spleen is the prominent clinical and pathological feature.

In recent years the tendency to treat these forms of splenomegaly by splenectomy has become more and more pronounced, but it must be recognized that this treatment is purely empirical. Now, while no one will demand that medical and surgical treatment must always wait upon an exact knowledge of pathology—for this would almost reduce us to therapeutic impotence—and while no one will deny the triumphs of empiricism in clinical practice, yet when surgical interference implies, as it does in these cases, the removal of an organ, it is not too much to ask that we

* Sir Kennedy Dalziel performed splenectomy on this patient on August 3rd. Unfortunately, as the result of giving way of stitches, a mild peritonitis supervened and caused death six weeks later.

should at least consider what we are removing, even if we are undecided upon the justification for this course of action.

The Physiology of the Spleen.

Our first difficulty in attempting to understand the pathology of the various types of anaemia is the influence of the normal physiology of the spleen. The spleen is a mysterious organ, and we know little of the part it plays in normal life; but one thing, at least, is certain: neither functionally nor anatomically is the spleen an entity in the sense that organs such as the liver and the kidney are, but structurally and physiologically it must be regarded as a constituent of a system or systems. Attempts have been made to link the spleen physiologically with the ductless glands and the sympathetic nervous system, and also with the alimentary canal, but the evidence in support of these views is as yet scarcely conclusive. But the place of the spleen in both the haemopoietic system and the reticulo-endothelial system is well established.

As a constituent of the haemopoietic system the spleen is chiefly active in foetal life; after birth it ceases to form red or white cells, except in pathological conditions, when the pulp may undergo a myeloid metaplasia. A moderate degree of this may sometimes be seen in pernicious anaemia and even in acholuric jaundice. I have seen it very pronounced in polycythaemia rubra, and it is, of course, a commonplace of myelogenous leukaemia. But it must be remembered that any abnormal cells present in large numbers in the circulation will tend to accumulate in the meshes of the pulp, and give the appearance of a local origin. However, though it is not normally active as an organ of haemopoiesis, the spleen is active throughout life in removing senile or imperfect red corpuscles from the circulation. This is effected by phagocytosis carried out by the endothelial and reticular cells of the pulp and not by any extracellular process of haemolysis; an important fact which must be borne in mind when considering the possible influence of the spleen in the anaemias.

Probably the most important rôle of the spleen is that which it performs by virtue of the membership of the reticulo-endothelial system which it shares with the bone marrow, the lymph nodes, and the liver. In this capacity it acts as one of the great phagocytic organs of the body, and is intimately concerned in processes of infection and immunity. Organisms reaching the spleen, either in the bodies of mobile phagocytes or in the blood stream, are engulfed by the endothelial and reticular cells, and if not destroyed may remain latent for a considerable period of time; in these circumstances they are obviously dangerous as a possible source of general infection. Such a condition is commonly seen in the splenomegaly of malaria, and a similar process of phagocytosis, with incomplete destruction of the microbes concerned by the corresponding cells of the bone marrow, is an important factor in the incidence of acute osteomyelitis and tuberculosis of bone. There is also a good deal of evidence to show that the production of immune bodies takes place in the spleen and bone marrow, for in guinea-pigs infected with cholera vibrios or typhoid bacilli extracts of the spleen and marrow are found to be far richer in these substances than extracts of other organs. Further, it has been shown that splenectomized rats are more liable to infection than normal animals.

Experimental Work.

An enormous amount of experimental work has been done in the attempt to discover what part the spleen plays in normal life. R. M. Pearce and his co-workers have been pre eminent in this field, and in their various publications, particularly in their book on *The Spleen and Anaemia*, the literature of the subject is well surveyed. Two main lines of investigation have been pursued—the excision of the spleen, and the administration in various ways of splenic extracts. On the whole, the results have been disappointing, and there is a considerable discrepancy between those obtained by different workers. The administration of splenic extracts has given little or no information, and in any case such a line of research must always be scrutinized with care. Reasoning from the analogy of the action of thyroid and other extracts of the ductless glands, it has almost come to be accepted that the action of an extract of an organ is invariably the same as the action of the whole organ in the body. But this is not always so. The red blood corpuscle is essential to life, but the haemoglobin extracted from it is not only useless but actually poisonous when present free in the circulating plasma.

Excision of the spleen has given rather more definite results. It has long been known, of course, that the spleen is not essential to life; and careful experiments, carried out chiefly on dogs, have shown the immediate and remote results of splenectomy. Briefly these are as follows: An anaemia of the secondary type develops immediately and becomes progressively worse for about a month, when it begins to improve, a normal condition of the blood being found in about two and a half to three months. Sometimes the whole reaction may be delayed, and occasionally the final blood count is higher than before the splenectomy. The change affects the haemoglobin content as well as the number of corpuscles. There is, on the other hand, an immediate increase in the number of leucocytes, due entirely to a polymorphonuclear leucocytosis, and usually amounting to three or four times the normal. This falls rapidly to about double the normal, and then more gradually till in from one to four months the count becomes the same as before the splenectomy, though some observers state that there is a relative lymphocytosis.

A more important result, however, is seen in the increased resistance of the erythrocytes which rapidly follows splenectomy and lasts for a long period—months or even years. This increased resistance may be studied *in vitro* by exposing the corpuscles to haemolytic serum, to haemolytic agents such as saponin, or to hypotonic solutions of sodium chloride. Similarly, it may be demonstrated *in vivo*, for jaundice and haemoglobinuria can only be produced in splenectomized animals by the administration of two or three times the dose of a haemolytic poison which is required to produce a similar result in normal animals. How these results are brought about is quite unknown. The increased resistance of the red cells does not depend upon the presence of immature and possibly more hardy forms in the circulation, for these cannot be demonstrated in any numbers. But it is apparently definitely associated with the anaemia, because it is often present in non-splenectomized animals rendered anaemic by bleeding or other procedures. The lessened tendency to jaundice in anaemic animals may possibly be due to the fact that in these conditions the normal destruction of red cells is diminished, and there is less accumulation of haemoglobin and its derivatives in the liver. It is presumed that the liver has a normal saturation point of haemoglobin; if this is exceeded it is no longer possible for it to deal with the pigment and secrete it in the bile in the normal way, and jaundice ensues. In the anaemic animal the liver is hypersaturated with haemoglobin and can tolerate the amount of pigment brought to it as the result of the action of haemolytic agents, so jaundice does not occur. For the splenectomized animals a somewhat similar explanation has been brought forward. Whereas the spleen under normal conditions is the chief site of blood destruction, and rapidly passes on the haemoglobin derivatives to the liver, in splenectomized animals the blood destruction is carried out in lymphatic glands and in the bone marrow. From these widespread foci the haemoglobin derivatives reach the liver gradually and slowly; the liver is not suddenly overwhelmed by these products, but has time to assimilate and secrete them in the normal way. Those explanations, however, are purely theoretical.

Later results of splenectomy are seen in the bone marrow and the lymph nodes. In the bone the fatty marrow is transformed into red marrow. This change, again, is obscure, but it possibly represents the assumption by the marrow of the function normally exercised by the spleen, of the storage of iron for utilization in the formation of fresh red corpuscles. In the lymph nodes there is hyperplasia of the endothelial cells, which become actively phagocytic of red cells and haemoglobin in conditions of artificial blood destruction. The lymph nodes therefore take over the functions usually exercised by the spleen.

These observations have all been made on experimental animals. Splenectomy, except for rupture of the organ, is rare in the healthy man or woman, and the difficulty of obtaining data from the normal human subject is very great. Such cases as are recorded, however, seem to show that the blood counts show the same variations in man after splenectomy as are seen in experimental animals.

The Pathology of the Spleen.

If the physiology of the spleen is obscure, the pathology is even more difficult. The two conditions in which it is claimed that splenectomy is of real value are Banti's disease, or splenic anaemia, and acholuric jaundice. In the primary blood diseases, pernicious anaemia and the leukaemias, there is no

THE LATE SIR JAMES GALLOWAY: HODGKIN'S DISEASE.

theoretical justification for the operation. In malaria the enlarged spleen may be a source of reinfection, and in this, as in other types of splenomegaly, the enlarged organ may cause considerable discomfort. Further, it is liable to rupture spontaneously, or from slight trauma. For those reasons splenectomy may be justified, not only in malaria but in other splenomegalies, although the primary cause of the lesion is not influenced by the operation. But in acholuric jaundice and Banti's disease it is claimed that the spleen is the primary focus of the disease, and its removal is justified on these grounds.

In acholuric jaundice, although the spleen shows no specific change in structure, the results of splenectomy appear to be really very good, and the experimental observation that the fragility of the red blood corpuscle is diminished after splenectomy is a strong argument in support of this treatment; for increased fragility of the red cells is the characteristic feature of the disease. But in a considerable number of cases the fragility of the red cells has not altered after splenectomy, though clinically the patients have been cured by the operation. Further, all our information goes to show that the spleen is not an entity, but that its normal functions are taken over, if it is removed, by other tissues. Is it not reasonable to assume that its pathological or evil influences may likewise be exhibited?

Splenic anaemia, or *anæmia splenica*, presents an even more difficult problem. The terms are frequently employed synonymously, though of recent years the tendency has been to drop the name "*splenic anaemia*," since it is recognized that it may include a variety of conditions besides the disease described by Banti. In a small series of cases of clinical splenic anaemia (*Journal of Pathology and Bacteriology*, vol. xxiii, 1920, p. 413) I found examples of Gaucher's and Stengel's splenomegaly, as well as Banti's disease.

Banti's disease possesses the following characteristics: It occurs in young, healthy adults and runs a very chronic course. The first stage may last for twelve years, and in it the patient exhibits a gradually increasing weakness and pallor with digestive disturbances, progressive enlargement of the spleen, and a moderate anaemia. The second stage is short, being measured in months, and presents attacks of dyspepsia and diarrhoea, an excess of urobilin in the urine and slight increase in the size of the liver. The third stage is practically that of an increasing cirrhosis of the liver. On examination, the spleen in Banti's disease shows little beyond a general fibrosis. In some cases I have found increased phagocytosis of red cells, with proliferation of endothelial cells and the presence of megakaryocytes, but the changes are far from specific. Further, the clinical entity of a chronic disease lasting for so long and with such indefinite symptoms is open to question. It may well be that Banti's disease covers a variety of conditions; in any case I cannot regard it as proved that the spleen is the primary focus. It may reasonably be hoped that careful study of a larger number of cases, combined with further experimental observations, may clear up the obscurity which at present surrounds the condition of splenomegaly. But in our present state of ignorance surgical treatment must be regarded as in the experimental stage.

III.—SIR KENNEDY DALZIEL, M.B., C.M., F.R.F.P.S.,
Surgeon, Western Infirmary, Glasgow.

[Abstract.]

SIR KENNEDY DALZIEL congratulated the previous speakers on the important aid they had given to splenectomy. The subject was one of enormous importance and required all the elucidation that the physiologists, pathologists, and clinical workers could give in determining the functions of the organ and so clarifying the field for surgical interference.

Already it was obvious that haemolytic jaundice and splenic anaemia were materially benefited by removal of the spleen. Tumours, tuberculous disease, and possibly malarial spleen required removal. Splenomegaly by its discomfort ought to be treated by removal of the spleen.

The operation presented no great surgical difficulty, and was not attended by a greater mortality than was to be expected in operations on asthenic patients. The post-operative diminution of the red cells had not been found to decrease, nor increase of the white cells more than was to be expected after a major operation. Little shock had been noted and

the mortality up to date had been nil. No doubt haemorrhage was to be feared, and the distended veins in the gastro-splenic omentum might well cause alarm. A free incision along the inner border of the rectus would generally be found sufficient; in a large spleen a second lateral incision along the course of the tenth nerve enabled the organ to be fully exposed, and after dividing the costo-colic membrane which supports the spleen the vessels could be controlled by a long clamp applied close to the tail of the pancreas. A second clamp close up to the spleen enabled the organ to be removed without soiling the peritoneum. Thereafter the vessels in the stump were ligated separately. Adhesions were apt to be troublesome in cases of splenic anaemia, but if the splenic arteries had been ligated these could be separated with the loss of very little blood if tampons were used as the separation progressed. The spleen was not essential to life. Disorder of it might threaten life, and it could be removed with a great measure of safety.

A FIVE YEARS' SURVEY OF THE ROUTINE TREATMENT OF FRACTURES BY OPERATIVE METHODS;

WITH SPECIAL REFERENCE TO CERTAIN PRACTICAL DETAILS
AND MODIFICATIONS IN THE USUAL PROCEDURES
OF DIRECT FIXATION.

BY

ARCHIBALD YOUNG, M.B., C.M., B.Sc., F.R.F.P.S.G.,

Professor of Surgery, Anderson College of Medicine, Glasgow;
Visiting Surgeon, Western Infirmary, Glasgow.

[With Special Plate.]

THE title of this paper is perhaps somewhat misleading in that it is hardly my intention to deal exhaustively or comprehensively with all the material that the five years have brought under our observation, nor, indeed, do I propose to take up, in detail, or in more than a casual way, the more or less technical points which a full consideration of the large series of cases might suggest. Nor, indeed, would the time allowed to me permit of it.

I propose to deal shortly with some of the conclusions that seem to be suggested by the figures I am able to submit, and thereafter to draw attention to certain special points of technique, and to the particular applicability of certain fixation procedures to certain types of fractures or fracture separations, which our experience, more particularly in the five-year period in review, has led me to deal with more freely than I had formerly done, and perhaps in a manner somewhat novel. I shall express my views and give my reasons for the faith that is in me at the appropriate stage.

First of all, may I refer briefly to a contribution I had the opportunity of submitting to the Surgical Section, at the discussion on the operative treatment of simple fractures, when the Association met in London in 1910? The reference that I wish to make here is to the tendency to limit the term "operative" in such a way as to include only such methods as require open incision. As I said then, I am of opinion that such a limitation is unwarranted. The term "operative treatment" should not necessarily imply open operation. A form of manipulation, especially if under a general anaesthetic, is an operative procedure. So much being said, I may proceed to admit that the chief purpose of this paper is concerned with the more limited field of open operation, and specially with the methods by which direct fixation of bone fragments can best be achieved.

It will be well, perhaps, if I plunge at once in *medias res*, and lay before the Section the facts and figures which emerge from our survey of the five years referred to in the title of the paper.

The period taken is from May 1st, 1917, to May 1st, 1922. The cases included were all confined to my own surgical unit in the Western Infirmary, Glasgow, during that period. No cases have been included from my private practice, nor from any other clinic, nor have there been included any case from other surgeons. A small number, though dealt with in my wards, were not treated by myself; but these were in the hands of my junior colleagues—my assistants—whose procedure and methods are, I know, not antagonistic to mine. It is not that my interest in open operative procedures, and in the modern methods of fixation by open operation, is

fractures of the most varied kinds, is a thing of recent birth; nor is it that I cannot look back upon, and even produce figures from records of, now a good many years. Far from that, I expressed my faith and indicated the general principles that guided me in the open operative treatment of fractures at the discussion on the subject in 1910. I had been operating on many fractures before that time. I have continued to do so since, and on an increasing scale.

My reason for taking this period of five years is that it represents a well-defined period of time, within recent view, for which I have full records, in a single surgical unit over which I have had, throughout the period mentioned, practically complete control. For the figures, the reports of my colleagues who have assisted me throughout, and my own reports, are able to vouch fully. I shall take the opportunity of contrasting the figures of this period with the figures, on certain points, from the records of the Broadstone Jubilee Hospital, Port Glasgow, for the nine years (1908-16) during which I had charge there.

The total number of cases of fractures of all kinds—skull, trunk, and limbs—in my wards in the Western Infirmary, during the five years, May 1st, 1917, to May 1st, 1922, amounted to 693. In the treatment of these, a general anaesthetic was administered in 459—usually chloroform—in some cases several times. The total number of administrations in the treatment of the whole series of fractures was 638. Out of the 693 cases, open operation was carried out in 272. In the remaining 421 there was no open operation. Of the 272 cases submitted to open operation the immobilization of the fragments was secured by some method of direct fixation in 103.

It emerges, therefore, that (1) open operation was carried out in 39.25 per cent. of the series; (2) direct fixation was carried out in 14.86 per cent. of the series; (3) direct fixation was carried out in 37.86 per cent. of the cases of open operation.

In the table which follows (Table I) I have presented the corresponding figures for each year. In the first column are shown the total numbers of fractures treated indoors in each year. In the second column are the numbers of cases submitted to open operation each year. Column three gives the numbers of cases in which direct fixation of fragments was carried out. The fourth column shows the percentage, in each year, of the whole series, of those submitted to methods of direct fixation. The fifth column gives the percentage, in each year, of cases submitted to open operation, in which methods of direct fixation were resorted to.

TABLE I.—Number of Cases of Fracture of all Kinds, Treated in the Wards of Mr. Archibald Young, in Each of the Five Years, May, 1917, to May, 1922, along with the Number of Cases submitted to Open Operation and the Number Treated by Direct Fixation; with Relative Percentages for Each Year.

Year.	Total Fractures.	Open Operation.	Direct Fixation.	Percentage of Total.	Percentage of Open Operation.
1917-18 ..	127	42	9	7.85	21.4
1918-19 ...	135	49	11	8.14	22.4
1919-20 ...	161	62	28	17.39	45.16
1920-21 ..	152	58	19	12.50	32.76
1921-22 ..	118	61	36	30.50	59.0

For comparison is shown the following table from the records of the Broadstone Hospital, Port Glasgow, while under Mr. Young's care, 1907 to 1916.

TABLE II.

	1908	1909	1910	1911	1912	1913	1914	1915	1916	Total for 9 yrs.
Total fractures ...	40	54	74	84	90	101	68	82	74	667
Treated by direct fixation	1	2	6	5	8	1	8	6	3	40
Percentages ...	2.5	3.7	8.1	5.9	8.8	1.0	11.7	7.3	4.05	6%

It will be seen from Table I that (1) the percentage of all fractures in which direct fixation was employed has mounted up from 7.86 in the first year (1917-18) to 30.50 in the fifth

year (1921-22); (2) the percentage of all cases of open operation in which direct fixation methods were employed rose, in the same period; from 21.4 to 59. This is, I believe, a very striking fact. It becomes more striking still when taken in contrast with the figures which I give, from the Broadstone Jubilee Hospital, Port Glasgow, showing, for each of the nine years 1908 to 1916 inclusive, the number of cases of fracture, with the number submitted to direct fixation by open operation, and the relative percentages. (See Table II.) Contrast the highest percentage in this series (that for 1914—namely, 11.7) with the lowest in the present series—namely, 21.4; and again with the percentage of last year—namely, 59.

I feel that I am entitled to advance here, on these figures, the claim that direct fixation of fragments by open operation in an increasing proportion of fractures has been well established. The mere fact that year by year we resort to an ever-increasing number of direct fixations by open operation of itself proves our faith in its efficacy and our belief in its value compared with the older methods. It is not that other modes of comparison are wanting, nor that such other comparisons have not been made. Indeed, following more particularly upon the discussion in 1910, the special methods advocated with so much enthusiasm by Sir Arbuthnot Lane, and their results, were investigated by a committee of the Association, and the report drawn up by that committee will be within the memory of members of the Section. I do not know that the report in question gave much satisfaction to anyone, nor do I think that anyone was really convinced that it proved the case for either side—either the non-operative or the operative. After all, it is well recognized that figures may be made to prove almost anything, provided that one looks at them from the proper angle. Results, too, are apt to be construed differently by different observers, some desirous to be severely impartial—but perhaps not too sanguine or very sympathetic—others disinclined to admit that their own technique or their operative dexterity is in any respect faulty or in any way defective.

The figures of these five years, on the other hand, show that we, for our part—for our part, I say, in that I am desirous to include, in this expression of faith, my various colleague assistants, who have helped me all throughout—that we have not only not lost faith in the methods, but have, indeed, been increasingly confirmed in our confidence in their advantage over the methods previously employed. After all, it is not merely a case of "another scalp to my belt." Anyone who has witnessed many open operations for direct fixation of fractures, anyone who has ever taken part, either as assistant or as principal, in many such operations, will admit readily, I am sure, that it is too often the case that the physical energy and the endurance of all concerned are taxed to the uttermost in their execution; that, in fact, all concerned directly in the operation have very commonly to "sweat over it"—in a very real and literal sense. Speaking for myself, I am bound to say that my own physical strength has too often been stretched to the uttermost in such operations to encourage me to continue to resort to them, were it not that I am more and more convinced of their efficacy, and, indeed, of their unchallengeable superiority, in a very large proportion of cases. Under such circumstances, our continuance—nay, our increasing employment—of direct fixation by open operation would seem to me to be a very powerful argument in its favour.

I shall proceed now to give details of the different fractures dealt with in the series in which direct fixation was carried out. In Table III there is presented a list of all the bones affected, with a note, in succeeding columns, of the actual procedure adopted. The methods included wiring, fixation by different kinds of pins or nails, screws, plates and screws, by combinations of pin and plate; also, in only one case, by ring plates (Adams).

Wiring was resorted to in 21 cases, pinning or nailing was employed, in 29, plating was used in 48, fixation by screws in 2, pin and plate were used together in 2, and ring plates were used in 1. The bones dealt with included lower jaw, clavicle, humerus, olecranon, radius and ulna, metacarpal, phalanges of fingers, femur, patella, tibia, and metatarsus. It will be seen from the table that a considerable number of epiphyseal fracture-separations were treated by this method, including upper and lower epiphyses of the humerus and upper epiphysis of the femur. A few words have to be said of the different types of procedure, as well as of certain special groups of fractures and fracture-separations.

TABLE III.—Showing the Numbers of the Fractured Bones Submitted to the Different Methods of Fixation in the Five Years' Series.

	Wire.	Plating.	Plating.	Screwing.	Pin and Plate.	Ring Plate.	Total.
Lower jaw	7 [*]	7
Clavicle	1	...	3	4
" outer end	1	1
Humerus, upper end	4 [†]	1	5
" shaft	6	6
" lower end (T)	2	2
" lower epiphysis	16	16
Olecranon	5	5
Ulna	3	3
Radius	2	2
Radius and ulna	2	2
Metacarpal	1	1
Phalanx, finger	1	1	2
Femur, upper end	2 [‡]	2
Femur, shaft	12	2	...	1	15
Patella	4	4
Tibia	3	...	22	25
Metatarsus	1	1
Totals	21	29	43	2	2	1	103

* In 4, the jaw was wired direct; in 2, the teeth were wired; in 1, the jaw was wired, and the teeth also.

† One of these was an upper epiphyseal separation.

‡ One of these was a separation of the upper femoral epiphysis.

METHODS AND MATERIAL.

1. Wiring.

The use of wire in the fixation of fractures has fallen to some extent out of fashion. The chief reason for this is, I think, not far to seek. The material used was, for long, silver wire, and this has not the necessary strength to allow of fragments being fixed at all firmly by its use, unless very thick wire is used. Over and over again it must have happened to most surgeons employing silver wire that,

just at the point of securing something like the desired degree of fixation by its use, the wire has snapped short at the twist point, and no end of trouble has followed in the effort to retrieve the calamity. Often, indeed, its use was completely unsatisfactory by reason of this recurring difficulty. Thick wire, too, is always a disadvantage. The finer the wire it is necessary to introduce into the tissues to bury in the bone or to leave embedded in the soft tissues the

Fig. A—Showing different kinds of pins, also "sprigs," used. At the lower part of the figure are seen two long steel pins, actually used in fixing fractures of femoral neck, showing absorption of tip.

better. But, after all, the prime necessity is that the wire so introduced shall efficiently serve the purpose for which it is employed. A wire that is not capable of standing the strain that may be required if it is to be made really taut—for, short of that, it is not of real value as a fixation material—is so unreliable as to be hardly worthy of use.

For some time now I have been in the habit of making use of a brass wire of very much less thickness than I should ever have dreamed of using, or of attempting to use, had it

been of silver. I used it first of all with some little doubt as to its effects on the tissues, and as to the effects of the tissues on it. Experience, however, has shown that it has no obvious harmful effects on the bone or on the soft tissues; nor have the tissues any harmful effect on it. One cannot, say, of course, that the tissues will not produce in time some effect on it. Indeed, from what one has observed even in the case of steel pins long embedded in bone one must have it in mind that, sooner or later, the tissues will exert some resorptive effect. We have observed on several occasions how the sharp point of a long steel pin has been eroded by the tissues, even in a short period of four to six weeks (see Fig. A). But, in any case, it will be found, I believe, that even the thinnest grade of brass wire that we have employed will resist the action of the tissues for a much longer time than the period required of it.

I am able to show to the Section samples of this brass wire in different grades—most of them, as will be seen, of comparative thinness—which I have been able to obtain from the original source where I got my first supply. Each grade is marked with its appropriate number according to the wire workers' gauge. The samples of wire shown have the following numbers, and I am able to give, with the numbers, the thickness according to gauge, thus:

Brass wire—

No. 21032 gauge.
22028 "
23024 "
24022 "
25020 "
260184 "
270164 "
280148 "
290136 "
300124 "

Sample of nickel wire—

No. 230148 gauge.

Sample of monel wire—

No. 300124 gauge.

From the same source I have obtained recently samples of two other kinds of wire, which may prove to have certain advantages. The one is of pure nickel, the other is of a comparatively new metal, named monel metal. It is, I believe, an alloy of copper and nickel (copper 67 per cent., nickel 33 per cent.), is very pliable, and my friend claims for it that it is of greater tensile strength than either brass or nickel wire of the same thickness. I have not tried it yet.

The point of importance, however, is that one is not restricted to the use of silver wire; indeed, silver wire is, in my opinion, quite unsuitable, for the reason stated above. Possessing, however, in brass wire, or in one or other of the wires mentioned later, a really efficient and reliable substitute for the older silver wire, I find, once more, a considerable field for the operation of wiring. It may be said, here, that it is my practice to pass the wire through the flame of a spirit lamp immediately before introducing it. It has been sterilized in the usual way beforehand, of course. This final heating has the effect not only of "making sear" the sterilization, but it makes the wire much more pliable, even if it does take away—perhaps because it does—its temper.

By using brass wire we can obtain a very high degree of stabilization. Repeatedly I have been able to tighten a wired junction so completely as to fix it by one a single wire. In one case of fracture of the lower jaw, for example—the case is shown in Fig. 1—it will be seen that there is only one small wire used. Yet the fixation was absolute, and the result was never in doubt. It was as nearly as possible perfect.

In the series under consideration wiring was employed twenty-one times as a sole fixation agent—for fractures of the jaw, olecranon, patella, clavicle, tibia, and in one case of fracture of a phalanx. The results were in all cases good. It may be said, in passing, that in fractures of the lower jaw we may combine—and often do—direct wiring of the bone with indirect fixation of fragments by wiring of the teeth. Brass wire serves admirably for this purpose also, and it will be obvious to anyone who has ever made the attempt to wire the teeth in such circumstances what a great advantage it is to be able to employ a wire of such fineness, and which can be slipped so easily between the often very closely set teeth. A thicker wire would be quite useless for the purpose. The thin wire, too, can be wound several times round the teeth it is intended to secure.

2. Pinning or Nailing.

It will have been observed that the group of cases treated by this method is a relatively large one—29 cases in all. Using, at first, different sizes of the old steel plated pins, such as have been in use for many years for such purposes as fixation after resection of the knee, we have, for certain special purposes, resorted to much finer agents. Now we are following, to some extent, the same idea as justifies our use of a finer wire. Obviously, the less bulky the pin or nail, so long as it is of sufficient strength to fulfil its paramount purpose, the better it must be; the less likely will it be for bone fragments to be split in its introduction; the less drilling will be necessary; the less bone dust will be scattered about the tissues; the less disturbance of the parts generally will be required (see Fig. A).

For certain purposes, of course, such as fixation of the upper femoral epiphysis, or of fractures of the femoral neck, by a nail driven along the femoral neck into the head, a very long nail is required. A nail of such a length must be thick and strong. So also in fixation of fractures of the upper end of the humerus, where a long nail is employed—whether it be passed from the epiphysis down into the diaphysis, or in the reverse direction. A thin, light nail will not serve in any of these cases (see Figs. 2 and 2A).

In another class of fracture, or fracture-separation—namely, fracture separations of the lower epiphysis, or epiphyses, of the humerus—a much smaller, much finer nail or pin is much more suitable. We used to employ at first nails of the ordinary type as referred to above, but of course of much shorter size. I very soon came to the conclusion that a much finer agent must be obtained. Accordingly I began to use very fine pins, or "sprigs"—you may perhaps know them by different names. I think the carpenter calls them "sprigs" or "fine wire nails." The first I used I took from a small store kept in my house for the purpose of fixing photographs to the wall. These were slightly flattened in section, head as well as nail length. These we have been using for a long time now are of the rounded type, and we procure them as we require them from the infirmity carpenter. Their cost is practically nil. We do not worry about plating them. Even if we do not in time remove them, though they may erode in due course, they do no harm in the tissues or in the bone.

I have used them now in a considerable number of cases, both alone and also in combination with other agents. It is not only in the case of fracture-separations that they find their field of usefulness. I have used them in fractures of forearm bones (Figs. 3 and 3A) and elsewhere. In the more recent months I have been employing them in certain badly displaced fractures of the phalanges of the fingers, and in similarly badly displaced fractures of metacarpals. The pin is passed from one fragment—usually the smaller—into and along the other, being left as a permanent central axis in the corrected phalanx. It does no harm in its new bed.

One advantage in the use of these fine pins or nails is that they are so easily driven home, and that they do not split the often very fragile fragments. Likewise, they do the very minimum of damage to epiphyseal cartilage or growth centres. In a young person it is often possible to drive the fine pin well home without any preliminary drilling, without any great force being called for. Occasionally a few light taps with the heavy end of a periosteal elevator may be required, but that is all.

3. Plating.

So much has been written regarding plating that it is not necessary to say much more here. Besides, we have had to-day, from another surgeon, already a paper on the subject. Suffice it to say that we have employed, during the five-year period, the method of fixation by plate and screws in 48 cases, and certainly with satisfaction. We have applied it to the clavicle (Figs. 11 and 11A), forearm bones, humerus, femur, and tibia. Properly employed, it gives satisfactory fixation, and does not retard union. Whether the plate and screws require to be removed later on does not greatly matter, so long as they serve their immediate purpose. I am of opinion, however, that more and more the field for application of plating will tend to become narrowed down to shaft of humerus, shaft of femur, and to tibia. In other situations, it seems likely that wiring or pinning will become the operation of choice.

As in wiring and in pinning, we always pass the plates and screws through the spirit lamp flame prior to introducing them.

4. Screwing.

In certain fractures of the shaft of the femur, or of others of the longer bones, it will occasionally happen that the introduction of a plate may be undesirable or difficult. In two cases of the kind in this series we fixed the fragments quite satisfactorily by screws alone. One, by my colleague Dr. A. J. Hutton, was fixed by one screw. The other, by myself, was fixed by two screws. Both did well. It is probable, however, that this method will have only a limited application.

5. Pinning and Plating.

In the series are included two cases of very severe fracture of the lower end of the humerus, T-shaped, into the elbow-joint. Every surgeon knows how difficult these fractures are to deal with by any other method than open operation. Any surgeon who has tried will know also how difficult they are to deal with, even by open operation. The chief difficulty lies not in the freedom of access to the fragments, but in the great difficulty there is in keeping the lower fragments in apposition while they are fixed to each other, and while they are being fixed to the shaft fragment. We have found, as Figs. 4, 4A, and 4B show, how great is the tendency for the two lower fragments to rotate on their long axes, by the action, no doubt, of the group of flexor-pronator and extensor muscles respectively, arising, as they do, from the epicondyles and epicondylar ridges. We have adopted the expedient of first fixing the two lower fragments by the introduction of a long steel pin, passed from side to side, right through both, and thereafter applying the X-shaped plate and screws. The x-ray illustrations, which I am able to show, will abundantly illustrate the difficulty referred to and the result of the method as described.

I may say that in both of the two cases referred to the result as regards union, outline, and function has been most gratifying.

6. Ring Plates.

The use of Adams's ring plates may be dismissed in a very few words. We have used them only once, and they did not give satisfaction. The plates were not difficult to apply, but they shifted somewhat, and allowed of the fragments—of the femur—assuming an acute angular bend, which did not leave a good effect, aesthetically; nor was function easily restored. I do not think that we are at all likely to employ them again.

One more word, with reference to methods and material, may be permitted here. It may be assumed that the simpler the methods, and the simpler the materials, the greater will be the field of application of the direct fixation procedure in the open operative treatment of fractures. Complicated apparatus, complicated instruments, heavy nails, screws, and plates will always be undesirable if simpler appliances and materials are available. I ventured to say, in my contribution to the discussion in 1910, that I had no use for certain of the complicated instruments advocated by some surgeons. I am of the same opinion still.

The most important requirement of all is a competent assistant (preferably a plurality of competent assistants), and such I have had the great good fortune to possess all along. I am also indebted more than I can say to the willing help of my nursing staff. And I desire here to make acknowledgment of this.

In what remains of this paper I wish to refer to the open operative treatment of three types of injury in which we have been doing, for some time now, a considerable amount of direct fixation. These are:

1. Epiphyseal fracture-separations.
2. Certain fractures of the phalanges and metacarpals.
3. Fractures of the outer end of the clavicle and, incidentally, that troublesome injury, so difficult to treat satisfactorily in any other way—namely, dislocation or fracture-dislocation of the outer end of the clavicle, with displacement upwards of the outer, or acromial, end of the clavicle.

Fracture-Separations of Epiphyses.

Many of these, of course, call for no open operative interference. There is often no displacement at all, and the fragments are often capable of easy maintenance in their proper relation with the diaphysis; perhaps by a simple splint, often without splint altogether; nothing more than a firm bandage

may be necessary. This applies to most fracture-separations at the lower end of the forearm bones, and to others such as the lower epiphyses of the tibia and fibula. Even in these, however, the correctness of apposition should be made certain by manipulation under a general anaesthetic, and where possible checked by x rays subsequently.

This is, unfortunately, not always, or indeed usually, the case with the lower end of the humerus. If it should happen to be slight, or nil, we consider the fact a fortunate one, both for the patient and for the surgeon. It means, as a rule, little trouble and a favourable result, as regards appearance, function, and later growth. Where, however, displacement is, as so often happens, more or less marked—often extremely marked—open operation with direct fixation is in my opinion imperative. I used to think that many such injuries, even with considerable displacement, could be effectively treated by non-operative means, but that idea I have given up completely. I here admit unhesitatingly a change of view on the matter.

I remember that Sir Arbuthnot Lane, in 1910, said in this connexion, "an epiphysis if separated rarely requires to be retained in position by a plate and screws; but should it be necessary to employ such means the plate should be removed as soon as union has taken place, to avoid any interference with the growth of bone at the epiphyseal line." I wonder if he is still of the same opinion as to the necessity for direct fixation in these cases. I, at any rate, cannot subscribe to this view. In any case plate and screws are not at all suitable for the treatment of such injuries, where one has to deal with the small fragile bones of young people, and with small, delicate epiphyseal fragments, which ought to be damaged as little as possible. The employment of fine pins, or "sprigs" such as I have referred to already, is a much more easy, more effective proceeding, and I think their use gives the very minimum of injury to the delicate growth areas.

If it be said, as said it is by some, that even without operative means—open operation—it is possible to get union, in many cases, with quite good function as a result, I still urge that open operation affords the best prospect of avoiding such interference with growth later—in virtue of disturbed epiphyseal centres—as every surgeon knows to be a very real and serious possibility.

It is certainly the case that there are many such injuries where, even with open operation, it is not always easy to accomplish accurate readjustment of a separated epiphyseal segment. How much more, then, must be the difficulty if no open operation is done!

Now, it is just this accurate readjustment of separated epiphyseal centres that, in my opinion, makes all the difference between practically normal continuance of growth of the bone, and the failure, or defect, or irregularity of growth which is so likely to follow if non-operative treatment is adopted, and displaced epiphyseal centres are not brought back into their proper relations. If they are brought back to their proper positions, with reference to the diaphysis and to each other, my opinion is that normal, or almost normal, growth is likely to occur. We shall not have to regret, then, the ugly "gun stock" deformity, and other deformities that we have all had occasion to warn parents of for the future of their child.

I had a very instructive lesson in this respect a year or so since, when in the course of a resection of the knee for tuberculous disease I had the misfortune to completely disengage the whole lower epiphysis of the femur from the diaphysis. I fixed it in position again, but feared the worst in the way of suspended growth. To my surprise such suspension of growth did not result, as shown by continued increase in length of the limb, and as demonstrated beyond doubt by x rays many months afterwards.

I believe that if accurate reapposition of epiphyseal centres be not brought about the failure to do so is the very factor that will lead to the growing parts being smothered up in callus and crushed in new, irregular bone, which will effectually lead to suspension of the normal growth at the epiphyseal lines.

That nothing short of full exposure of the fracture-separation area will suffice, if accurate readjustment is to be accomplished, my now considerable experience of these cases has proved to completeness. I have found the whole lower epiphysis of the humerus so completely displaced as to be tilted in almost unbelievable fashion;

I have, on quite a number of occasions, found it almost completely inverted, articular surface looking upwards, and epiphyseal cartilage downwards. I have found a fragment, including the capitellum, part of trochlea, and the external epicondyle, so completely tilted on its axis that the articular surface of capitellum looked outwards, while the fractured surface looked inwards, towards the radius. We have had several such cases.

Then separation of the centre for the internal epicondyle, especially if the muscular attachments to it and above it are torn away, means so considerable longitudinal displacement that nothing short of open operation and direct pinning of the fragment in its proper relation can possibly suffice.

In short, the argument in favour of operative treatment of these lower humeral epiphyseal fracture-separations—open operation, accurate readjustment, and direct fixation—seems to me sound beyond dispute.

As to the method of procedure little is necessary to be said. In almost any type of epiphyseal displacement at the elbow, whether of the whole lower epiphysis or of one or more of the separate centres there, I have found the best incision one made just behind the radio-humeral joint, and extending a little way upwards. The joint named is first opened, and usually from this opening it is possible to accomplish all that is desired. The fragment or fragments, once adjusted, are readily fixed by one or two—generally one is sufficient—of the fine sprigs I have described and shown here. The pin is pushed easily home, and the wound is completely closed without drainage. I generally put the limb up flexed. It is usually placed for a few days on a simple splint, and may be put in a light plaster-of-Paris sheath for at most two or three weeks. From that time the child is given almost complete freedom in movement. (Figs. 5, 6, 7, 8, 9.)

CERTAIN FRACTURES OF PHALANGES AND METACARPALS.

It may be conceded quite readily that most simple fractures of the phalanges of the fingers admit of satisfactory treatment without open operative means, and probably even most compound fractures are capable of adequate adjustment without direct fixation of fragments, but we have had recently several examples of such fractures—rather neglected at the time of their occurrence—on which there had resulted such tilting of the fragments, and such a degree of displacement without some method of adjustment by open operative means was quite impossible. It has happened, too, in several cases, that a single x -ray view failed to display adequately, or at all, the considerable palmar displacement which was in the main responsible for the annulment or limitation of function. It is obvious that serious disability must result in such cases from the sharply tilted fragments interfering with the flexor tendons. In several cases, examination of a simple antero-posterior x -ray picture gave the impression that the fragments were not much, if at all, out of place, and yet the other view completely altered the picture, and showed how necessary it was to carry out open operative treatment. Such interference of an open operative nature is desirable, also, in not a few fractures of metacarpals where the break has taken place so close to the end of the bone that no non-operative method could possibly ensure proper control of the very short fragment.

Our method in such cases is the same as in the fractures of the phalanges to which I have just referred. The fracture area is exposed usually by a lateral incision, slightly to the dorsal aspect of the finger. The extensor tendon is avoided, or drawn out of the way, and the fragments are disengaged by the simplest means. The ends are then freshened, and brought into as good alignment as possible. A single fine sprig is then driven home, usually from the smaller fragment, along the central canal or soft central bone of the larger fragment, the length of sprig being so chosen as to measure about two-thirds of the length of the reunited phalanx, and the head of the sprig is either nipped off with bone forceps, or buried in the substance of the smaller fragment. It is remarkable how easy is the whole proceeding, and how effective the adjustment. The wound is closed, without drainage. A simple splint may or may not be used, according as the operator has confidence in the fixation or not. In any case, it should be dispensed with as soon as possible.

We have been pleased with the results in the cases we have tried the method upon. Bony union has been good, alignment has been well maintained, deformity has been almost nil, and the functional result has been gratifying.

FRacture of Outer End of Clavicle and Dislocations or Fracture-Dislocations at Outer (Acromio-Clavicular) End of Clavicle.

The treatment of fractures of the outer end of the clavicle has been recognized for long as difficult and unsatisfactory. Further, the outer fragment is often so small that application of a plate and screws is often quite impracticable.

Recently we had a very striking example of the condition in which the small outer fragment was displaced forward and so tilted as to rest on the front of the inner fragment in a direction almost directly forward. It was quite impossible to control it in any other way than by operative means. The method adopted for its treatment was simple, but completely effective. The fracture area was exposed, the small fragment was fixed temporarily, and a long resection pin was passed from a puncture wound made externally right through the fragment and on into the shaft of the bone. This effectively immobilized the fragments. The main wound was closed and the arm was fixed up across the chest in a light plaster-of-Paris sling, which was worn for three weeks. Thereafter it and the long steel pin were withdrawn. Union, position, and function were in every way satisfactory. (See Fig. 10.)

I interpolate here, though it is not quite in the ordinary purview of this paper's purpose, reference to the use of a similar expedient which I have employed several times in the treatment of the troublesome upward displacement of the clavicle at its outer (acromial) end, in the not uncommon dislocation at the acromio-clavicular joint. I know of no other way of controlling the upward rising acromial end of the clavicle than by fixing it by plate and screws, or by pinning. Wiring is of no real use. The introduction of a simple long steel pin in this way I have found easy, effective, and satisfactory. Further, the result as regards function, movement in every direction at the shoulder, and strength of limb, has left, in the cases in which we have employed the method, little to be desired.

CONCLUSION.

It but remains for me to mention—it should not be necessary to do more than mention—that, in all such procedures as are involved in the open operative fixation of fractures, such as are dealt with in this paper, asepsis is assumed. I mention this but to pass from it. In none of the cases in this series did any trouble arise from the introduction of sepsis. All pursued an aseptic course.

THE TEMPORARY PLATING OF FRACTURES OF THE LONG BONES.

BY

G. H. EDINGTON, D.Sc., C.M., F.R.F.P.S.G.,

Surgeon, Western Infirmary; Lecturer in Clinical Surgery, University of Glasgow.

THE deliberate operative treatment of recent simple fracture may be said to have commenced in 1877 when Lister wired a fractured patella. The way to this had been prepared by similar operations on ununited fracture of the olecranon (Lister, 1873) and of the patella (Hector Cameron, 1877). In the same paper, originally published in 1883, in which the above facts are set down, Lister strongly commends the practice of wiring in ununited fractures of the shafts of the long bones, and he gives details of its employment in a case of malunited fracture of the femur about the junction between the middle and upper thirds. It must not be forgotten that these operations were rendered possible by the antiseptic method of treatment, and in the paper in question Lister emphasizes what he believed to be "the truth, that by antiseptic means we can do, and are bound to do, operations of the greatest importance for our patients' advantage, which, without strict antiseptic means, the best surgeon would not be justified in recommending. . . . That which justified me in operating . . . was simply the knowledge that strict antiseptic treatment would convert serious risk into complete safety" (loc. cit., p. 469).

In the case of the olecranon and of the patella accurate apposition of the fragments is required if crippling is to be avoided; and the need of such apposition is much more clamant in them than in the case of the long bones. That circumstance may explain why surgeons were slow in systematically applying operative treatment to the latter. The impetus was not given, in this country at any rate, till the appearance, in 1905, of Arbuthnot Lane's monograph²;

but, since then there has been an increasing number of surgeons addressing themselves to treatment by open operation. Lane's teaching focused the attention of many on the results of non-operative methods, and stimulated efforts towards the improvement of the same. But Hey Groves³ is correct in saying that it has also served as a stimulus to workers to improve operative methods. To-day it may truly be said that the operative treatment of fractures has come to be recognized as a method of wide applicability. It seems to me that it is to be recommended in all cases where the anatomical form of the bone has been altered sufficiently to impair the function of the part, and where restitution of that form cannot be obtained by non-operative methods. This recommendation is subject, however, to the proviso that the operation be performed only in suitable surroundings.

It is admitted that incomplete anatomical restitution may be compatible with a good functional result. This is especially the case in fractures of the upper limb; but it obtains also in other fractures in children in whom the education of the parts is preceding; and in slightly older patients in whom re-education of the limb is comparatively easy. In adults, and still more in middle-aged and elderly subjects, such re-education of the muscles and readjustment of the joint surfaces is more difficult. It may easily be incomplete, and a weakened or painful limb may result, a matter of special importance when the fracture involves the lower limb. In any case re-education takes time and delays the recovery of the part. It is to obviate or minimize the need for such re-education, and consequently to expedite restoration of function, that open operation is employed. By operative treatment the surgeon is enabled not only to place the fragments in good alignment, but also to coapt the broken surfaces without muscle or fibrous tissue intervening, and at the same time to employ, if required, some form of retaining apparatus. In this way an almost complete restitution of the form of the bone may be obtained, and the way presumably opened to a speedy firm bony union. I say "presumably" of set purpose; because, as I shall have later to mention, such union does not always follow.

Of the various forms of retaining apparatus at present in use I wish at present to confine myself to the consideration of steel plates and screws, and to record conclusions based upon observations extending over the last dozen years or so.

Bones.

The fractures which most commonly require plating are those of the tibia, the femur, and, less frequently, the humerus. Still less frequently it is required in the case of the fibula, the forearm bones, and the clavicle.

Exposure of Seat of Fracture.

The skin having been purified by a watery solution of phenol, the fracture is exposed through either a linear or a curved incision, which latter allows of a flap being raised. The linear incision is employed where the bone has a good covering of muscle—for example, the shafts of the humerus and femur, and the antero-lateral surface of the tibia. In these situations, as the retractors are removed the muscles fall together and separate the seat of fracture from the skin wound. The curved incision is found more suitable when the plate is to be applied to a subcutaneous area of bone—for example, the medial aspect of the tibia. In this situation a flap is desirable, and its replacement buries the fracture and the metal appliance away from the skin wound. In the case of the leg this incision lies for the most part over the soft tissues behind the inner border of the tibia: the horns alone extend forwards over the subcutaneous bony surface.

When Operation should be Performed.

It is advisable in simple fractures to operate as soon as possible after the skiagram has been obtained. If the operation be done early not only will the skin be free from possible vesication or ulceration, but the adjustment of the fragments will be comparatively easy. If interference be delayed the skin may have in the interval become septic, while the muscles will have become fixed, and their extensibility impaired by infiltration with exudate. When this has happened the adjustment of fragments may be fraught with great difficulty, and may require very forcible handling, either by an elevator or the more powerful Murphy's lever; in some cases—for example, the femur—overlapping fragments may be angled on one another and the bone then

straightened by manipulation. After coaptation the fragments may be held in position by Lano's forceps or Lowman's clamp till the plate is adjusted and screwed on.

In the case of a compound fracture one must play for safety, and in such I purposely delay plating till after the lapse of a few days, when it may be ascertained that sepsis has been secured.

Periosteum.

The periosteum should be incised and stripped off the area of the bone to which the plate is to be applied. This stripping not only removes the periosteum from hurtful pressure, but it allows the formation of more callus than would be likely if the plate were fixed down on the top of the periosteum. In fractures which have been plated there is a tendency to lessened formation of callus. This tendency is probably due to close coaptation and immobilization of fragments, and is a factor in the production of delayed or of non-union, when such occurs.

Plates and Screws.

The pattern which I have found most convenient is Lano's simple flat plate with straight parallel edges. As a rule I employ one with four holes: in some cases a three-hole plate suffices. The plate should be sufficiently pliable to allow of adjustment to a curve or angle in the long axis of the bone. I always use Lano's screws. It is said by some that the sharp thread of these screws does not give a secure hold on the bone, and Hey Groves (*loc. cit.*, p. 177) gives it as his opinion that a screw used for dense bone ought to be of the engineer's variety. This opinion would seem to be based on the fact that this author expects that a plating operation should render the patient independent of external splints.

Splints.

I make it a rule to secure immobilization, so far as that is possible, by the use of external splints. My object in plating is merely to keep the fragments in accurate coaptation till the chance of displacement is over, after which I remove the plate and screws. Before going into the details of the removal of plates, I would just mention that in applying splints care should be taken that the limb be kept in such a position as will facilitate restoration of function after the fracture is healed. It seems almost superfluous to mention this; but I have, both in the army and in civil practice, frequently come across cases in the lower limb where insufficient attention to the position of the foot had led to crippling of an obstinate nature. When the time had come to discard the splints it was often found that the ankle had stiffened with the foot in the pointed position. Passive movement under an anaesthetic had frequently to be resorted to, and in some cases operative lengthening of the tendo Achillis was required before the foot could be restored to the position at right angles to the leg—a position which is essential to the patient who is beginning to walk again.

Removal of the Plate.

This is carried out as a routine, with the object of avoiding possible trouble in the future. I refer to pain in the bone, swelling of the bone and neighbouring soft parts, loosening of the screws, sometimes sinus formation, and occasionally even refracture. I am aware that some surgeons hold the opinion that if the operation has been aseptically performed such trouble is unlikely, if indeed it ever occurs. I regret that I cannot agree with such opinions; and I remove the plate when it has fulfilled its function as an internal splint—that is to say, during the third or fourth week. During the operation of removal I am accustomed to find in the wound a great or lesser quantity of thick muddy fluid of dull greyish-yellow, sometimes greenish-yellow, colour. This fluid is usually struck between the bone and the plate, and if unassociated with a sinus or communication with the skin surface it has always been proved sterile on attempts at culture. It is also unassociated with any necrosis of the bone, and does not prevent aseptic healing of the reopened wound in the soft tissues.

At the operation of removal the screw nails may be found holding as firmly as when first introduced, or they may be loose enough to be picked out with dissecting forceps. The difference depends on the reaction of the bone to the presence of the foreign body. When they are loose I find as a rule that union of the fracture is proceeding satisfactorily. On the other hand, it seems to me that when they are holding

firmly there is a deficiency or want of reaction on the part of the bone—in other words, that the bone is sluggish; and I am not surprised when in such cases I find delayed union. Of course it may be that loosely holding screws permit some movement of the fragments, with consequent increase of callus production; but such a view does not explain the loosening of the nails.

After-Treatment.

Splints are discarded about the end of the sixth week; and, in the case of the lower limb, a plaster-of-Paris support is applied and kept on for four to six weeks. Should it be found, in the case of the leg, that when splints are left off the union is not firm, my practice is to encase the limb from the toes to mid-thigh in plaster-of-Paris, with reinforcing wooden strips on inner and outer sides. The patient is then made to walk about with stiff knee. This ensures mild traumatism of the ends of the fragments, by no means a new device in the treatment of delayed union,⁵ and usually succeeds in bringing about firm union. If, as rarely happens, this manoeuvre be unsuccessful, comminution at seat of fracture is practised. For this purpose a chisel or osteotome is carried in long axis of the bone from the upper fragment through the weak union into the lower fragment.

Comminution for non-union has recently been recommended by Waring and Milligan.⁶ These authors freshen the ends of the bone and expose the medullary canal before comminuting the bone. In the few occasions on which I have had to employ comminution I have simply used the chisel or osteotome as above described, and have found the procedure to give very certain and satisfactory results.

Conclusions.

1. Operative treatment should not be a routine, but properly reserved for cases where non-operative measures fail to secure restitution of fragments.
2. Temporary plating is in the case of the tibia, femur, and humerus a reliable form of internal splinting.
3. Skin incision should be placed so as not to be in immediate contact with the fracture.
4. With the object of encouraging the formation of callus, the periosteum should be reflected from the area to which the plate is to be applied.
5. Flat four-hole plates, bent if necessary to fit, and fixed with Lano's screws, give satisfactory results.
6. External splint support is necessary.
7. Plates and screws are removed in from three to four weeks.
8. Looseness or fixity of screws at time of removal is in proportion to reaction or sluggishness of the bone, and would seem to be an index to the progress of repair.
9. Plating does not prevent delayed or non-union.

TREATMENT OF UNUNITED FRACTURES BY BRIDGE GRAFTS.

BY

DONALD DUFF, F.R.C.S. EDIN., F.R.F.P.S.G.,

Visiting Surgeon, Ministry of Pensions Hospital, Bellahouston, Glasgow; Assistant Surgeon, Royal Infirmary, Glasgow.

ANY discussion on the treatment of fractures is incomplete without reference being made to a class of fracture which has been brought to our notice by the late war, and to which the usual methods of treatment of recent fractures do not apply. I refer to those cases where there has been considerable loss of bone in addition to violent sepsis at the seat of fracture. In some of them as much as three or four inches of a gap has been made in the continuity of the bone, and the problem we have to face is the bridging of the gap. Most of these cases have been extensively involved in a septic process and not only the bone but the soft parts around are converted into scar tissue which encapsules micro-organisms. If a sufficient, and indeed a generous, length of time has not elapsed since the final healing of the soft parts, sepsis will flare up almost inevitably if operative procedures are attempted. I have had the opportunity of treating over

sixty of these cases, and I have learned some lessons which I desire to bring before the notice of the Section.

General Considerations.

In the first place those cases must have efficient and sometimes prolonged preliminary treatment of the scar tissue; and as far as possible deformities which have resulted from contracting scars must be corrected by suitable mechanical means.

I have had good results from complete excision of the scar and the use of pedicle or tubed skin grafts to fill in the area thus excised. This method serves two purposes: First, it shows whether latent sepsis is present in the tissues before operating on the bone gap; because if no flare-up occurs the gap can be dealt with as soon as the skin graft has healed. Secondly, it provides healthy skin through which to make the incision when the bone gap is bridged. I have used the tubed pedicle graft for shoulder cases and legs. Small scars are given a course of deep massage and ionization of two or three weeks' duration as a test for the presence of latent sepsis.

The operation for the bridging of the bone gap must be carried out with the most scrupulous care as regards asepsis. The bone scar tissue, if this has not been already removed when excising scar tissue in the soft parts, must be cut away widely until healthy bone is encountered, and if it can safely be attempted the removal of all scar tissue—soft parts and bone—should be done in one piece by block dissection. Ligatures should be handled and tied with forceps, and stitching of the soft parts also carried out with needle holder and forceps only—in fact, the gloves at the end of the operation should be free from blood stains, thus showing that they have not come into contact with any part of the wound edge.

I have tried the various methods recommended from time to time, all of which have had their advocates—namely, wedge, intramedullary, inlay, combined inlay and intramedullary, also stopping and comminution of the bone ends. My experience with these various methods is that I find, while success may attend the use in certain cases of any one of them, the greatest success has been with the inlay method or its modification the combined inlay and intramedullary method.

The Graft: Essentials for Success.

There are some essential points that emerge in connexion with the graft itself if success is to be attained. It must be long enough to overlap the gap by a wide margin at either end; the greater the overlap the better the contact with the host bone, and better blood supply is secured by the graft while union is being established. It must be thick enough to stand the strain of the natural pull of the muscles in the long axis of the bone; a cross strain favours non-union. While a graft denuded of periosteum will unite and grow it is better if the periosteum is not removed, as that membrane ensures a better blood supply to the graft through its capillaries linking up with the capillaries of the soft parts around. The periosteum also acts as a limiting membrane, preventing small outgrowths of bone from penetrating the surrounding parts; these outgrowths are not uncommonly seen in x-ray plates of grafts where the periosteum has been removed or has become stripped up during the grafting operation.

The contact with the host bone should be secure and as rigid as possible. While it is possible to secure rigidity by the use of absorbable suture material such as kangaroo tendon, this suture tends to soften too soon. I have not been able to satisfy myself of harm being done by metal suture, such as phosphor-bronze wire, which gives the necessary firm contact and retains its grip until union has taken place. It has been stated that wire interferes with the blood supply of the bone, but that is an unproved assertion, and if the graft be thick enough the wire cannot be tightened so as to strangle the whole thickness of the bone; in any case it need not be tightened more than sufficient to ensure contact.

Various Types of Graft.

The wedge-shaped graft is unsatisfactory because it is impossible to obtain sufficient contact with the host bone without splitting the host for a considerable distance; and also, if the wedge is to be thick enough, the spreading of the host bone at the base of the wedge makes a clumsy thickened boss of bone when union has taken place.

The inlay graft satisfies the requirements stated above in an efficient manner; it can be cut the required size so as to

secure the proper thickness and length for the overlap. It can be neatly mortised into the host bone, and can be fixed with the rigidity necessary.

The intramedullary graft is easy to insert into one end of the host but a difficult matter at the other, and while one can get good contact with the first inserted end the second is not possible, and here non-union frequently results. The medullary cavity is often unhealthy, although the compact bone may appear fairly normal. In some cases I have seen, the compact tissue has been a mere shell enclosing soft semi-fluid marrow, and the bone has frequently to be cut away for a considerable distance before tissue healthy enough to receive the graft can be found.

The thrust graft modification of the inlay is a risky method to employ unless one is sure that sepsis will not flare up. If the case becomes septic then the pus may track up the whole length of the shaft of the two fragments.

I have given up the use of the purely intramedullary graft. The combined inlay and intramedullary is a very useful method, especially in the heavier bones where one wants thickness of graft. Where there is much deviation of the fragments from one another laterally, the fragment most out of alignment should be selected for the insertion of the intramedullary portion of the graft; the other end can then be contracted with the host bone by a long overlapping inlay.

Stepping is a method for use under certain circumstances. In the humerus it gives good results, but it necessarily shortens the arm, and if the gap is large the shortening may be very considerable. The other methods give quite as good results as regards union, without the disability of a short arm.

In flail-shoulder I have used a double graft between the glenoid and the humerus; this has given the requisite strength, and kept the arm of normal length, the patient being able to abduct the arm to a right angle by scapular action.

In the ulna non-union frequently occurs after grafting, and this probably happens in the majority of cases where there is a large gap near the upper end of the bone, and where the bone has not been kept as rigid as possible by apparatus during the healing of the septic wound.

Normally the radius in pronation and supination rotates through an arc, the centre of which is the line joining the upper and lower radio-ulnar joints—the so-called "bucket handle" action. When, however, the ulna is fractured in its upper third, especially if there is a gap between the fragments, the radius is drawn toward the upper fragment of the ulna by the contraction on the pronator radii teres and the flexor group of forearm muscles. The radius then rotates through its own long axis and the lower fragment of the ulna is carried to and fro with it; a joint is thus easily formed at the junction of the upper fragment of the ulna and the graft—at least the upper end of the graft is subjected to a lateral strain during healing instead of a longitudinal one. In these cases, when the graft has consolidated at the lower end and thickened throughout, a fairly useful arm results even although a joint remains at the upper end of the graft. When a case has reached this stage further operation should not be recommended.

In gap fractures of the tibia the sliding inlay or ordinary inlay graft gives good results. In some cases a portion of the fibula may be cut out and used as a strut, placed in the gap in the tibia.

After-Treatment.

The after-treatment of these cases is very important. The limb should be encased in plaster at the operation, in the best position as regards longitudinal strain on the grafted bone. A window should be cut in the plaster over the wound on the next day, for relief of pressure on the wound area and for future dressing if necessary; the window is filled in with plaster again as soon as the skin is healed. The plaster must remain undisturbed for at least two months or longer if necessary.

After the plaster has been removed the limb should be supported in a light apparatus, poroplastic or other mould, and muscle movements carried out, at first by massage and later actively, so that growth in the graft may be stimulated in accordance with Wolff's law. Sometimes union appears to be delayed for no obvious reason; in these cases a further period of rest in plaster and massage sometimes results in firm union without any further active operative procedure.

EXTRAPLEURAL THORACOPLASTY IN THE TREATMENT OF PULMONARY TUBERCULOSIS:

EXPERIENCES FROM 75 OPERATIVE CASES.

BY
P. BULL,

Professor of Clinical Surgery at the Royal Fredrik University of
Christiania.

SINCE to-day, for the first time, I have the honour of reading a paper to the British Medical Association I am especially glad that it is possible for me to do so at Glasgow, for, as we all know, Glasgow was the cradle of modern surgery—it was here that Lord Lister began his famous experiments with carbolic acid in the treatment of wounds. His work finally led to such brilliant results that no surgeon in any country or in any period of history has rendered such great services to mankind. There is, however, another reason why it is specially gratifying for me to read a paper dealing with a branch of pulmonary surgery at Glasgow, and that is because in this city there lives Sir William Macowen, who performed daring operations on the lungs before the majority of other surgeons. If I might be permitted to express myself in this country in a German expression, I would say that Sir William is *der Altmeister* of all pulmonary surgeons.

In electing to speak of the importance of extrapleural thoracoplasty in the treatment of pulmonary tuberculosis, I do so because I suppose that I have, so far as I know, a greater experience in this domain than any British surgeon, for since 1914 I have operated upon 75 patients suffering from pulmonary tuberculosis. I cannot enter here into all the details connected with this subject, but I should like to draw attention to my paper in the *Lancet* of October 16th, 1920, and to-day I shall give you a short general review of the indications, the technique of the operation, the after-treatment, and my results. To supplement this review I shall show a number of lantern slides, and I shall also demonstrate three patients who were operated upon with success three to four years ago, and who have crossed the sea with me to be shown to this meeting. It must be stated, however, that the operation in its present state of development was first planned by Braun, at that time professor of internal medicine at Marburg, and that the technical development of the operation is mainly due to Friedrich and Sauerbruch. The operation was first performed by Friedrich in December, 1907.

Indications.

Extrapleural thoracoplasty belongs to the same category in the treatment of pulmonary tuberculosis as artificial pneumothorax; both aim at a collapse of the lung with resulting retraction on account of the increased development of connective tissue, and thereby healing. As, however, artificial pneumothorax is less risky than thoracoplasty, I demand as a rule that inflation shall have been employed either without result, or unsuccessfully on account of extensive adhesions, before the patient is advised to have thoracoplasty. On the whole it may be said that the indications for thoracoplasty coincide with the indications for artificial pneumothorax, and that the former should be employed when the latter cannot be used.

As regards the so-called "healthy" lung, it should be required that there are not, nor have been, demonstrable clinical symptoms in that lung, or that such symptoms in any case have quite disappeared, or, during a long period of expert observation, that they have remained stationary and of slight extent. Even though there may be little or nothing to find clinically in the "healthy" lung, it happens not infrequently that in the x-ray photograph we can find such extensive changes that an intended operation has to be abandoned. An x-ray examination of both lungs is therefore absolutely essential.

It must be strongly emphasized that this branch of surgery demands intimate co-operation between the surgeon and the physician in charge of the case. Best of all, the patient should be observed and treated at a special sanatorium before the operation. In the case of the sanatorium physician, who may be assumed by daily observations to know the patient thoroughly, there appear two difficult problems for solution: (1) Can it be decided whether any existing physical alterations in the "healthy" lung are due to a healed-up, stationary, or a progressive process? (2) How must ascertain at an early stage the moment when he considers continued

expectant treatment, including artificial pneumothorax, to be of any value for the patient's health. It is an easy matter to wait too long, so that when at last the patient is sent for operation large cavities have already developed in the lungs. Even if I have patients who, in spite of cavities as large as a hen's egg, or even larger, are still healthy from one to five years after the operation, there is no doubt that cavernous unilateral pulmonary tuberculosis gives a much more unfavourable prognosis as regards permanent cure after thoracoplasty than the infiltrating shrunken forms. Repeated haemoptyses should, in cases of doubt, hasten the decision to undertake thoracoplasty.

A slight tuberculosis of the larynx is not a contraindication of operation, as it may well be assumed that any further improvement in pulmonary tuberculosis, with diminished cough and expectoration, will have a favourable influence upon the laryngeal tuberculosis, in analogy with the improvement in a tuberculosis of the bladder after removal of a diseased kidney. Neither does tuberculosis in one kidney constitute an absolute contraindication; in the autumn of 1921 I removed the left kidney, and at the same time performed thoracoplasty on the same patient, who at the present time is doing very well. Absolute contraindications are found in an advanced stage of tuberculosis in the other lung, and the general contraindications which militate against any serious operation.

Technique.

The patient is placed upon the healthy side, with a large sandbag beneath, in order to press forward the diseased side. I have always performed the operation by the aid of the hook-shaped Sauerbruch incision. The arm is drawn outwards and the skin and muscles are cut down to the lumbo-dorsal fascia. The scapula with the covering soft parts can then without difficulty be lifted out from the thoracic wall, and it is then possible to remove as large portions of the ribs as may be desirable. The question is now, which ribs to remove and how much of them. As the object of extrapleural thoracoplasty is not only to get the lung to collapse, but also to put the diseased lung out of function, the resection must include many ribs. Even if the infection of the lung is limited, the resection of the ribs should proceed far beyond the diseased part of the lung; indeed, it may well be said that extrapleural thoracoplasty has developed into a typical operation, in which resection is always made into a typical to the eleventh, up to and including the first rib.

It is sufficient to resect 6 to 7 cm. of the eleventh rib, 12 cm. of the tenth and ninth, and 15 cm. of the following ribs up to and including the fourth; of the three uppermost as much as possible is taken, which in general will be 12 cm. for the third, 10 cm. for the second, and 2 to 3 cm. for the first rib. The total amount of the resected ribs thus amounts to about 120 cm., varying from 90 to 180 cm. I have resected about a hundred yards of ribs from my 75 patients.

An extremely important point in costal resection is that the ribs ought to be resected as far back as possible—that is to say, far beyond the costal angle, right up to the costal tubercle, and the point of the transverse process. It is almost emphasized how important it is in the treatment of chronic empyema to remove the posterior parts, which are the stiffest and most curved part of the ribs; if we remove only the posterior part, the anterior part of the ribs, on account of the flexible costal cartilage, will easily be pressed inwards towards the thoracic cavity and the costo-vertebral angle will to a large extent be effaced. It is this principle in costal resection which has now been transferred to extrapleural thoracoplasty.

When, after having resected the ribs lying below, I reach the fourth or the third rib, I always perform apicolysis—that is to say, after resection of the fourth or third rib I reach you can now with the finger, without difficulty, loosen the top of the lung from the thoracic wall, so that between the lung and thoracic wall there arises an extrapleural cavity larger than a hen's egg. If there are then cavities in the apex, we may sometimes both see and feel how they collapse. If apicolysis has been performed, resection of the two upper ribs, the most difficult part, from a technical point of view of the operation, will proceed more easily since it is then unnecessary to entertain any fear of injuring the lung. In order as far as possible to avoid the contents of the cavity being forced into the bronchi, it is necessary for the patient on the morning of the day of operation to cough up as well as he can all the contents of the diseased lung.

Resection of the first rib may be somewhat troublesome. In order to facilitate this I have modified the usual Doyen's costal respiratory, so that the effective part of the instrument does not cut vertically in relation to the handle, but coincides with the axis of the latter.

The muscles and skin are each sown up separately. A large glass drainage tube is placed in the lower posterior angle of the wound, although I have sometimes entirely closed the wound without any disadvantage. The bandage must be supported by three broad strips of plaster, running horizontally, so that the thoracic wall, which has been mobilized by the operation, may not give way too much to the shock of coughing during the first few days after the operation.

It may be difficult to get cavities in the apex to collapse by thoracoplasty alone. I have on twelve occasions performed (by the method of Tuffier) free transplantations of subcutaneous fat, first resecting the third or preferably the fourth rib in the axilla, and then performing apicolysis from the place of resection. In the extrapleural space, larger than a hen's egg, thereby created, there is then placed a large piece of fat taken from the anterior abdominal wall. In one case I used with good results half of the right breast instead of fat; in another case recently operated upon, after resection of the anterior parts of first to the fourth ribs, I loosened the lung from the thoracic wall and pushed the pectoralis major and minor muscles into the cavity, after having severed their attachment to the humerus and the coracoid process respectively.

The next important question is: Should the operation be performed in one or two stages? I have tried both ways, and my experience shows that two stages are less risky than one. In 54 cases I planned to complete the operation in two stages. It happened on two occasions that the second stage of the operation was not performed, because the patient's general condition was too bad. Two patients died after the first stage of the operation, but 50 survived both stages—a mortality of about only 4 per cent. Of 21 patients whose the operation was performed in one stage, 6 died—a mortality of about 30 per cent. I must therefore advise those who desire to try these operations to perform the first of them at any rate in two stages.

In performing the operation in two stages, the cut in the second stage is much higher up than in the first and proceeds downwards to about angulus scapulae and from thence farther forward. In the operation in two stages I resect ribs eleven to six or five costal in the first stage, and five or four to one in the second stage. As a rule from two to three weeks should elapse between each stage of the operation. On the other hand, I have sometimes obtained good final results when I have been obliged to postpone the second stage of the operation for many weeks, because the general condition of the patient did not permit the operation to be performed before.

Should general or local anaesthesia be employed? Most of my patients have been operated under local anaesthesia, but by degrees I have more and more resorted to general anaesthesia and I am astonished to find how well on the whole my patients stand this.

Course of the Disease and After-Treatment.

During the operation the pulse rate often rises to 120 or 130 or even more, and the respiration rate to 40. When the patient has been put to bed again, the pulse and respiration usually improve quickly. In some cases the pulse does not rise to more than 80 or 90, the respiration to more than 26 or 28. Some patients vomit during the operation.

Immediately after the operation we observe a marked collapse of the thoracic wall with paradoxical respiration, the mobilized part of the thoracic wall being drawn inwards during inspiration and pushed outwards during expiration. Dyspnoea, troublesome expectoration, and pains in the chest, radiating to the shoulder and upper arm, especially trouble the patient during the first days after the operation. The dyspnoea is partly due to "mediastinal flutter," partly to the laboured action of the heart on account of the displacement. The heart has to grow accustomed to the latter before it can act normally.

Expectoration must be relieved. This is done in various ways. An extra nurse remains with the patient day and night in order to support the operated side during attacks of coughing, and in order to encourage him to expectorate. A good compressing bandage is of importance both as regards the cough and in order to produce collapse of the operated

side. But above all it is important to give the patient sufficient narcotics, morphine or omuopon, in order to relieve pain and thereby facilitate expectoration, and moreover narcotics have a beneficial influence upon an eventual "mediastinal flutter."

The amount of sputum diminishes often while the patient is still in hospital, and in a number of cases it diminished in the course of a few weeks from 150 grams in twenty-four hours to 30 or 25 grams or even to zero. As a rule a rapid diminution in the amount of sputum is a good but not completely reliable prognostic sign. At the same time that the amount of sputum diminishes the number of tubercle bacilli also diminish. Frequently on a patient's discharge from hospital we may find only a few or even none, even if on his arrival at the hospital his sputum swarmed with tubercle bacilli.

The temperature often remains high and the pulse frequent for four or five days, but in cases progressing favourably it then falls to about normal; at the same time the pain also diminishes considerably. The patient soon begins to feel better, and is especially gratified because the cough is so much less troublesome. The large wound almost always heals by first intention, and the patient, even two or three weeks after the operation, can begin to sit up, or if the operation has been performed in two stages five or six weeks after the first operation.

The operated side of the thorax falls in considerably, so that the anterior margin of the scapula can be seen from the front. With the cystometer we can measure a diminution of the operated side amounting to 5 or 6 cm., or up to 10 cm. We can feel distinctly how the anterior ends of the resected ribs approach the posterior ones, so that the distance between them decreases from 12 to 15 cm. to 5 or 6 cm., 3 or 4 cm., or even less. At the same time the anterior ends move downwards, so that, for instance, the anterior end of the seventh rib rests opposite the posterior end of the eighth rib.

There develops scoliosis of the spinal column with the convexity towards the diseased side—the reverse of the post-empyemic scoliosis—presumably because at the operation we cut or paralyse a larger or smaller part of the long back muscles; the muscles on the healthy side therefore gain the supremacy so that the spinal column is bent convexly towards the operated side. The mobility of the arm is at first greatly restricted on account of pain, but by degrees it returns, except where the scapula has been entirely fixed. On the whole it may be said that the permanent inconveniences of the operation *per se* are slight.

After-Treatment.

When the patient is discharged from hospital he is sent back to the sanatorium in order to undergo the necessary after-cure for at least three or preferably six months. In favourable cases improvement continues there, evincing itself by a constantly diminishing amount of sputum, the fall of the temperature right down to normal (if it has not done so before), improved appetite, increase in weight, and better spirits. In order to judge whether the patient has derived any benefit from the operation we must lay some stress upon whether the amount of expectoration diminishes, whether the tubercle bacilli disappear, or see whether the temperature remains normal or increased, and last, but not least, we must pay regard to the patient's general condition. On the other hand, the physical conditions of the operated lung are so difficult to determine after the operation that very frequently they cannot be given any appreciable importance. If prior to the operation there were marked symptoms of cavity formation, we may, in favourable cases, be able to find that the metallic and amphoric breathing are replaced by crepitations, with or without bronchial breathing. But all abnormal sounds do not disappear; weak amphoric breathing may be found even though it was lacking before, and is due to the large bronchi, which pass through a stiff, retracted pulmonary tissue. Even in the very best cases we never achieve normal physical conditions in the operated lung. The percussion sound continues to be subdued, in some places very faintly tympanitic, at others quite dull. Abnormal respiratory sounds may be heard, because both lung and thoracic wall have lost their elasticity, so that it is difficult for the lung to get rid of expectoration. Therefore a slight cough and meagre expectoration without tubercle bacilli, in connexion with the above physical changes, cannot be taken to be bad signs, provided that the general condition, temperature, and pulse of the patient are satisfactory.

CONCLUSIONS.

Between May 1st, 1914, and June 1st, 1922, I performed 75 extrapleural thoracoplasty operations for pulmonary tuberculosis. Of those operated upon 37 were men and 38 women. The operation was performed 46 times on the left side and 29 times on the right side. With regard to men the operation was performed 20 times on the left side and 17 times on the right side. With regard to women the corresponding figures are 26 and 12. Of these, 8 (3 women and 5 men) died from the operation; 7 when the disease was in the right lung, 1 when in the left. Thus I have had, out of 46 cases of left-sided pulmonary tuberculosis, 1 death from operation, and out of 29 right-sided cases 7 deaths.

Results of 75 Extrapleural Thoracoplasties.

Year.	Number.		Dead, 29.			Still Alive, 46.		
	Men.	Women.	From Operation.	From Tuberculosis.	From Other Causes.	Symptomless and Able to Work.	Tuberculous.	Result not yet Fixed.
1914	1	4		3		2		
1915	2	2	2	2				
1916	1	3	1	3				
1917	3	11	1	7	1	4	1	
1918	4	2		1		3		2
1919	6	6	1	1		7	2	1
1920	5	5		3		2	4	1
1921	10	4	1			7	2	4
1922	5	1	2					4
	37	38	8	20	1	25	9	12
	75							

Several of the deaths took place with the same clinical appearances; one or two days after the operation the temperature rose to 102.2° or 104°, the pulse rate to 120 or 140 or more, and remained so until death, after the lapse of four to eight days. In one case a patient died the following morning, with a temperature of 106°. These patients had usually no dyspnoea, and the tongue remained moist. At the post-mortem examination there were found small submucous haemorrhages in the stomach and duodenum, and flabby cardiac muscles, but otherwise nothing to explain the cause of death. This is regrettable, for it has happened several times that precisely in these fatal cases the operation passed off particularly well, the patient has not been visibly affected, and we considered ourselves justified in entertaining the highest expectations; then fate suddenly delivered one of those unexpected blows which to a special degree it seems to have reserved for us surgeons. If, therefore, we could find a method which could tell us in advance which patients it would be dangerous to operate upon—a test, for instance, of the same value as the determination of the quantity of urea in the blood of kidney patients—much would be gained. We could then hope to take away much of the ominous character which still surrounds thoracoplasty. It is in that direction that we are at present carrying on investigations at my clinic in Christiania, although I am unable to say as yet whether we shall succeed in obtaining any useful results.

What is the fate of those patients who survive the operation? To judge of this it is necessary, in any case, to wait at least until one year after the operation, and it is preferable, as in the case of cancer, to wait for three years. Sixty-four of my patients have been under observation for more than one year, up to eight years, after operation. Thirty-eight (59 per cent.) are still alive, 26 are dead. Twenty-five (39 per cent.) are alive and have no symptoms and are more or less able to work; 9 are tuberculous; and in the case of 4 the result is not decided. Of the 26 deaths 5 were due to the operation, 20 to tuberculosis, and 1 to influenza. Thirty-seven patients have been observed for more than three years, up to eight years, after operation; 16 (43.2 per cent.) are alive, of whom 12 (32.4 per cent.) have no symptoms and are more or less able to work; 1 has tuberculosis, and in the case of the other 3 the results remain to be seen; 21 died, 4 through the operation, 16 of tuberculosis and 1 of influenza.

These results show that the danger to the patients lies in a new outbreak of tuberculosis in the other lung, and, further, they agree to a considerable extent with the results of our operations for cancer, resembling especially, as far as my own cases are concerned, the statistics of the operative results of cancer of the rectum. The immediate mortality resulting from the operation is 10 per cent. and the number of cures after three years' observation amounts to one-third. As the years pass more and more of the patients die of the original disease: cancer patients of recurrence or metastases, phthisis patients of tuberculosis in the lungs or elsewhere. Just as unexpected cases of recurrence or metastases can be met with in cancer patients several years after the operation, I have, after thoracoplasty, met individual cases where patients can be for three to four years without cough or tubercle bacilli until one day they die on account of a new outbreak of tuberculosis in the other lung.

Discouraged by the results of our cancer operations, we make a point of impressing upon practitioners that the diagnosis must be made earlier so that patients may come up sooner for the operation. An improvement of the results of extrapleural thoracoplasty is, on the other hand, not a question of early diagnosis, but, as mentioned before, a question of early correct prognosis. Just as an early diagnosis cannot save all cancer patients, no more can an early correct prognosis save every case of unilateral pulmonary tuberculosis. As long as we have no specific against cancer and tuberculosis there will always be, in spite of our best efforts, a number of patients for whom our science can do nothing. We must not give in, however; the more doctors who work in the same direction, the greater are the prospects of obtaining better results from all operations, including thoracoplasty.

Since I commenced to perform these operations in Norway eight years ago several of my colleagues have followed suit. In all 67 thoracoplastic operations have been performed in Norway by other surgeons, with only 6 deaths following the operations; in other words, rather better results than I can show. I have come over here on purpose to interest my British colleagues in this work, and I do not doubt that they will make valuable contributions to this branch of medical science.

The concluding points which I wish to make are as follows:

1. In unilateral or mainly unilateral pulmonary tuberculosis which is not cured by rational expectant treatment or pneumothorax, good results can be achieved by means of extrapleural thoracoplasty.
2. The operation should only be performed after an exhaustive conference with the physician treating the patient, who must have been enabled, by observation during a considerable period, to form a considered opinion of the prognosis with continued expectant treatment.
3. Resection of the ribs should be carried out, under local or general anaesthesia, through a paravertebral incision so that the posterior part of the ribs from the eleventh, or in any case from the tenth, to the first inclusive can be removed.
4. If a cavity remains, it can be brought to collapse by means of intrathoracic transplantation of fat.
5. It is necessary that medical practitioners should acquire knowledge of the indication and results of extrapleural thoracoplasty. As one can rely upon saving one-third of the patients who, without the operation, would be deemed no doctor has now the right to withhold the chance of operation from suitable patients.

CHRONIC DUODENAL ILEUS.

BY

D. P. D. WILKIE, M.Ch., F.R.C.S.,

Assistant Surgeon, Royal Infirmary, Edinburgh.

The duodenum may without doubt be regarded as the most vitally important segment of the gut. We know that a duodenal fistula is associated with rapid wasting and tends to be fatal if not promptly dealt with. A complete obstruction of the duodenum, such as occurs in the condition generally known as acute gastro-mesenteric ileus, is followed by very striking symptoms of shock and collapse, and, if unrelieved, quickly ends in death.

Anatomically the duodenum occupies in the greater part of its course a secluded retroperitoneal position, owing to the rotation of the gut in foetal life. This rotation of the gut

has the effect of bringing the superior mesenteric vessels to lie athwart the terminal part of the duodenum, so that the latter passes, as it were, under a bridge, the arch of which is subject to variation of level according to the tension on the mesentery of the small intestine and proximal colon. If the rotation of the gut were constant in its manner and degree, and if the support of the viscera by the tone of the abdominal wall were a constant and standard factor, then this retromesenteric course of the duodenum would present no peculiar difficulties or abnormalities. It is common knowledge, however, that the rotation of the gut is subject to frequent abnormalities, that the fixation of the proximal part of the colon is likewise subject to great variation, and that the support of the abdominal viscera is a factor prone to the greatest variation of all. Consequently it is no matter for surprise that the duodenum should under certain circumstances be exposed to compression and obstruction where it courses behind the root of the mesentery. Does such compression, short of the acute, complete, and fatal form, give rise to any recognizable symptoms? Is there, in fact, such a clinical entity as chronic duodenal ileus, and if so is it susceptible to surgical treatment? These are the primary questions with which I propose to deal.

The appreciation of any pathological condition almost necessarily begins with a recognition of its grosser forms. These once established, we are in a position to appreciate the lesser degrees of the same process.

My experience of this condition dates from the case of a woman, aged 54, operated on by me in the wards of our President (Professor Alexis Thomson) in the Royal Infirmary, Edinburgh, in which acute and fatal duodenal ileus from compression of the third part of the duodenum by the superior mesenteric vessels followed on symptoms of flatulent dyspepsia and vomiting. Since then I have had a second fatal case in a young man in whom repeated attacks of bilious vomiting culminated in a final and fatal attack. The patient was seen when in a practically moribund condition, and he died on the table as the abdomen was being opened. An opportunity was thus given to fix *in situ* the striking pathological appearances, and these are well brought out in the drawing made at the subsequent *post-mortem* examination. (Fig. 1.)

Apart from these two fatal cases I have now encountered 27 cases in which this condition gave rise to symptoms which had persisted in spite of medical treatment and were sufficiently pronounced to call for surgical interference. Before entering into any analysis of these cases it will be well to look at the clinical picture in this condition.

Symptomatology.

The patient is usually a female who complains of flatulent dyspepsia—for example, of pain or discomfort in the epigastric region coming on from one-half to two hours after meals, associated with a feeling of distension. The latter may be so pronounced that she may have to loosen her clothes to get ease. She further complains of headaches, nausea, loss of appetite, and constipation. She will usually state that for years she has been subject to bilious attacks lasting for one or two days and characterized by headache, nausea, and bilious vomiting. Such attacks usually give a temporary relief from the other symptoms.

According to the age of the patient—and she may be of any age—she will date back her trouble for many years, usually to school days, although there may have been intervals, sometimes amounting to years, of relative freedom. The acute crises or bilious attacks may be altogether absent,

and the patient's complaint is more of chronic epigastric discomfort and distension after meals with possibly loss of weight. Occasionally pain is a prominent feature, and the explanation given by Leveuf that in such cases a tonic pylorus resists regurgitation into the stomach is probably correct. When the pylorus relaxes the pain ceases, vomiting follows, and relief is obtained.

Sometimes the picture may be somewhat obscured by secondary developments—for example, by symptoms of duodenal or gastric ulcer or those of gall stones, conditions which tend to complicate chronic duodenal ileus. In pronounced cases the great loss of weight and almost cachectic appearance of the patient may suggest gastric carcinoma.

The neurasthenic state which is apt to supervene in long-standing cases may make the assessment of symptoms a matter of considerable difficulty. The long-standing history is, however, always suggestive, and if the patient volunteers as several of mine have done, that the only way to obtain relief from this discomfort is by lying on the face or adopting the genu-pectoral position, then a strong suspicion of duodenal ileus is warranted.

When an acute crisis supervenes the patient may rapidly pass into a critical condition, characterized by sunken eyes, rapid pulse, and distension of the upper part of the abdomen. The prompt recognition of this is of the utmost importance, as the extreme dilatation of the stomach may lead to paresis of its musculature, vomiting may cease, and death ensue.

Physical Examination.

This may be entirely negative, but may reveal obvious epigastric distension or a large splashing stomach. In two cases I have elicited splashing in the duodenum to the right of the umbilicus, but this is exceptional. Some tenderness will usually be found just above and to the right, and also in some cases just above and to the left of the umbilicus. Evidence of a general visceropneumosis or of a low ballooned and gurgling caecum will frequently be present.

X-ray examination will offer the most convincing proof of the presence of duodenal obstruction. To be of value, however, the examinations must be

made at repeated short intervals after the bismuth meal, and in various attitudes. If made when the patient is complaining of symptoms, the radioscopic findings will not fail to be of value; made during a period of freedom from symptoms, they may be altogether negative. As a rule, the stomach is seen to be low and dilated, the duodenal cap greatly enlarged and showing a soap-plate retention. The second part of the duodenum throws an abnormally dense shadow, is enlarged, and frequently shows evidence of antiperistalsis. In the milder cases the third part of the duodenum may not show clearly; in the more severe cases it is a striking feature. There may be, in addition, definite signs of the presence of a gastric or duodenal ulcer, or of the entry of bismuth into a dilated common bile duct.

Complications of Chronic Duodenal Ileus.

Sufficient has been said already to indicate what these are. Chronic stasis in the duodenum must be regarded as a factor predisposing to duodenal ulcer. By this I do not mean that in the majority of cases of duodenal ulcer a duodenal ileus is present, for it is not. What I have found, however, is that in quite a fair proportion of patients suffering for many years from symptoms of duodenal obstruction a duodenal ulcer eventually develops with its own typical symptoms. In six cases I have found this combination; in one of these a gastro-enterostomy relieved all symptoms. In two no relief followed

Fig. 1.—*Post-mortem* appearances in fatal case of chronic duodenal ileus. Transverse colon pulled up, showing greatly dilated third part of duodenum.

Synopsis of 21 Cases of Chronic Duodenal Ileus Treated by Duodeno-jejunostomy.

No.	Sex.	Age.	Duration of Symptoms.	Pain.	Vomiting.	Biliary Attacks.	Loss of Weight.	Previous Operations.	Operative Findings.		Result of Operation.	Remarks.
									Dilatation of Duodenum.	Other Conditions.		
1	F	38	2 1/2 yrs.	+	+	+	2 st.	—	+++	—	Immediate relief	One year after some pain under the costal margin.
2	F	44	7	—	++	+	—	—	++	Cholecystitis and gall stones	Cure	No vomiting since operation.
3	F	35	21	+	+++	+	14 lb.	Two gastro-ent. ostomies, Roux's Y	++	Two old gastro-ent. blind loop com. with stomach	Greatly improved	Case much complicated by previous operations.
4	F	51	35	++	+++	+	36 lb.	—	++++	Gastric ulcer	Complete relief	Gained over 2 st.; can eat anything
5	F	55	15	+	+++	+	14 lb.	—	+++	—	Relieved	Some acidity for 6 months, then rapid improvement.
6	F	39	8	+	++	—	slight	Ventral fixation, oophorectomy, appendec. coloproxy	++	—	Greatly improved	Vomiting ceased, and put on weight
7	F	26	14	+	+++	—	Nil	—	++	—	Greatly improved	No more vomiting, seen 10 months after operation, in very good health.
8	F	36	8	+	+++	+	14 lb.	Cholecystectomy, appendectomy	++	Cholangitis, stenosis of common duct	Greatly improved	Cholangitis not completely relieved, required further operation on common duct.
9	F	61	40	+	+++	+	28 lb.	—	+++	—	Complete relief	Steady gain in weight after operation.
10	M	32	12	—	+++	—	30 lb.	Gastro-ent., adhesions, g.e. enlarged	+++	Old duodenal ulcer	Partial relief	Symptoms persisted; jejunal ulcer at gastro-enterostomy later resected.
11	F	40	22	+	+++	+	—	—	++	—	Complete relief	
12	F	25	8	+	+++	+	3 1/2 st.	Appendectomy	++++	Great dilatation of stomach	Great relief	The most pronounced case met with.
13	F	23	9	+	+++	+	1 st.	—	+++	Gall stones in gall bladder and common duct	Immediate and complete relief	Rapid and complete recovery.
14	F	61	22	+	+	+	2 st.	—	+++	—	Complete relief	A very poor emaciated subject.
15	M	41	5	+	+	—	2 st.	—	++	Duodenal ulcer with stenosis	Cure	Rapid gain in weight.
16	F	32	8	++	+++	—	7 lb.	—	++	Appendix	Entirely relieved	
17	M	49	2 mths.	—	++	—	2 st.	—	+++	Carcinoma of stomach, infiltration of mesentery	Greatly improved	Previous to operation 48 hours' gastric retention; after operation empty in 6 hours.
18	M	29	3	++	++	+	20 lb.	—	++	Duodenal ulcer with stenosis	Complete relief	Gained weight very rapidly after operation.
19	M	35	13	+	++	+	12 lb.	—	+++	—	Complete relief	The hypertrophy of the duodenal wall was noteworthy.
20	F	49	33	+	++	—	2 st.	—	++	—	Complete relief	Immediate improvement in general condition after operation.
21	M	44	15	—	—	—	7 lb.	—	++	Hepato-colic lig.	Striking improvement	Dilatation of stomach and flatulence the prominent symptoms.

Note.—In addition to the duodeno-jejunostomy, other operative procedures were necessary in some cases—for example: Case 2, cholecystectomy; Case 3, removal of old gastro-enterostomies; Case 8, choledochostomy; Case 13, cholecystectomy and choledochostomy; Cases 15 and 18, posterior gastro-enterostomy; Case 16, appendicectomy; Case 21, division of hepato-colic ligament.

a gastro-enterostomy, and in one of these a subsequent duodeno-jejunostomy effected a cure. In two cases complete freedom from all symptoms followed the combined operations of gastro-enterostomy and duodeno-jejunostomy.

In one case the patient died with unusual rapidity after the perforation of the ulcer. In one case of very pronounced and old-standing duodenal ileus in which the patient was wasted and cachectic and had latterly suffered from constant severe boring pain in the back there was found at operation, in addition to an enormously dilated duodenum, a chronic ulcer of the lesser curvature of the stomach. Using this as a test case the ulcer was left untouched and merely a duodeno-jejunostomy performed. The patient was immediately relieved of all pain as well as her distension and flatulence, rapidly gained 2 st. in weight, and from being a chronic invalid is now in good health fifteen months after the operation. As might be expected, chronic stasis in the duodenum with recurring catarrhal and obstructive attacks which so often accompany it is not infrequently associated with trouble in the biliary passages. The relative frequency with which post-operative acute gastro-mesenteric ileus followed on operations on the biliary tract suggested the possibility of a preceding chronic duodenal obstruction. The coincident occurrence of vomiting and escape of duodenal content through the opening in the common bile duct after an operation for the removal of a stone from that duct, a condition of which there are several cases on record and of which I have personally encountered one case, points again to the presence of duodenal obstruction.

The similarity in the symptomatology of the two conditions makes it frequently a matter of great difficulty to say whether a case is one of gall stones, of duodenal ileus, or of both. I have had to deal with three cases where the two

conditions were combined in such obvious degree that the adequate handling of the case appeared to demand the treatment of both. In one case duodeno-jejunostomy was combined with removal of gall stones and cholecystostomy, in the second with removal of bile sand from and drainage of the common duct, in the third with cholecystostomy and with choledochostomy, stones being present in both gall bladder and common duct.

In none of these cases did the simultaneous performance of a duodeno-jejunostomy appear to add appreciably to the risk of the operation, and the convalescence in all was unusually smooth and rapid. In the case where stones were present in a dilated common duct it was of interest to note that a large gall-stone scoop and even the tip of the index finger could be passed readily through the common duct into the greatly dilated duodenum. The resemblance to a dilated ureter opening into a chronically dilated bladder was noteworthy.

A complication which must be mentioned is the presence of a previously performed gastro-enterostomy with symptoms suggestive of vicious circle. I have dealt with two such cases, and in both after removing the gastro-enterostomy performed a duodeno-jejunostomy.

Treatment.

For the milder cases treatment on medical lines may suffice. As visceroptosis is so frequently associated with the condition treatment directed to support the abdominal viscera, tone up the abdominal wall, and obviate constipation, is indicated. Most cases, however, are not diagnosed until the condition is so pronounced that treatment on the above lines would prove ineffective.

Surgical measures will aim at relieving the obstruction either by removing it or short-circuiting it.

If the obstruction be due to a drag on the mesenteric vessels from a mobile and prolapsed proximal colon, it may be relieved by fixing up the caecum and ascending colon. In two cases in which this seemed to be the factor operative, I obtained satisfactory results by colopexy. In the majority of cases, however, the colon is not mainly at fault but the tension on the mesentery appears to be due to the prolapse of the small intestine. The typical appearance in these cases is to see all the small intestines lying below the sacral promontory. Only with difficulty can they be dislodged, and they come out of the pelvis with a dull pop.

For such cases and for those in which the obstruction is due to a thickening and infiltration of the root of the mesentery either by chronic inflammatory, tuberculous, or malignant disease, much the simplest and surest treatment is to short-circuit the obstruction by performing a duodeno-jejunosotomy—that is to say, by anastomosing the third part of the duodenum just proximal to the obstruction to the first coil of jejunum just beyond it. This operation is by no means difficult to perform in the type of case requiring it, involves little risk, has a surprisingly smooth after-course, and gives the most gratifying results. In order to demonstrate the condition at operation a stomach tube may be passed and the stomach inflated. The degree of duodenal dilatation and obstruction will then be evident.

I have now performed the operation in 21 cases with uniform success, and have been struck repeatedly by the immediate relief which it gives. Within twenty-four hours of the operation the patients express themselves as feeling relieved of symptoms which they have suffered from for years, and their progress is usually uninterrupted.

It would be out of place here to enter into technical details of the operation. It will suffice to say that efficient mobilization of the third and the lower end of the second parts of the duodenum is the secret of easy anastomosis. Although not covered by peritoneum the duodenum unites without difficulty, and I now use only the finest catgut for the anastomosis. The use of a special angled clamp simplifies the operation, but is by no means essential. When the operation is combined with a posterior gastro-enterostomy in cases of stenosing duodenal ulcer along with duodenal ileus, the duodeno-jejunal anastomosis should be planted on the jejunum about six inches beyond the gastro-enterostomy. Where an operation on the biliary tract is necessary the duodeno-jejunosotomy should be done first to avoid the possibility of contaminating the subcolic area. The immediate results of this operation have in my experience been most encouraging. Apart from rupture of the abdominal wound owing to taking out through-and-through stitches too early, I have seen no post-operative complication and I know no other major abdominal operation followed by so smooth a course.

It is perhaps too early to speak of ultimate results, but in some of the most severe cases the results have been remarkable, the patients rapidly putting on two stones or more in weight, losing all nausea and flatulence and enjoying health such as they could not remember ever having had before.

In all cases improvement has followed, and so far I have encountered no complication peculiar to the operation comparable to jejunal ulcer following gastro-enterostomy.

The table (p. 1221) gives a synopsis of the 21 cases treated by duodeno-jejunosotomy.

The operation of duodeno-jejunosotomy was first suggested by Barker in 1906 and was first performed by Stavely¹ in 1908. Within the past two years numerous cases have been recorded and important papers on the subject have been published by Kellogg,² Leveuf,³ and Duval and Gatellier.⁴

DISCUSSION.

Mr. L. A. DINGLEY (Wedgebury) said how grateful he was to Mr. Wilkie for his publication of the paper on chronic gastro-duodenal ileus in the *British Journal of Surgery* in October, 1921. Up to that time he had not been aware of this condition except in so far as it occurred following surgical operations, and then in the acute variety. Since the appearance of this paper he had seen three cases, one following a miscarriage, the other two occurring in patients without any immediate cause. He stated that the three cases gave the typical history as given by Mr. Wilkie, a history of flatulent dyspepsia for many years with the sudden onset of signs and

symptoms of acute obstruction high up in the alimentary tract. Two of the cases certainly, and one probably, had suffered from previous neuro attacks. The physical signs were as follows: The patient was usually a woman with rapid pulse, normal or subnormal temperature, vomiting, either bilious or faecal in character, with absolute obstruction. The abdomen was greatly distended in its upper half, resonant, and giving a stomach splash, whereas there was no distension on the flanks or lower part of the abdomen. On auscultation and percussion there was a resonant band occupying the whole of the upper half of the abdomen, which on the right side often took an acute bend in a downward direction for two or three inches. Peristalsis could frequently be seen from left to right, and one case showed a contraction giving the appearance of an hour-glass stomach. Mr. Dingley especially wished to draw the attention of all medical men, especially general practitioners, to that little known condition because by immediate treatment by the medical man who first saw the patients many lives might be saved. The treatment was very simple and was usually effective if carried out early. It consisted in placing the patient in the left lateral or knee-elbow position for several hours after drawing off the stomach contents with a stomach tube. After the acute attack had subsided the question of operation as suggested by Mr. Wilkie should be discussed.

Sir KENNEDY DALZIEL (Glasgow) described a case seen in consultation with the late Professor Samson Gammell of Glasgow sixteen years ago, in which he recognized ballooning of the duodenum; the patient had been vomiting bile for ten days and was beyond operative help when seen by him. From that time he had been aware of the condition described by Mr. Wilkie. He had never dreaded it where there was no pathological change, but he agreed with Mr. Wilkie that sometimes they found old tuberculous glands which so thickened the mesentery that a by-pass had to be made. Mere pressure of small intestine would turn the scale against peristaltic action of the duodenum and acute dilatation. This condition of acute dilatation of the duodenum occurred sometimes and no operation was necessary; if there was no organic change in the mesentery he questioned if the formation of a by-pass was required. A Curtis belt often relieved, not so much because it pushed up the stomach, but because it aided and supported the whole intestine and prevented traction in the duodenum.

Mr. WILKIE, in reply, said that the point of greatest interest was that of vomiting after abdominal operations as an aggravation of the tendency to duodenal obstruction. It was thought by some to be paralytic, but the treatment, by passing a stomach tube and turning the patient on his face, made it evident that pressure was occurring on the duodenum. In several cases where the common bile duct had been opened and where vomiting had followed, duodenal contents had come out through the fistula by route of the common duct. In one case the dilatation of the common duct and ampulla of Vater was so wide that the finger could pass into the duodenum, so that it was not surprising that the duodenal contents passed back into the fistula. The prompt treatment was by turning the patient on his side, passing the stomach tube, and raising the foot of the bed.

At a meeting of the Royal Statistical Society on December 19th Mr. T. T. S. de Jastrzebski read a paper on "Changes in the birth rate and in legitimate fertility in London boroughs, 1911 and 1921." In the administrative county of London in the nine months following the census of 1921 there was a fall of 9.4 per cent. from the same period of 1911, although the proportion of married women under 45 years of age in the population should have given an increase of 1.7 per cent. The decline in infant mortality, however, reduced the fall in the effective birth rate—that is, the rate obtained by deducting the deaths under 1 year of age from the births—to 4.2 per cent. Legitimate fertility showed a decline of 12.8 per cent., or when standardized for variation in the ages of the married women under 45, of 11.7 per cent. The gap between the boroughs with better economic conditions and those with a poorer population had diminished sensibly. The natural increase by excess of births over deaths in 1921 was 390,335 as against 354,328 in 1911, and this gain was at the first period of life. There was no reason to consider an infant mortality of between 50 and 60 per 1,000 births as beyond the scope of legitimate expectation. The general conclusions were that the reproductive forces at work in the nation are greater than the destructive, and that the problem of the immediate future is one of over- rather than of under-population.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

INFECTION BY BACILLUS PYOCYANEUS SIMULATING LEPROSY.

A MAN aged 35 had been suffering from perforating ulcers of the foot for a year before he came to me. He then had two perforating ulcers on the right foot—one on the heel about one and a half inches in depth, and the other on the second toe about half an inch in depth. He had also white discoloured patches over the left cheek, on the outer surface of the left arm, on the outer side of the left leg, and on the dorsal surface of the left foot. These patches were not anaesthetic. Besides these he suffered from burning and tingling sensation in both feet. These symptoms resembled those of leprosy, and in fact he was treated for this disease, before I saw him, with sodium glycoeardate and sodium morrhuate, without much benefit. He had no nodules on the face, and the ears were not thickened. The ulnar nerve on the left side, however, seemed somewhat thickened. On examining the scrapings from the ulcer I was not able to find *Lep. bacilli*, but I found a large number of slender bacilli with rounded ends, which on cultivation proved to be *B. pyocyaneus*. I prepared an autovaccine of *B. pyocyaneus* containing 100 millions of organisms in each cubic centimetre. This was given subcutaneously every week. The ulcers completely healed after eight injections. The discoloured patches were due to *Microporon furfur*, and they cleared completely when treated with sodium hyposulphite. The burning and tingling sensation of the feet also disappeared under vaccine treatment, and the left ulnar nerve seems normal.

HEREDITARY DEFORMITIES.

ON December 4th I attended Mrs. W., who was delivered of a premature female child with a marked deformity of the left forearm and hand. The radius and ulna were shortened and the hand was inverted and at right angles to the forearm. The family history is as follows:

1. The woman had eight brothers, all born with talipes of the feet; six died in infancy; the two survivors grew up and had several operations performed.
2. A sister had a child with both arms deformed.
3. A cousin on her father's side had a child born with talipes and cleft palate and absence of the rectum necessitating colotomy.
4. On the other hand, the paternal grandmother had eighteen and the maternal grandmother sixteen normal children.

Wivenhoe, Essex. G. TRAVERS KEVERN, M.R.C.S., L.R.C.P.

VAGINA INFRA SEPTA, SUPRA SIMPLEX.

ON November 2nd I attended an East Indian woman at her fourth miscarriage. An East Indian woman friend had been called in to assist, and she felt unable to deliver the foetus. On examination I found a foetus of about 3½ months lying between the thighs and still attached to the cord. By its side was a mass like a blanched after-birth, also attached to what appeared to be a cord. What seemed strange was that the centre portion of the cord remained in the vagina into which the two parts disappeared. To my surprise, on pulling the foetus the placenta was drawn up to the vulva; and on pulling on the placenta the foetus approached the vulva. This was somewhat unusual. Passing two fingers into the vagina, I felt the cervix and the os, which appeared to be single. I could feel nothing to explain what had occurred. But by tracing the cord with the finger in the vagina it was found to disappear. By pressing firmly with the bent finger against the vaginal wall, I at length found the finger was hooked over a partition, and finally it reappeared at the vulvar orifice. It was evidently a case of partially septate vagina—infra septa, supra simplex.

What led to the discovery of the malformation was the accident of the foetus passing on one side of the septum, and the placenta on the other, each appearing by a separate vulvar orifice. This was proved by severing the cord. A fortnight later I made a more careful examination. The two vaginal openings were distinct and equal in size. Two

fingers introduced into the vagina—one through each opening—met above the septum, which reached to about two-thirds the length of the index finger. I could discover no other abnormality.

Reports of Societies.

MYOCARDIAL DISEASE.

A PATHOLOGICAL meeting of the Liverpool Medical Institution was held on December 7th, with the President, Professor J. HILL ABRAHAM, in the chair, when there was a large attendance of members and associates. A number of interesting pathological specimens were shown, and a short discussion followed.

Dr. JOHN HAY then read a paper on myocardial disease as observed in five hearts, in each of which there were present abnormal electrocardiograms indicating inco-ordination in the manner of ventricular systole. Microscopical examination revealed some degree of pathological change in and around the junctional tissues in all except one, which was a case of Stokes-Adams disease; no explanation was offered to account for the complete block or the periods of ventricular stoppage, and this block was not modified by a hypodermic injection of atropine. After investigating these cases and considering the literature it might be said that it did not appear possible to estimate from an electrocardiogram the degree of the pathological change; but an abnormal electrocardiogram of the nature described justified the assumption of some myocardial damage. As a matter of clinical experience there appeared to be little doubt that electrocardiograms conforming to this type materially added to the gravity of the prognosis.

CASES.

Case 1.—Female aged 20; rheumatic myocarditis; mitral stenosis. Clinically there was a moderate degree of heart-block, made complete by digitalis, relieved by atropine.

Case 2.—Male aged 68; Stokes-Adams disease causing death. Clinically there was complete block.

Case 3.—Male aged 55; angina pectoris. Electrocardiograph indicated right bundle lesion.

Case 4.—Male aged 55; auricular fibrillation; chronic renal; adherent pericardium. The electrocardiogram was bizarre.

Case 5.—Male aged 67; with varying degree of heart-block. Involvement of the bundle.

Dr. PHOEBE INCE, describing her technique in the foregoing cases, said that a block of tissue was cut from the heart to contain the auriculo-ventricular node, the main bundle, and the upper part of the right and left branches. Serial sections were cut, one block being cut in the horizontal and the other four in the longitudinal plane. The sections were stained by van Gieson's stain, a few in each case being also stained by Verhoeff's elastic tissue stain. Disease of the arteries was demonstrated in Case 4. In Case 3, although there was marked atheroma of the coronary arteries, the artery to the node was unaffected. In the case of syphilitic myocarditis the arteries were apparently unaffected. In the rheumatic heart, Case 1, the main bundle had become involved through the extension of the inflammatory reaction at the base of the tricuspid valve. In Cases 2, 3, and 4 the bundle had suffered in varying degree from chronic fibrosis spreading inwards from the fibrous septum. In Case 5 the damage was most marked in the auriculo-ventricular node, where the nodal elements were almost entirely replaced by vascular tissue. The main bundle showed lymphocytic infiltration and fibrosis, becoming less severe as the bundle was traced to its branches. The left ventricle showed a patchy syphilitic myocarditis.

Professor ERNEST GLYNN spoke of the possibility of lesions occurring in the nervous mechanism of the heart as well as in the myocardium, in such cases.

Dr. I. HARRIS thought that heart-block due to disease of the auriculo-ventricular bundle alone would never give the Stokes-Adams syndrome. As long as the ventricles were normal they would develop a rhythm of their own, which, although at a slower rate, would be quite regular. Asystole for a long period would not take place. In cases where the syndrome appeared the long period of asystole suggested that there was something wrong in the part of the heart below the auriculo-ventricular bundle. Either the ventricle under certain circumstances was unable to develop stimuli of its own or it was unable to respond to stimuli, owing to the fact that its refractory period was longer than normal. It was

therefore possible that the Stokes-Adams syndrome might appear in cases where the auriculo-ventricular bundle was normal. The Q.R.S. complex was usually abnormal in such cases.

THE SCOPE OF DIATHERMY.

A MEETING of the Midland Medical Society was held in the Birmingham Medical Institute on December 6th, with the President, Dr. PURSLOW, in the chair, when about seventy members were present. The evening was devoted to a discussion of the scope of diathermy.

Dr. C. G. TEALL introduced the subject by outlining the physiological principles underlying the method, and gave a brief historical sketch of its development.

Dr. A. E. MILNER of Derby read a paper on the treatment of lupus by diathermy, in which he described in detail the operative procedure necessary, and gave a summary of his results. To illustrate his paper Dr. Milner showed twelve cases treated by this method; considerable periods had elapsed since cessation of treatment. Many of the cases had previously proved resistant to other methods of treatment, and the results were undoubtedly good.

Mr. MUSGRAVE WOODMAN spoke of the value of diathermy in the treatment of malignant diseases of the mouth and throat. He pointed out that although the primary seat of the growth might be totally destroyed by diathermy, it was impossible to deal with the lymphatic glands by this method, and that consequently the method had to be employed in conjunction with surgery. Mr. Woodman also touched on certain dangers connected with the method, and emphasized particularly that of secondary hæmorrhage. He was of the opinion, however, that with improved technique these dangers would be considerably reduced. Subsequently Mr. Woodman and Dr. Teall demonstrated the technique of diathermy on pieces of meat.

Dr. E. P. CUMBERBATCH, of St. Bartholemew's Hospital, acknowledged the excellence of Dr. Milner's results, but pointed out that actually they had not been obtained by the use of diathermy properly so called—Dr. Milner's treatment by sparking the patches of lupus was not true diathermy. He then gave a review of the work that had been done lately at St. Bartholemew's Hospital by this method, emphasizing the fact that it had been possible to reduce an inoperable carcinoma to a state which had rendered operation possible.

Mr. B. J. WARD drew attention to the value of diathermy in the treatment of papillomatous tumour of the bladder, and showed several beautiful pictures made at the time of operation.

The PRESIDENT expressed the thanks of the Society to the speakers, and particularly to Dr. Milner and Dr. Cumberbatch, coming from so long a distance. He invited Sir Gilbert Barling to review the communications in the light of his long experience.

Sir GILBERT BARLING said that he was satisfied that diathermy was a method of value in well-chosen cases. He congratulated Dr. Milner on his results, but said that in some of them he thought as good, or even better, results might have been obtained by simple surgical operations. He thought that in the treatment of papillomata of the bladder it undoubtedly constituted a great advance, and also in nose and throat diseases. He believed, however, that wherever it was possible for an operating surgeon to excise a growth complete with its lymphatic drainage diathermy was unnecessary.

SENSORY DISTURBANCES IN RELATION TO DIAGNOSIS.

At the seven hundred and first meeting of the Brighton and Sussex Medico-Chirurgical Society Dr. E. FARQUHAR BUZZARD gave an address on the subject of "Pain and other sensory disturbances in relation to diagnosis." He emphasized the extreme importance of a correct understanding and interpretation of subjective symptoms and expressed the opinion that without this the early diagnosis of many morbid conditions could not be obtained. Accuracy in obtaining a detailed history from any patient was the chief guide towards determining the nature of a lesion however effectively physical signs pointed to its localization. The difficulties connected with obtaining a satisfactory description of symptoms, such as pain, were very great, and the medical man needed as much patience and skill in cross-examination as did a barrister. He was always handicapped by the lack of

education in all classes of patients, who had rarely been taught to think clearly or to be conversant with the use or meaning of the language they spoke. Dr. Buzzard illustrated the importance of accurate descriptions in relation to the various forms of headache, and discussed the possible causes which determined the time and incidence of pain in connexion with the headache due to gross organic disease as well as that due to anxiety states. He pointed out that while the lay mind might be most impressed by the constancy and persistency of headache, the trained medical mind should really pay perhaps more attention to those forms of headache which were transient and paroxysmal. The importance of other sensory disturbances in relation to diagnosis was illustrated especially by reference to the sensory disorders resulting from early patches of disseminated sclerosis, and emphasis was laid on the fact that slight sensory abnormalities unassociated with any disability or gross objective disturbances of function were always of organic origin and not hysterical. Such symptoms were often of great diagnostic importance and might lead to diagnosis of disease when treatment was most likely to be beneficial. In conclusion, the speaker referred to the various sensory symptoms characteristic of early stages of tabes dorsalis, and pointed out how diagnosis of that disease could be made when the lightning pains were present even in the absence of Argyll Robertson pupils and other well-known features of locomotor ataxy.

The PRESIDENT (Mr. A. J. Hutchison) congratulated Dr. Buzzard on his choice of subject and asked him if he could explain intracranial pressure. How was it, for instance, that a tumour the size of a pea could cause intense headache, and how was periodicity of headache to be explained? Mr. ROBERT SANDERSON thought that the lessening of the neurasthenic headache as the day went on was caused, not, as Dr. Buzzard had suggested, by the feeling of relief that the cares of another day were over, but by the strengthening influence of food. Mr. GEORGE MORGAN quoted the late Sir Lauder Brunton's observations of his own trigeminal neuralgia and his theory of an acid wave. Dr. HENRIEUX spoke of the early morning headache associated with increased arterial tension. In neurasthenics the headache might be greater in the early morning because at that time they had nothing but their symptoms to think of. It was remarkable how often neurasthenics, re-examined after an interval of six months gave a different localization to their headaches. He had had a patient, aged 47, in whom the pressure of a cerebral tumour had forced open the frontal suture.

Dr. HELEN BOYLE thought it remarkable that very high blood pressure was associated so frequently with absence of headache. In neurasthenics the pressure usually was low, and she thought the lessening of headache during the day was caused by the circulation brisking up, hence the benefit of Weir Mitchell's prescription of early morning black coffee. Dr. GORDON DILL spoke of the type of intense frontal headache, with vomiting, which he attributed to auto-intoxication dependent upon failure of the filtering action of the liver. Dr. A. ORLEBAR asked for information as to the etiology of disseminated sclerosis.

Dr. BUZZARD, in reply, said that he thought Dr. Hobhouse's case most remarkable; it was unique in his experience. Dr. DILL's cases he took to be migraine. In disseminated sclerosis it was practically certain the cause was a spirochaete, and the most likely treatment to be successful was by arsenic on the same lines as in syphilis.

On the motion of Dr. GORDON DILL, seconded by Dr. WALTER BROADBENT, a hearty vote of thanks was accorded to Dr. Buzzard for his interesting address.

GYNAECOLOGICAL EXPERIENCES.

The Obstetrical Section of the Royal Academy of Medicine in Ireland met on December 1st, with the President, Dr. BETHEL SOLOMONS, in the chair, when Dr. GIBBON FITZGIBBON showed two specimens of adenomyositis of the uterus.

The first was from a woman aged 37, who had had four children, the last one born three years before she consulted Dr. Fitzgibbon. She had been curetted twice, and examination of the curetting showed nothing of note. When she consulted him she complained of constant bleeding, and he took out the uterus to stop this. Except that it was slightly enlarged and soft there was nothing unusual in any part of it. The pathological report he received, however, was that the condition was adenomyositis of the uterus. The second specimen was from a woman aged 50, who had had hæmorrhage for three or four months, lasting from ten days to three weeks. He removed the uterus, and the pathological report was again adenomyositis of the uterus.

The PRESIDENT said that the differential diagnosis of fibrosis and adenomyositis uteri was impossible until the examination of the enrettings or of the specimen had been concluded. He felt that the correct and safest treatment for "bleeding uterus" about the menopause was hysterectomy.

Dr. DOMINICK CANNON said that in his opinion treatment by x-rays in cases of adenomyositis was useless.

Dr. STEVENSON thought that x-ray treatment had been proved to be of benefit in these cases, and that they were also amenable to treatment by radium; the structure of the uterine mucous membrane could be altered to a greater or less extent by radium.

Dr. ROWLITTE said that the first case resembled what was found in cases of fibrosis uteri, as it showed one very big dilated gland; the history of the case also was similar to cases of fibrosis uteri.

Dr. FITZGERALD, in reply, said that both the specimens showed a well-defined tumour in the uterine. He had taken out a good many uteri which he would classify as fibrosis uteri, but if examined it would probably be found that a great many of them showed adenomyositis. In his opinion adenomyositis was not cured by radium.

The President, Dr. BETHEL SOLOMONS, showed a uterus with a large cervical myoma.

The patient was aged 35, and first consulted him in 1918 because of sterility. She had been married for eleven years to her husband, whose age was 54. The uterus had been curetted twice by different gynaecologists; a third gynaecologist had curetted and divided the cervix and later had opened the abdomen to dilate the Fallopian tubes. Dr. SOLOMONS, having examined her and found everything normal except a discharging sear from the divided cervix, informed her that he could advise nothing further without examination of the husband; this was refused. In 1920 she consulted him again, and as there was no difference in symptoms or signs, nothing further could be recommended. In October, 1922, irregular menstruation started, with the passage of clots; she felt ill, and examination revealed a fibroid condition of the uterus. At laparotomy total hysterectomy was performed, with removal of one ovary which was cystic. The specimen revealed a fibromyoma springing from the anterior cervical wall; its weight was 15 oz.; microscopically it was a simple fibromyoma with hyaline degeneration. The cervix revealed an nubled discharging wound from the divided cervix. The specimen called forth several interesting points, and was a comparatively rare specimen. In operating the ureters were isolated, an important and necessary procedure in these cases. The sear in the cervix revealed once more that the operation of posterior division, instead of helping sterility, usually caused it. Dr. SOLOMONS considered that although cases might occasionally become pregnant despite this operation, its malperformance made it a danger in the hands of most operators.

Thereafter Dr. L. CASSIDY read a paper entitled "Recent experiences in Vienna," and Dr. DOMINICK CANNON a paper on treatment of malignant disease by radium.

The PRESIDENT said that there were many questions for discussion in the paper of Dr. Cassidy. Why did the Viennese school give chloroform in eclampsia? In Dublin it had been found disastrous. Why was hysterectomy done in addition to Caesarean section in concealed accidental haemorrhage? Many successful cases had been reported without hysterectomy. He regretted that plugging the vagina was not adopted as the treatment for revealed accidental haemorrhage; probably it had been tried and given up because of ignorance of the exact technique. He was surprised to hear that vaginal hysterectomy was still practised for cancer of the cervix; when in Vienna he had been impressed by the number of occasions when the uterus had been cut during the course of this operation. Interposition was advocated in the treatment of prolapse of the uterus; he believed that nearly all these cases could be cured by careful and thorough plastic work on the vagina. In conclusion, he hoped that the fact that for many years operations in Vienna had been started at 7.30 a.m. would make the people in this country start work earlier; in his opinion, work either in hospitals or in private should not be started later than 8.30 a.m.

Radium, continued Dr. SOLOMONS, had become such a popular method of treatment that the time had come when the status of the radiologist and the gynaecologist must be defined. He believed that the latter should decide when a case required radium treatment, and that the former should carry it out and should send the patient to the gynaecologist from time to time for observation; the gynaecologist should not attempt radium treatment without the assistance of the radiologist.

Dr. ELLA WEBB said that she had taken a course in obstetrics in Vienna, and in her opinion there was no comparison between the teaching of obstetrics in Dublin and in

Vienna. Dr. MacFETRIDGE said that he went to Vienna with great expectations, which in a great many respects were not realized. He went to the ophthalmic clinic, and the material there was very disappointing and scanty; on several mornings no operations at all were performed. The nursing there did not seem to him to be as good as it was in Dublin, but in many points they were far ahead, especially in research work and in pathology.

Reviews.

WOMEN IN THE FACTORY.

DAME ADELAIDE M. ANDERSON, late Principal Lady Inspector of Factories, has employed some of her leisure since her retirement in writing a book, *Women in the Factory*.¹ As Viscount Cave says in a brief preface, it tells the story of the women inspectorate from its beginning in 1893 until 1921, and a wonderful story it is of early opposition and obstruction patiently overcome, by conciliation and persuasion where possible, but when necessary by invocation of all the somewhat limited powers of the Factory Acts. In legal contests with persistently defiant employers the women inspectors had to fight their own battles in the courts, without solicitors to represent them, and in opposition to the expert pleaders whom the other side could engage. Nevertheless, the stone of David was often effective against the armour of Goliath, and intimate practical acquaintance with the statutes served frequently to counter the forensic art of the defence. Much better was it, however, when Miss Anderson and her staff could by friendly representation of plain facts bring over the employers to their side, as they often did, and persuade them not merely of the humanity or the decency of the proposals for amelioration, but of the actual profit which would result from reform. The authoress writes with great restraint throughout, even where the rhetoric of indignation might have been excused; but reading between the lines it is easy to understand how keenly she has felt during her quarter of a century's crusade for a better life for women workers. The reader will wonder how the conditions of labour, now in great measure remedied, ever came into existence or were for so long allowed to continue, but it is good to think that the women inspectorate has done so much to enlighten employers and the public and Parliament. The work, of course, is by no means finished.

While Dame Anderson is careful to avoid criticism of the administrative changes of 1921, which largely abolished the differences in the sphere of work of the men and women inspectors, the reader is led to suspect that she doubts or disbelieves in the wisdom of the change. That, however, is a question for experts intimately acquainted with factory work, and "fusion was the line of development chosen by the Home Office." We take it also that the authoress says a good deal less than she thinks when she refers (p. 236) to the Home Office memorandum of 1919 on Substitution of Women, which declared that "there were good prospects for women in this industry," whilst, on the other hand, early in 1920 it was reported that "the steady withdrawal of women from employment in men's industries that began after the armistice was almost completed," so that Miss Anderson herself concluded at the end of the year that there was "as yet no fulfilment of the expectations that after the war a body of industries and operations offering a hopeful field of fresh employment would be open to women where their war experience would be turned to account. On the contrary, an automatically operating force has closed all these expected new avenues."

In the course of the eight chapters which the book contains many other subjects are discussed, such as excessive hours, wages and the Truck Acts, dangerous and injurious trades, accidents and safety, employment of mothers, child labour, labour saving, fatigue, food and efficiency, workers' committees, and welfare management. Every chapter is well worth reading, and the reader will conclude that, whatever philosophers say, life in Dame Adelaide Anderson's ease has not been a failure.

¹ *Women in the Factory. An Administrative Adventure, 1893 to 1921.* By Adelaide Mary Anderson, D.B.E., M.A. London: John Murray, 1922. (Gr. 8vo, pp. 316. 7s. 6d. net.)

DISEASES OF THE HEART.

SINCE Dr. John Cowan's *Diseases of the Heart*, with chapters on the electrocardiograph by Dr. W. T. Ritchie, and on the ocular manifestations in artorio-sclerosis by Dr. A. J. Ballantyne, appeared in 1914 and was reviewed in our columns (BRITISH MEDICAL JOURNAL, 1914, i, 1356), opinions have been much tested and in some respects modified by research and by the practical experience furnished by the great war. Accordingly, though nominally a second edition, the volume now put forth by Drs. Cowan and Ritchie²—for the latter now appears as joint author on the title-page—is really a new book, and instead of being dedicated to Dr. Cowan's ancestral tree is inscribed to those roots of knowledge—the Royal Infirmarys of Edinburgh and Glasgow.

The first two chapters give a condensed but clear account of the anatomy and physiology of the heart, and contain useful illustrations of the conduction system. The chapter on morbid changes in the myocardium contains a number of well-executed figures, especially one of infarct and rupture of a muscular papillaris from disease of the coronary arteries. The section on examination of the heart begins with an account of polygraph curves and then describes the electrocardiograph. The next chapter on stimulus production deals with sinus tachycardia, bradycardia, and irregularity, while the chapter on excitability is devoted to extra-systoles of various kinds, which, with the exception of sinus arrhythmia, are the commonest of all forms of cardiac irregularity; thus, to quote the authors, "hardly a day passes but we observe them, whereas auricular fibrillation is seen once or twice a week, auricular flutter once a month, and heart-block once or twice a year." Ventricular extra-systoles, which constitute 70 per cent. of all extra-systoles, are copiously illustrated by electrocardiograms; a ventricular extra systole recurring regularly after each physiological beat is the most frequent form of coupled rhythm or pulsus bigeminus, is a sign of cardiac weakness, and when digitalis or strophanthus has been taken an indication for their cessation or diminution.

Under the heading of conductivity the various forms of heart-block are considered, and it is clearly pointed out that heart-block and the Adams-Stokes syndrome, though frequently associated, are not synonymous, for many cases of complete auriculo-ventricular block without the syndrome are on record, and the syndrome may occur without heart-block. The account of auricular flutter (in the recognition of which Dr. Ritchie played an important part) is clear and gives full attention to the observations of other workers; that it is comparatively rare is shown by the occurrence of only one case among 2,500 soldiers admitted to a heart hospital during two years. The features of auricular fibrillation are well portrayed, attention being drawn to the more favourable prognosis in cases with mitral stenosis as contrasted with those due to other causes and to the ominous significance of extra-systoles. The drawbacks and dangers of quinidine sulphate, such as sweating, diarrhoea, abdominal pain, embolism, and fibrillation of the ventricles, are mentioned, and the conclusion is reached that on the whole this new drug appears to have little therapeutic value.

Under the heading of nodal rhythm are described three groups of cases, all showing synchronous contraction of the auricles and ventricles in response to stimuli arising in the auriculo-ventricular node; in order to avoid any confusion which might be engendered by Sir James Mackenzie's use of the term "nodal rhythm" for what is now known as auricular fibrillation it might be more convenient to speak of this condition as auriculo-ventricular rhythm. These three groups are (1) nodal rhythm without tachycardia, (2) continuous nodal tachycardia, and (3) paroxysmal nodal tachycardia. Many of the cases commonly spoken of as paroxysmal tachycardia belong to the last group, but others are examples of auricular flutter, paroxysmal auricular fibrillation, or of the rare form paroxysmal ventricular tachycardia.

In speaking of the treatment of malignant endocarditis the poor results from vaccine therapy—four cures—are emphasized, and the authors consider that the most important factor is probably a good digestion, whereby the patient's nutrition is maintained in a satisfactory state. After accounts of chronic valvular disease and myocardial failure angina pectoris is described as a symptom arising from many causes, about which if there is anything certain it is its

uncertainty as regards its occurrence and significance. In some cases the blood pressure is raised during the attacks, and in these amyl nitrite almost invariably gives instantaneous relief, whereas patients whose blood pressure is not elevated during the attacks are seldom helped by inhalation of this drug. In general the outlook is better in cases with high blood pressure than in those with cardiac weakness, but whatever the cause, the heart or the aorta are always exposed to stress and strain. Bromides given between the attacks are useful in nearly all cases, and particularly in hypersensitive patients who sleep badly. Disordered action of the heart, acute pericarditis, adherent pericardium, pneumopericardium, and congenital heart disease are passed in review, and finally arterial disease and aneurysm are summarized, with the inclusion of Dr. A. J. Ballantyne's description of the ocular manifestations in arterial disease, illustrated by a coloured plate of the fundus in chronic nephritis.

This well-written work is so admirably balanced that it is well fitted for students and practitioners; it gives due prominence both to the well-established principles and to the recent advances of cardiology, criticizes them out of the fullness of long personal experience, and is often refreshing in its diction—for example, in the reference to the case of "a man of forty-seven years, a stono-breaker by occupation and an alcoholic by choice." The authors may be confidently congratulated on their success in providing a handbook that deserves popularity.

A FRENCH TEXTBOOK OF THE EAR, NOSE,
AND THROAT.

It is just over two years since a review of the first edition in English of Dr. GEORGES LAURENS'S *Oto-Rhino-Laryngology*³ was published in this Journal. The appearance of a second edition after so short an interval is sufficient evidence of the favourable reception accorded to the work in this country. It is significant, too, that the present volume is a translation of the fourth French edition, and that the book has also been translated into Spanish. The general style and purpose of the book remain unchanged; neither is there any alteration nor addition of outstanding importance to note in matters of detail; but it is satisfactory to observe that the translation has been improved and some mistranslations of French idioms have been remedied. The text has been brought well up to date. As before, descriptions of the great operations are properly regarded as beyond the scope of the work, but the minuteness of detail and the wealth of illustrations should prove of great value to the practitioner in the examination and management of patients. It is, however, right to repeat that the teaching is by no means a mirror of the practice of otology and laryngology in this country. The descriptions of the methods of removing tonsils and of treating malignant disease are examples of this difference, of which other instances are frequent. The book is, on the other hand, an accurate and detailed exposition of the methods generally accepted and practised in France. With this reservation the second edition may be commended as heartily as was the first to all interested in the subject.

SOCIOLOGY AND PSYCHOLOGY.

WE take two books, Mr. ROGER'S *The Individual and the Community*⁴ and Dr. ARTHUR LYNCH'S *Ethics*,⁵ together because both the authors aim at establishing new principles in human conduct, and both seek a basis for speculations which are not scientific or scientific fact. Both Dr. Lynch and Mr. Roper may be credited with the desire to improve human conditions; and though the results of their speculations may differ little from the Utopias of the past, they may be useful in stimulating thought.

Mr. Roper is one of those who speak with contempt of all present and past statesmanship as "old men's games," modelled on the ruins of past empires. He says quite truly—or platiniduously—that the laws which govern human nature may be found in the daily lives of men, women, and children; he then builds up a system for which the only suitable name would seem to be individualistic communism—

The Student and Practitioner. By Dr. English translation by H. Clayton Fox, 2nd edition. Bristol: John Wright and Sons, 1922. 17s. 6d. net.

Community. By R. E. Roper, M.A., M.F.P.S. 2nd edition. (Demy 8vo, pp. 224, 8s. 6d. net.)

Ethics. By Arthur Lynch, London, 1922. (Post 8vo, pp. xii + 323, 7s. 6d. net.)

²*Diseases of the Heart.* By John Cowan, D.Sc., M.D., F.R.F.P.S., and W. T. Ritchie, O.B.E., M.D., F.R.C.P.E. With a chapter on the Ocular Manifestations of Arterial Disease by Arthur J. Ballantyne, M.D., F.R.C.P.S. Second edition. London: Edward Arnold, 1922. (Demy 8vo, pp. xvi + 635; 321 figures, 3 coloured plates, 3 folding plates. 30s.)

a contradiction in terms. Community of effort, he says, does not depend upon authority, but on natural control evolved by daily life, such as common sense, sympathy, tact, self-reliance, creative work, voluntary association, and the like. Therefore Mr. Roper objects to discipline and punishment, and regards the gospel of duty as a means devised by the wicked rich for holding the poor in control. According to this view, an obedient democracy is provided for the maintenance of the present form of community by those who mishandle our destinies under the pretence of statesmanship. The whole of this argument is somehow based on "Brownian movement." Thus, Mr. Roper says that the whole solar system is permeated by vibrations. Vibration and movement are characteristic of the material in which man's physical nature is manifested. In order to receive and to generate vibrations man must evolve within himself an internal harmony between his own vibrations. Internal harmony and self-control are identical in their nature, and the attempt to substitute external authority for either is in the end disastrous. In this way does Mr. Roper misuse the scientific observation of Brownian movement for his own ends, and for the annunciation of such excellent exclamations as "We need a community where none go hungry and none are slaves." It is not surprising that the Master of Peterhouse, in a letter about Mr. Roper's book, quoted in the preface, seems to display some effort in being complimentary.

Dr. Lynch set forth "to see the drift of things in an ethical sense, to throw a beam of light upon the sources and the goal of our acts." He found very little guidance in the work of thinkers who had gone before. None of the systems of ethics appeared to him to rest on a deep base, rising by reasonings, cogent and consecutive, to the conclusions it expressed; so that some systems, and those not the least authoritative, seemed to dwindle into sheer absurdity. Dr. Lynch examines the philosophies of many writers, including Aristotle, Kant, and Herbert Spencer. He rejects them all as unsatisfying, though he has some good words to say for Aristotle. He states the central problem as follows:

"Standing in the universe, regarding all its phenomena and in face of all the world of thought, to endeavour to find by the force of reason alone, if not the goal or purpose of our lives, at least great cardinal lines of guidance towards higher development, and to exhibit these as derived from a fundamental base by clear and consecutive arguments."

No doubt Dr. Lynch is right in saying that in order to form correct notions of man's place in the cosmos it is necessary to gain some true conception of the cosmos itself. Consequently the study of ethics demands the subsidiary study of the physical, biological, and mental sciences. He set himself to find in the conditions of nature the sanctions of an ethical system; he considers that he has discovered these sanctions, and that his system of ethics has "reality of life." His fundamental principles are truth, energy, and sympathy. The principle of truth becomes extended into the development of science; the principle of energy gives rise to the standard of efficiency; the principle of sympathy implicates that of co-operation, and at length that of justice. So far these principles do not seem to differ much from the principles of many ancient systems. But having started with science Dr. Lynch proceeds to deal with the problem of the immortality of the soul, which he says is vital to ethics. The arguments of the religious, those of Plato, of Paul, of Berkeley and others of the idealist school, are all faulty, says Dr. Lynch, and it is possible to show that science is not inconsistent with the doctrine of immortality. "The verdict is for the immortality of the soul." "Over all our lives looms a great purpose"; but we cannot find any very definite statement as to what that purpose is. The fourth and last part of Dr. Lynch's book deals with his notion of government; the elimination of war; the definition of some favourite ethical qualities in a pleasantly cynical manner; the statement that the motive force in ethics is not pleasure but the "natural satisfaction of needs that correspond to development."

Dr. Lynch's "purpose" is far too intangible. The impartial observer might come to the conclusion that in the present state of our knowledge the Christian system of ethics may possibly be more satisfying than the hazy system of Dr. Lynch. If Dr. Lynch desires to investigate scientifically human conduct he would probably find that the best method would be to begin with the individual and find out in a detached manner exactly what his motives are or have been. Thence he could proceed to the ethics of communities, and so to generalizations, which must still be tested against the solid fact of the individual.

NOTES ON BOOKS.

AMONG the books which are really difficult to write are those on medicine for non-medical persons. It is an everyday experience to discover how dangerously little the ordinary patient understands of the instructions given him or her about the prescription or bottle handed over as part of the treatment. The writers of most books on domestic medicine are wise in counselling resort to the medical man. Missionaries, however, are in a specially difficult position: they may be far from professional assistance or within reach only of the nostrums of native quacks; at all events they are going to live in places very different from the home countries and with risks of novel illnesses and unsuspected morbid causes in alarming numbers. The Association of Medical Officers of Missionary Societies, London, is, therefore, rendering a useful service in sending out a third edition of *Health Instructions for Missionaries in the Tropics*.⁵ Good advice is given on prevention of illness (with special reference to mosquitoes, flies, and food) and regarding dress and habits (exercise, bathing, sleep, and alcohol). There is a section, too, on the emergency treatment of malaria, blackwater fever, dysentery, and cholera by Dr. Basil Price and Sir Leonard Rogers, which may save lives and probably has already done so. It is, perhaps, rather a high compliment to the intelligence of the ordinary missionary that he should be advised to make blood films before he administers quinine in malaria, but one remembers how in some parts of the world (as in Central Africa) the missionary must be, as Horace calls him, *centum puer artium*, or, as we say, jack of all trades.

It is proposed to issue a series of psychological reprints and translations with Professor KNIGHT DUNLAP of Johns Hopkins University as editor. The first volume of these "Psychology Classics" has been published under the heading of *The Emotions*.⁷ It contains a new translation of Lange's *Ueber Gemütsbewegungen*, made by Miss Istar A. Hanft from Kurell's German version; together with a reprint of James's *What is an Emotion?* and his chapter on "The Emotions" from the *Principles of Psychology*. The James-Lange theory has exerted a profound influence upon the development of psychology, and in making these contributions readily accessible to students of psychology, philosophy, and physiology a real need has been met. Further volumes will be awaited with interest.

The new number of *Brain*,⁸ which is now edited by Dr. GORDON HOLMES, contains a series of papers mostly of a special character. The first is an article by Dr. J. Bahinski on "Réflexes du déçusse"; Drs. Bazett and Penfold follow with a study of the Sherrington decerebrate animal. There is a paper by Drs. A. F. Hurst and J. R. Bell on the pathogenesis of subacute combined degeneration of the spinal cord, and another by Professor Harvey Cushing on the meningiomas.

The handy little pocket commentary entitled *Common Errors in First Aid*,⁹ in which Dr. N. CORBET FLETCHER indicates various mistakes frequently made by ambulance students, should be read in conjunction with one of the recognized manuals, as where the official instructions leave any loophole for doing a thing the wrong way Dr. Corbet Fletcher clearly points out the correct procedure and the reasons for it. The author's long experience as teacher and examiner has given him an unrivalled opportunity of discovering where first aiders may go wrong, and readers of this little book should reap the benefit of this wide knowledge.

We own to a feeling of admiration for any medical man who undertakes the writing of a full length novel and brings his self-imposed task to a successful conclusion. Dr. HERBERT HARRISON has occupied his leisure in this way, and the result is *The Braganza Necklace*,¹⁰ described in the subtitle as "an account of the strange adventures in the early life of Sir John Swayne, M.D., physician to the Court of His Majesty King George the Third." This kind of romantic tale is beyond the sphere of our criticism; but Christmas books are now in season and we wish Dr. Harrison's volume, with its wealth of stirring incident, all the prosperity it deserves.

⁵ *Health Instructions for Missionaries in the Tropics*. Edited and published by the Medical Officers of Missionary Societies, 25, (Cr. 8vo, pp. 36. For further part to the Honorary Secretary.) Psychology Classics. By Carl Georg. Baltimore: Williams and Wilkins Company. dollars for foreign countries.

THE PLIGHT OF THE RUSSIAN DOCTORS.

A Christmas Appeal to the British Medical Profession.

In June last the Council of the British Medical Association made an appeal for the starving doctors of Russia. In order that the response should be as widespread as possible the subscription was limited to 5s. Within the next few weeks the sum of £1,610 was received and was paid over to the American Relief Administration, which promptly dispatched food parcels to those doctors and members of deceased doctors' families whose names had been supplied by an organization of Russian doctors in this country. The Association has had a signed receipt from Russia for every parcel delivered.

Since the appeal many letters have been received from individual doctors and from bodies of doctors in Russia, testifying in the most touching way the gratitude of the recipients of the food parcels, not only for the gift but for the evidence that the doctors in Russia had not been forgotten by their more fortunate colleagues in other parts of the world.

A typical individual letter is one recently received from a woman doctor in Russia who is working at a clinic for mental diseases. She gives full particulars about herself and her professional status and goes on to say:

"My family, which lives solely on my earnings, consists of my aged mother of 70, two brothers (both war invalids from 1914-15: one, 45 years old, was wounded in arm and leg and is almost totally disabled; the other, 47 years old, was wounded in the head and is mentally deranged), and a sister who recently underwent a serious operation—half her stomach was removed. I ask you to help these four persons who are unable to do any work, be it only by sending them one food parcel."

The following acknowledgement from Petrograd is typical of many received from collective medical bodies:

"The section of the American Relief Administration in Petrograd has in the name of the British Medical Association transmitted to the Academy of Medicine for the professors and assistants 44 boxes containing in all 132 pounds of different nutritive substances. The professors and assistants of the Academy of Medicine are glad to see in that gift a token of the unity of the whole scientific world and wish to express their deep gratitude to the representatives of the British Medical Association." (This was signed by the vice-president of the Academy and eleven other representatives.)

It is only too clear that what has been done is a mere scratching of the surface, below which is a dreadful mass of want and misery. The situation is perhaps best described in the words of Mr. W. E. Haigh, F.R.C.S., a British doctor who is attached to the Nansen High Commission. In a letter addressed to the Association, dated "Moscow, September 24th," in which he expressed his satisfaction with what the Association had already done, he went on to say:

"The position of our colleagues becomes steadily worse. . . . The depreciation of the rouble and soaring prices make it impossible for them to provide food for their families, even were such obtainable in plenty. The salaries paid are fantastic, being much less than those of workers; for example, I pay my chauffeur one hundred millions a month and food packets; doctors working in the cholera blocks of the Odessa City hospitals receive 27 millions and, happily, have gifts of maize from the American Relief Administration, but pay is always in arrears. There are doctors in the country who have had no pay this year, and depend on small gifts from the peasants, but this in famine-stricken areas cannot be much. The doctors in Cherson on the Black Sea have had no pay for six months, and their lot is desperate. That city, once of 80,000 inhabitants, passed through all the horrors of famine last winter, combined with epidemics of typhus and relapsing fever, followed by a severe epidemic of cholera in the summer. Hospitals, unheated, without soap, appliances, drugs, provided with a ration for all of 600 calories a day, often mixed with surrogates, conditions have been such as require the pen of Dante to describe. . . . The sole means of keeping doctors and nurses alive was the American maize. . . . I know those (doctors) who have had their children at home with oedema, living on surrogates, those who have eaten linseed cake instead of bread, or the pressed mass after the extraction of oil from sunflower seeds; some have died on duty, and typhus has taken fresh toll, and for their wives and children there is nothing. The best off financially are poor and their means are often the sale of books, silver, the furs, clothing, and jewellery of their wives, and these reserves are now exhausted. . . . Surgeons of repute may have no stockings, medical women no fires in their room in winter, yet they will entertain one if they can, and it is pathetic to see their enthusiasm to talk 'shop' . . . and their joy at having a colleague from abroad even for half a day. The needs of the professors are

great . . . but the rankers are in worse straits, and I wish to point out that all forms of help can now be administered best through the local medical societies; if we find the food they know the needs best. . . . Wood for firing costs to-day in Odessa 40,000 roubles a pound, petrolum is 8 millions a pound, butter 1,800,000 a pound, and with such a market the doctor's wife has to sell necessary clothes, not to buy."

Dr. Haigh's evidence is borne out by many pathetic letters the Association has received, and the Council at its meeting on December 13th resolved to make a Christmas appeal to the medical profession in this country to do something more to alleviate the terrible conditions in which our colleagues in Russia, through no fault of theirs, are living—and dying.

The results of the present appeal will be divided between the American Relief Administration and the All-British Appeal of the Nansen High Commission. There is plenty of room for both bodies, and each in its own way can be depended upon to see that money subscribed by the British medical profession is spent in providing the necessities of life to Russian doctors and their families.

Clothing is almost as badly needed as food. The American Relief Administration in its latest report (December, 1922) says: "While the need of foodstuffs in Russia continues a grave problem, the needs of the population for warm clothing are equally grave." The American Relief Administration has entered into an agreement with the Soviet Government to allow clothing remittances to be made for individuals. This arrangement will be utilized to send clothing where we are advised that clothing is more urgently needed than food.

Subscriptions of 5s., or multiples of 5s., should be made payable to the Russian Doctors Relief Fund and sent to Mr. L. Ferris-Scott, the Financial Secretary of the Association, 429, Strand, London, W.C.2, who will acknowledge their receipt. The amount collected will be acknowledged week by week in the BRITISH MEDICAL JOURNAL, but not the names of individual subscribers.

We ask each of our readers who is looking forward to a happy Christmas to send something to help to keep alive medical men and women in Russia, who are striving to carry on their work under almost impossible conditions and in a spirit of devotion and self-sacrifice which is an inspiration to the profession the world over.

WILLIAM MACGOWEN,
President.
R. WALLACE HENRY,
Chairman of Representative Body.
R. A. BOLAM,
Chairman of Council.

Treasurer.

NOTES ON SMALL-POX.

BY

W. McCONNEL WANKLYN, B.A. CANTAB.,
M.R.C.S., L.R.C.P., D.P.H.

Differential Diagnosis between Small-pox and Chicken-pox.

THERE is no royal road to certainty in this subject, nor any rule of thumb upon which exclusive reliance can be placed; it is no more possible to recognize every case of chicken-pox by rule than that of any other disorder; the pathological manifestations in any given case being the result of the combination and reaction of various types of disease, skin, age, and occupation in varying degree and proportion. Experience must necessarily play a large part in the formation of an accurate diagnosis of the more difficult cases. Nevertheless, it is possible, and very material, for less expert observers to select, cultivate, and stress those points upon which sound experience may gradually be built up; to assist in that is the main purpose of this article.

In order to produce a clear impression at the beginning, a certain class of case which well illustrates certain leading features will be discussed. Allusion is made to those adult cases—often at first sight appearing formidable, though in reality they are not so—in which the diagnosis certainly rests between small-pox and chicken-pox. Long experience shows that in a majority—not all—of these cases their true nature can be demonstrated by the simple means of an actual count of parts of the rash. It is better known now than it used to be how in such cases the rash is frankly centripetal—that is, how it shuns the distal parts of the extremities and accumulates on their central parts and on the trunk; but it is not so well known how frequently this can be demon-

strated by a precise count; and this simple and most helpful factor it has long been my object to lay before my colleagues for their comfort and convenience. It is submitted that these facts should be known to every member of the profession, as no doubt in due course they will be, and included in all the medical textbooks.

An example or two will clear my meaning; the following have been taken at random from notes of some five hundred cases of varicella in which there was difficulty in differentiation from variola.

VARICELLA: COUNT OF SPOTS.

Case A.			
Right hand ...	4	Left hand ...	4
Right forearm ...	28	Left forearm ...	20
Right arm ...	97	Left arm ...	84
Face	(about) 130	...
Front of trunk	(about) 350	...

Case B.			
Right hand ...	0	Left hand ...	0
Right forearm ...	2	Left forearm ...	2
Right arm ...	11	Left arm ...	6
Face	69
Front of trunk	23

Case C.			
Right hand ...	0	Left hand ...	2
Right forearm ...	7	Left forearm ...	6
Right arm ...	13	Left arm ...	16
Face	54
Front of trunk	49

In the above the face means the mask of the face; and the front of the trunk is that space included between the lines of the clavicles and umbilicus and the anterior axillary lines. Such a count can usually be made in about five minutes; and not infrequently the patient or friends will check it.

It will be seen that the *relative* distribution is the same in each case; and in the majority of cases denotes the correct diagnosis to a certainty. Forty or fifty more such cases could be quoted did space permit.

When this relative distribution of the spots has been thus established, it is necessary to confirm or refute the evidence thus offered; for this purpose it is wise to refer to some tender and protected area of the skin, typically the flank, arm-pit, or chest. For this purpose the extremities should be avoided, and especially the face, a site on which the rash is more difficult to distinguish from that of variola than elsewhere.

In the flank or similar region will be found the most typical lesions of varicella; and there may be noted their superficial character, as estimated by rolling the lesions between the finger and thumb, the fact that the long axis lies parallel to the natural folds of the skin, the wrinkled outline and flaccid nature of the lesion.

When these two main features have been established—namely, the distribution and the character of the individual lesions—reference should be made to the condition of the patient just before the rash came out, great care being taken to arrive at the real facts. In one case lately the patient was able to show that she had attended a Girl Guides' function just as a copious rash was appearing; and in another the correct diagnosis was made for me by two bream which were swimming in a basin in the patient's scullery and had been caught by the patient during the stage of invasion of the illness; variola seldom permits of such diversions in the stage of invasion; varicella seldom forbids them.

If by this time the diagnosis still remains in doubt and there is no further opinion to consult, the development of the rash should be watched and noted from day to day; that usually is widely different in the two diseases, and as a rule points clearly to the true nature of the case.

Two more points perhaps once again may be mentioned. The best possible light must be insisted on; and the patient should be uncovered to the waist save for a shawl or other appropriate wrap.

These hints are the result of many years' experience, and have been found to be of the highest practical value. The method combines reliability with saving of time. For these reasons it is now offered to my colleagues as being, in this class of case, the most useful they can have.

Additional illustrative cases are as follow:

Case D: Chicken-pox.			
Right hand ...	0	Left hand ...	0
Right forearm ...	16	Left forearm ...	30
Right arm ...	46	Left arm ...	48
Face	106
Front of trunk	108

Case E: Chicken-pox.			
Right hand ...	0	Left hand ...	1
Right forearm ...	6	Left forearm ...	8
Right arm ...	15	Left arm ...	14
Face	20
Front of trunk	30

Case F: Chicken-pox.			
Right hand ...	2	Left hand ...	1
Right forearm ...	17	Left forearm ...	14
Right arm ...	34	Left arm ...	15
Face	40
Front of trunk	35

Case G: Small-pox.			
Right hand ...	42	Left hand ...	48
Right forearm ...	30	Left forearm ...	20
Right arm ...	25	Left arm ...	22
Face	150
Front of trunk	7

I should be glad of any similar notes of cases to add to my collection.

INTERNATIONAL HYGIENE.

We have received from the Director of the Office International d'Hygiène Publique a summary of the proceeding of the last session of that Office in Paris, which has been prepared and circulated to delegates with the object of its publication in the medical or technical journals of the different countries. The Office International works in liaison with the Health Committee of the League of Nations. Since it came into existence in 1907 it has published a number of communications in its monthly *Bulletin*, where they appear together with the statements of sanitary laws, conventions epidemic disease statistics, etc., which form the staple material of that publication. This is the first time, however that it has made any public communication of the proceedings of a session.

This year's session of the Permanent Committee of the Office International d'Hygiène Publique was held from October 23rd to November 1st, under the presidency of M. Velghe (Belgium). The British delegate was Sir George Buchanan, and the other countries represented were: Chili, France, Norway, United States, Roumania, Switzerland, Poland, French West Africa, French Indo-China, Egypt, Persia, Netherlands, Portugal, Italy, Tunis, Australia, Morocco, British India, Kingdom of Serbs, Croats, and Slovenes, Algeria, Monaco, Union of South Africa, and Madagascar.

Revision of the International Sanitary Convention of Paris, 1912.

The Committee concluded its examination of the revised draft of the International Sanitary Convention of Paris of 1912. At its preceding sessions the Committee had already agreed upon its proposals regarding Chapter I of the Convention, which contains all the regulations concerning the measures required for prophylaxis of plague, cholera, and yellow fever. At the present session Chapters II and III came under consideration. These chapters (II, Special Provisions for Countries in the East and Far East, and III, Special Provisions for Pilgrimages) bear on the carrying out in Egypt of the regulations laid down in Chapter I, the sanitary regulations for shipping in the Near East, Red Sea, and the Persian Gulf, and the supervision of the pilgrimage to Mecca. It was not proposed that Chapters IV (Supervision and Practical Application) and V (Adhesions and Ratifications) should be subjected to any revision. In connexion with Chapters II and III it is pointed out that at the beginning of 1922 the Health Committee of the League of Nations sent a mission to study on the spot the organization of measures against epidemic disease in the Near East. This mission, in collaboration with the Sanitary Maritime and Quarantine Board of Egypt, prepared a scheme which was taken as the basis for the work of the Committee of the Office. The revised text of Chapters II and III will be transmitted to the French Government, as has already been done in the case of the revised text of Chapter I, in order that it may be communicated to the various Governments concerned with a view to the assembly of the next International Sanitary Conference, at which these proposals will be decided upon.

International Nomenclature of Diseases.

The nomenclature of diseases, as defined by an International Conference in 1900 for use in the compilation of nosological statistics, was revised in 1909, and in 1920, on the initiative of the League of Red Cross Societies, the French Government convened another International Conference with a view to a further revision. The international nomenclature, as laid

down in the Conference of 1920, was circulated to the members of the Committee in the course of the session. The delegates were satisfied that most of the defects in the 1909 list had been corrected, and agreed to recommend the adoption of the 1920 nomenclature to their respective Governments. In this connexion, however, a special difficulty had arisen. M. Bertillon, the devoted secretary and moving spirit of the various conferences, died while the publication of the proceedings of the Conference of 1920 were still in preparation, and some delay and confusion was thus caused. Several members of the Committee who had also been members of the Conference represented that the text submitted did not always reproduce exactly the decision actually reached by the Conference. Negotiations are now in progress for the correction of these errors.

Therapeutic Serums and Derivatives of Arsenobenzol.

The Committee had on its agenda two questions, one concerning the derivatives of arsenobenzol—their toxic effects, the regulations governing the manufacture and importation of these products in different countries, and the possibility of their eventual international regulation; the other, therapeutic serums—the regulations governing their production and sale in different countries and the possibility of standardizing them internationally. In connexion with the first point, the Office had obtained a considerable amount of material, partly by answers to questionnaires addressed to the members of the Committee, and partly by its own investigations. The subject appears to be very complicated, and, in certain respects, incompletely elucidated. The unanimous opinion was that it would be better not to draw any immediate conclusions but to carry on the investigations already in hand. A report will be prepared to be discussed at the spring session, 1923.

With regard to the laws and regulations of different countries regarding therapeutic serums the inquiry has so far been limited to antidiphtheritic serum, on which a special report prepared by the permanent staff of the Office was presented to the Committee. This report was revised and completed as a result of suggestions by the different delegates, and in this form has been published in the November number of the *Bulletin* of the Office International. Certain conclusions of the report, particularly in regard to the preparation of a draft international regulation for the strength of diphtheria antitoxin, have still to be considered. The Committee decided not to undertake this at the moment in view of information which is now being obtained from the conferences on standards for therapeutic serums which are being held under the authority of the Health Committee of the League of Nations. One of these conferences has since taken place in Paris, and, at the invitation of the Health Committee of the League, the Office International d'Hygiène Publique was there represented.

Bills of Health and Sanitary Log Book of Ships.

During its preceding session the Committee had studied a series of questions concerning bills of health and the institution of a sanitary log book on ships. The report before us contains a closely reasoned summary by the President of the chief aspects of these complicated questions; in the course of this he stated that the staff of the office had collected a considerable amount of information concerning the form of bills of health actually in use and, as instructed, had prepared two schemes. The Committee reserved for further consideration these schemes drawn up by the Office, together with two others suggested by the sanitary administrations of Italy and Algeria. All these will be printed and circulated and a decision will be arrived at during the spring session of 1923.

Another matter discussed was the signals by means of which ships may make known, on arrival, the sanitary condition on board. The International Code of Signals in force since 1901 comprises a certain number of conventional signs (the yellow flag, representing the letter Q, and others) relating to the sanitary condition of ships. The Committee considered that it would be well to have a wider range of signals than those represented by the two letters Q and L. The signals required should be simple; they would enable the ship to give the sanitary authority certain information concerning the conditions this authority would find on board and would thus, by avoiding comings and goings, make the duties of this authority easier of execution. The following resolution was therefore passed:

The Committee of the Office International d'Hygiène Publique recommends that maritime powers should consider as soon as possible whether it would be desirable to complete the International Code of Signals by the introduction of special signals in the form of a flag by day and by lights at night to show:

(1) That the ship is free from all diseases and asks for free pratique, or

(2) That the ship is suspect—that is to say, that cases of infectious diseases or suspected cases of these diseases have occurred on board more than five days previously or that an unusual mortality among rats has occurred, or

(3) That the ship is infected—that is to say, that cases of infectious diseases or suspected cases of these diseases have occurred within less than five days.

The Committee also draws the attention of maritime powers, which have accepted the International Code of Signals and issue regulations for flags and lights which apply to ships entering their territorial waters, to the importance of securing that particular signals used for the suggested sanitary code are not utilized for any other purpose.

Measures against Abuse of Narcotics and Alcohol.

The Italian delegate communicated the draft of Italian legislation dealing with the illegal traffic in narcotics. The delegates from France, Holland, the United States, Denmark, and Tunis gave an account of the legislation in force or about to be introduced in regard to opium, cocaine, etc., in their respective countries. The greater part of the morphine and cocaine consumed in Europe comes from Germany. It was considered that the only way to put a stop to the international smuggling, which takes place in spite of all supervision, would probably be to have strict supervision in factories and to require, for instance, that an official representative should prevent the exportation of any quantity of these drugs to a destination which is not guaranteed. A note from the delegate for India drew attention to the consideration that a moderate use of opium as practised among the natives in India does not necessarily entail danger to the population, and that there is no need for the authorities to take repressive measures in regard to such use. The Polish delegate read a memorandum concerning the favourable effect of the prohibition of alcohol (spirits, etc.) during the war on the number and the development of psychic diseases in Poland. This memorandum will be published in the *Bulletin*. It was stated also that in Belgium mental specialists are agreed that the number of cases in asylums has diminished owing to the new legislation relating to spirituous liquors.

Epidemiological Data.

Communications were received and considered on the following subjects: the sanitary conditions of Poland, the sanitary state of Romania, small-pox in Switzerland, the measures taken against trachoma in Indo-China, the prevalence of yellow fever on the West Coast of Africa, plague in Madagascar, and international statistics concerning cancer. In regard to plague in Madagascar, attention was drawn to the occurrence of septicæmic cases extremely rapid in their development and sometimes causing death in less than forty-eight hours. In these cases no primary symptoms occurred and the evidence pointed to the transmission of infection from case to case by means of fleas without the intermediary of rats. Cases in which plague appears to have been carried in this way were also brought forward by the delegate for Algeria. This method of plague propagation would appear to be more dangerous, at least under certain conditions of housing and living, than has hitherto usually been admitted.

The Swiss delegate mentioned that in 1921 there were cases of small-pox in the cantons of Bâle and Zurich, where it had for many years been practically unknown; although vaccination is not compulsory in these cantons. The disease manifested itself in two different types: at Bâle the usual serious symptoms were present; elsewhere the disease was entirely benign, and not a single death occurred among many hundreds of cases. In many instances the general feeling of indisposition and discomfort which resulted from small-pox was less than that which resulted from vaccination. This was less than that which nevertheless is clearly only a mild manifestation of the serious type, of which all the characteristics are present, though in an attenuated form. The Swiss sanitary authorities are of opinion that in this second instance the outbreak was definitely an outbreak of modified small-pox. The discussion showed that this benign small-pox is present in other countries under various names—"white-pox" in the United States, "mild small-pox" in England, "milk-pox" in Gaboon.

The British delegate drew attention to the occurrence in August, 1922, of the first cases of botulism, at Loch Marce, which had been reported in Great Britain. A statement by the delegate for British India showed that Colonel W. Glen Liston's apparatus for the clearing of rats from ships by means of hydrocyanic acid gas gave excellent results in Bombay, and that the use of this apparatus, of which a complete description is given in the *Journal of Hygiene* of October, 1922, may possibly be extended to other ports of India.

British Medical Journal.

SATURDAY, DECEMBER 23RD, 1922.

ENVIRONMENT AND DIET IN THE CAUSATION OF RICKETS.

SEVERAL circumstances have recently combined to increase the interest in the vexed question of the etiology of rickets. There have been, in the first place, the striking results of the experiments on the effect of the absence of vitamin A (sometimes called the growth factor) from the diet. In the second place we have the results of what may be called the Glasgow investigations, which point to the importance of bad housing and want of exercise. Thirdly, recent views as to the therapeutic value of calcium salts and phosphates have to be taken into consideration; and, finally, we have the observations—some of them very astonishing—on the effect of light in preventing and curing rickets. The matter has been taken up by the Medical Research Council, which has recently published two reports, the one by Dr. Corry Mann, physician to the Evelina Hospital for Children, on the relative importance of environment and diet, and the other by Professor Koronchewsky, on the etiology and pathology of rickets from the experimental point of view.

The first report is a valuable contribution to the very vexed but highly important problem of the nature of the factors causing rickets. Animal experiments have shown that in young animals a large number of factors are capable of causing bony changes, which are apparently identical with clinical rickets. Mellanby's work emphasized the importance of vitamin A deficiency in the causation of rickets in puppies,¹ but in a more recent report² he has stated that attention must also be given to other factors, such as an excess of carbohydrate in the diet, in the causation of the disease. American workers have shown that deficiency of calcium and of phosphates may cause rickets in experimental animals, and observations on children have made it plain that the problem of the causation of rickets by dietary deficiencies is complex. The general opinion is that rickets cannot be attributed solely to lack of vitamin A, but any theory of its etiology must take cognizance of the fact that cod-liver oil has a remarkable preventive and curative effect. Paton and his co-workers have throughout maintained that the chief causes of rickets are deficient exercise and bad housing conditions, and this view was supported by investigations upon Glasgow children,³ which showed a relation between bad housing and the incidence of the disease. The view that rickets may be produced in this way has received powerful support from recent American work, which has shown that both sunlight and ultra-violet light prevent or cure rickets in animals. Similar conclusions were reached independently by Miss Chick and her co-workers, who made extensive observations on rickety children in Vienna.

Scientific investigations have therefore revealed the fact that an embarrassingly large number of factors are

involved in the production of rickets. Rickets, however, is one of the most widely spread diseases of infancy. Hess, indeed, has stated that 75 per cent. of children living in the temperate zone are affected. This may, we hope, be an exaggeration, at any rate for Europe; but it must be admitted that the slighter forms of rickets, which do not produce obvious deformity and can only be diagnosed with certainty by x-ray examination, are important causes of ill health. The severer forms which produce obvious deformity may fairly be described as a grave social menace on account of the lifelong impairment of efficiency they cause, and in the female sex of the pelvic distortion that they may produce. Obviously it is of vital importance to know what is the cause of the prevalence of the severer types in England and Scotland, and particularly whether the most important factor is to be found in errors in infant feeding or in bad housing, as suggested by Professor Paton and his co-workers. This is the practical problem which Dr. Corry Mann has investigated.

The children observed were attending the out-patient departments of the Evelina Hospital or of Guy's Hospital, or certain infant welfare centres in London. The cases of rickets numbered 533, and of these 449 showed slight or severe deformity. As a control 428 normal children were examined; of these, 242 belonged to families free from rickets, and 186 were members of families in which a case of rickets had occurred. The cases were followed for periods extending to a year or eighteen months; clinical examinations were made and careful investigations as to the home conditions in which the children lived were conducted by trained lady health visitors. The chief points studied were the income of the parents, the housing conditions, and the diet. The results, which are fully set forth in a series of well-arranged tables, point to certain very definite conclusions. There was no evidence that bad housing, overcrowding, or deficient air space, were responsible for the occurrence of rickets. The control cases and the rickety children appeared to be living under exactly similar conditions. On the other hand, clear evidence was obtained that certain errors in diet conduced to the development of rickets. Of the 242 cases of non-rachitic children in families free from rickets 77 per cent. were fed either by breast, or on fresh or dried milk, or on a combination of breast and fresh or dried milk, while only 11.4 per cent. were fed partly or entirely on condensed milks. Of the 533 cases of rickets, however, only 28 per cent. were fed either by breast or on fresh or dried milk, or on a combination of breast and fresh or dried milk, while 30.3 per cent. were fed partly or entirely on condensed milk.

The most important conclusion of the author is that "if a wide survey is taken of the conditions which predispose to the occurrence of rachitic deformities in children under the age of 2 years, the continual use of an unbalanced diet, characterized by deficiency of fat and excess of carbohydrate, will be found to have antedated the appearance of symptoms in about 45 per cent. of the total cases." This conclusion is of great practical importance, for it indicates clearly that, of the possible factors which can cause rickets, the most important factor actually producing the disease in the poorer quarters of London is improper infant feeding.

There is no doubt that lack of sunlight and of fresh air dispose to rickets, and that exposure to sunlight can cure rickets. The work of Paton and his co-workers definitely suggested that these hygienic factors were chiefly responsible for the incidence of rickets in Glasgow. The work of Dr. Corry Mann shows equally clearly that in South-East London rickets is chiefly caused by improper diet. Possibly the reason for this difference is that in London the housing conditions are not as bad as in Glasgow; indeed, it is specifically mentioned that in

¹ *Rickets: The Relative Importance of Environment and Diet as Factors of Causation.* An investigation in London by H. Corry Mann, O.B.E., M.D. Medical Research Council, Special Report Series, No. 68. 1922. (Pp. 99. 2s. 6d.)

the London report very few evidences of overcrowding, lack of cleanliness, and want of ventilation were observed. The poverty of the district investigated is, however, notorious, and the combination of moderate housing conditions with great poverty must tend to bring the dietary factor into prominence. The conclusion that in London rickets is due chiefly to improper diet is encouraging, for dietary defects can be remedied much more easily than can bad housing.

Professor Korenchewsky's experiments, to which we hope to recur on some future occasion, lead him to attach considerable importance to the existence of an hereditary factor. It is, he says, impossible to deny the existence of a congenital disease of the skeleton, if not of a rachitic character, at any rate predisposing to rickets. He considers that the most important factors for the prevention of rickets are an adequate amount, in the mother's diet, of an anti-rachitic factor, calcium, and phosphates during pregnancy, especially during lactation, and also the presence of the same substances in the infant's diet, combined with abundant light, fresh air, and muscular exercise. He also thinks that the presence of the substances mentioned in the father's diet may be of consequence.

Dr. Corry Mann's report contains some interesting information regarding the results of the work done at infant welfare centres. He states that during the two years April, 1919, to April, 1921, there was a rapid diminution in the number of cases of rickets, and that severe cases of deformity have become rare. "Rickets," he continues, "is not only becoming much less frequent, but such incipient cases of rickets as occur are almost invariably checked in the pre-rachitic stages by coming into touch with a welfare centre." The evidence obtained by this investigation suggests plainly that in ten years' time, so far as London is concerned, rickets will be relatively uncommon. No more conclusive proof can be given of the valuable work which the welfare centres are doing than these records, which indicate that where in a family the earlier children have been rickety, the later children, who alone have been under supervision of a welfare centre, and fed under the assistance of that agency, are free from rickets. This successful control has been noticed repeatedly. These are very encouraging words, and it is gratifying to learn that the labour and money that have been devoted to the development of the infant welfare centres are yielding such valuable results.

SOME FEATURES OF MYOTONIA.

THE rapid progress which medical science has made in the last fifty years has left untouched many forms of disease, some in spite of their ubiquity, others because of their rarity. Among the latter are many of the hereditary disorders which affect the neuro-muscular mechanism, of which we know little beyond the clinical manifestations and the gross pathological changes. The *causa causans* and the means whereby it effects the morbid results seem to remain as far as over from our grasp. Among such hereditary diseases is myotonia congenita, which was so intimately described by Thomsen in 1876. Its essential nature has so far completely baffled neurological investigations, and we are therefore still content to compile clinical observations in the hope that they may throw new light on the disease. For that reason we welcome the interesting paper by Rosett in the first number of the new volume of *Brain*. He describes an American family in which eight cases of the disease occurred in three generations. This family presents several points of interest. The grandparents were English. The husband, a big, powerful, and fair man, was healthy in every respect. The wife, a brunette of medium size, of a nervous disposition, and also became affected

in middle life with myotonia; this was most troublesome during the last ten or twelve years of her life. They had six surviving children, three of whom took after their father, while three resembled their mother. Those who resembled the father, and inherited his large muscles, inherited also their mother's myotonia. The others inherited their mother's nervous disposition and were liable to attacks of depression. In the third generation again those who resembled the big fair Englishman were affected with myotonia, while the others were normal. It seems as though this type of build and musculature were a soil on which the sensitive plant of myotonia, which appeared late and in a mild form in the grandmother, could flourish and develop into full maturity.

The hypothesis that some familial and hereditary diseases require the blending of two different strains has been suggested recently by Hall of Copenhagen in his study of hepato-lenticular degeneration. The way in which the cases occurred in the family he investigated suggested that the germ, A, of the disease is transmitted to several members of a family, possibly to every member, but only develops in the individual when another factor, B, is also transmitted. This factor B is much more common than A, but still sufficiently uncommon to allow only a small proportion of those affected with A developing the disease. Similarly in Rosett's family of myotonia we have on one side the germ of myotonia; on the other the much more common factor of big musculature, and an inheritance of both is necessary before the individual becomes myotonic.

The description of the cases of myotonia also brings out some interesting observations. One case, a woman in the second generation, was not affected until the age of 23, near the end of her second pregnancy. At that time and since then sudden attacks of myotonic spasms were induced by sudden emotion, such as fright, and affected all those muscles of the body which were in use at the time. Thus when standing she fell to the floor "like a log of wood," but when sitting only the muscles above the waist were affected. Except for these attacks she noticed none of the symptoms of myotonia, although the muscles gave a modified myotonic response on direct percussion. Four of her children who resembled her and their grandfather also showed myotonic phenomena in greater or less degree. Two girls were typical cases of the affection. The other two, a boy of 10 and a girl of 3½, showed no myotonic symptoms, but their muscles responded on testing with the myotonic reaction.

The relationship of myotonia with voluntary nervous control and with the autonomic and endocrine systems has within recent years been the subject of much speculation and some experimental observations. It has long been known that the myotonic reaction is only elicited by certain types of stimulus. Thus direct tapping of the muscle usually results in slow relaxation, but when the patellar and Achilles tendons are tapped in testing the knee and ankle jerks the muscles relax normally and rapidly from their contractions. Again, weak and short electrical stimuli produce a normal flicker in the muscle, whereas stronger or longer faradization gives a contraction which persists long after the stimulus ceases. Electromyograms of voluntary contractions show that the nervous impulses recorded by the string galvanometer only continue so long as the patient wills the contraction; but long after the string has ceased to vibrate the muscle remains in the same state of contraction as before. Clearly, therefore, the myotonic phenomenon is not under the control of the central nervous system.

But some measure of control by the sympathetic and endocrine systems is suggested by several observations. Thus, in the case recorded by Rosett emotional disturbance very rapidly brought on a severe attack of

myotonia, which persisted for nearly five minutes. Griffith, in 1912, recorded an interesting family in which a mother, son, and daughter were affected. The mother suffered from myotonia in a typical form, but only for a very short period—namely, during the last few weeks before the birth of her boy, who was her second child. Up till then, and from her confinement onwards, she had no symptoms of the disease. The boy was a typical case, and up till manhood, when he was observed, suffered from no remission in the severity of the symptoms. His older sister suffered from myotonia from childhood, but not so severely as her brother. She married and had several children, and she noticed that, although during her pregnancies her symptoms were considerably worse, after her confinements they improved to such a degree that each successive pregnancy left her less affected than before, so that at the time of examination the disability had almost completely left her. Other writers have noted the bad influence of pregnancy on the symptoms of myotonia, but this mother and daughter appear to be unique in experiencing the curative effects of the confinement.

Work on the metabolic aspects of the disease has been scanty and inconclusive. Cases are rare, and the patients seldom wish to be the subjects of thorough investigation, and it must be confessed that up to the present no satisfactory method of studying the metabolic exchanges in a living muscle has been devised. Still it is likely that before long progress will be made in this direction which may lead to a fuller knowledge of the conditions governing muscular contraction and relaxation, and to a rational method of treatment for sufferers from myotonia.

HODGKIN'S DISEASE.

A SAD interest attaches to the article on Hodgkin's disease published this week (p. 1201). Sir James Galloway was preparing a post-graduate lecture on the subject at the time when he was taken ill, and it was in his mind at the last. The notes he left have, as an act of piety to his friend, been put together by Sir William Hale-White, who has little doubt that the lamented author had intended perhaps to expand the lecture and almost certainly to complete it by some further discussion of the observations and theories he recorded. Even as it stands now it well illustrates Galloway's qualities as a physician and his attitude towards the more modern methods of studying disease. While he put first clinical observation, coupled in any particular case before him with a consideration of the individual patient, he always had in mind the institutes of medicine, and was ever ready to study the suggestions continually flowing from physiology and pathology into the broad stream of medicine. The lecture affords more than one illustration of this. The discovery that the urine in the first case he relates contained a peculiar protein at once aroused his attention. He recognized that it resembled Bence-Jones's albumin, and sought the expert help of Mr. Sydney W. Cole, who established the fact that the substance was a new protein, differing from Bence-Jones's albumin in the respects briefly stated in the lecture. We may express the hope that Mr. Cole may shortly publish a fuller account of it, and that other physicians will look out for it in similar cases. Early in his career Galloway had given special attention to diseases of the skin, and the descriptions in this lecture of the cutaneous manifestations to be observed in Hodgkin's disease are of great value; commonly these manifestations are mentioned only briefly in textbooks, and yet they may be of very considerable importance. That the pruritus occasionally observed may be so intense as gravely to affect the patient's general condition is a valuable observation. The further statement that arsenic, a favourite remedy in the disease, may increase the pruritus, is a useful clinical point. The etiology of Hodgkin's disease is still obscure; Galloway, in pointing out that it is a general specific disease associated with progressive infection of susceptible

structures, ranged himself with those who hold that the poisoning is of an infective and, in all probability, a parasitic nature. This view is supported by the occurrence of pyrexia of which a very good example is given, the temperature being plotted in the way recently suggested by Dr. Arthur Hall in the *Quarterly Journal of Medicine*. The periodicity of the temperature may depend on the life cycle of the hypothetical parasite. Finally the observations on the value of x-ray treatment are worthy of note: others also have seen the treatment do great good, and it seems clear that its application to the glands of the chest may relieve urgent symptoms.

THE PREPARATION OF INSULIN.

THE success of Banting and Best in obtaining, under laboratory conditions, an extract of the islands of Langerhans, and the effect of the injection of this extract on the blood sugar, has naturally attracted a great deal of attention. The account given in our columns by Professor Macleod (November 4th, p. 833), under whose superintendence the researches have been carried out in the Physiological Laboratory of the University of Toronto, has been, of course, very carefully studied by physicians and physiologists. It has also, naturally enough, aroused the interest of the general press, and in some cases the motive of the University of Toronto and of the Medical Research Council in taking steps to protect the method of manufacture, so that its commercial production should be carried out in a proper manner and with proper safeguards, has been misunderstood. The fact is that the preparation of insulin, even on the laboratory scale, is not free from difficulties and risks, and these become greater when its production on a large scale is attempted. Interest in the subject has also been displayed in the House of Commons, where a question was asked last week, the member who put it being under the impression that the preparation of insulin had passed beyond the experimental stage, and that there was an attempt to make it a Government monopoly. The Minister who replied said that everything had been done by the Medical Research Council to accelerate the production of insulin and that there was no thought of any Government monopoly. This, we believe, is quite well understood by the commercial firms engaged in the production of organic extracts; while ready to undertake the manufacture of insulin, they are properly averse from embarking on the project until a suitable method of manufacture on a large scale has been elaborated by the scientific experts. The reports published by Banting and Best of their original method of preparing insulin, and of its modification and improvement, have been closely examined by physiologists in this country, and a certain number of criticisms have been heard. One expression of them is to be found in the letter from Dr. Ffrangcon Roberts published in our issue last week (p. 1193). The points made by Dr. Roberts are of a technical kind, and the terms in which they were expressed, it must be admitted, were wanting in urbanity. Dr. H. H. Dale, who visited Toronto this autumn, has dealt with this aspect of the matter in a letter published elsewhere (p. 1241). While inviting Dr. Roberts to put his theories to the test, Dr. Dale states that no one can deny that a discovery of first-rate importance has been made. That this opinion is widely held is shown not only by the interest excited in this country and in America, but by the letter from Dr. Carrasco-Formiguera, of the Catalonia Institute of Physiology, Barcelona, published in our issue of December 9th. In the same issue were printed some "armchair reflections" by Dr. Otto Leyton, who showed anxiety lest the cost of insulin as prepared at present should prove prohibitive if made in London; he also expressed the hope that some other ferment, much more easily prepared, might be found to possess a similar property. He concluded by stating that preparations were being made to test the zymase group in the laboratories of the London Hospital Medical College. This is, of course, as it should be, and we may hope that the impetus given to the study of the functions of the pancreas by the Toronto experiments will not soon be lost. Lord Knutsford has never been backward in making an appeal to the benevolent in the interests of

manity or of the great hospital of which he is chairman. I should, therefore, not have been surprised to read an appeal from him for funds to carry out the suggested experiments in the laboratories of the London Hospital Medical College. So far as we are aware he has not made any such appeal. There has, however, appeared in the *Daily Telegraph*, and at least one other London newspaper, a long letter signed "Physician to a London Hospital," stating that since the cost of each dose of insulin must be great, and since it is probable that improvements in the method of production will shortly be made—so that it would not be a reasonable financial proposition for any manufacturing chemists to embark on the preparation of insulin—the work should be undertaken on a voluntary basis and the cost defrayed by subscriptions from the benevolent. The writer thinks that we are to wait until the method of production of insulin improves we must wait indefinitely. There is some reason to hope that he may prove to be mistaken in this; in any case, it seems to us that on his own showing it is premature to make an appeal for £30,000 to put up a factory to make 400 doses a day, although this is, in his opinion, the largest amount that could be made in London. The writer goes on to suggest that as it will be impossible to make all the insulin required it will be "only fair that those who subscribe substantial sums to the fund should have the right to nominate individuals to whom some of the pancreatic extract should be supplied." It falls to him, he says, to make the appeal, because his responsibility for cases of severe diabetes mellitus is heavier than that of anybody else. Exactly what this statement means we do not pretend to say, but no doubt the writer is strongly impressed with the necessity for immediate action, for he appeals for subscriptions to be sent to "G. Jodrell, 92, Portland Place, W.1," which is the same address as that from which Dr. Otto Leyton sent us the letter published on December 9th. We have no doubt—we may perhaps go so far as to say we know—that the Medical Research Council is losing no time. The method by which insulin may best be prepared is the subject of intensive investigation, and the Council is anxious to place the perfected method in the hands of responsible commercial firms at the earliest possible date. In these circumstances we are inclined to think that the benevolent would be better advised to send their contributions to the Treasurer of the Medical Research Council, the Right Hon. F. B. Mildmay, 15, York Buildings, Adelphi, W.C.2.

EXPERT WITNESSES.

In our issue of September 16th (p. 531) Mr. C. H. Fagge wrote a letter criticizing the method in which medical evidence is called both for the plaintiff and for the defendant in the courts. This was followed a fortnight later (p. 614) by a letter from Sir John Lynn-Thomas describing the course of action he had come to adopt when asked to give expert evidence. The publication of this induced Sir Clifford Allbutt to address a letter to Sir John Lynn-Thomas, which, with the writer's permission, is published in this issue (p. 1244). We are very glad to be able to do so, for Sir Clifford Allbutt's description of the plan adopted at Leeds to secure preliminary consultation between medical practitioners called to give expert evidence on either side in cases before the courts is of more than passing interest. Conditions have changed in many respects since the plan was devised, but the need for a more scientific basis for the trial of these cases has increased rather than diminished with the progress of specialization. The present practice, as Mr. C. H. Fagge pointed out, "scarcely advances medical prestige or makes for equity." This being so, it is difficult to account for the general failure to adopt the procedure followed with such signal and deserved success at Leeds, the more so because the attention of the profession has already been directed both to the importance of the principles involved and to this demonstration of their practicability. The question of providing for preliminary consultation between medical witnesses was raised by the

1903 and was referred to the Divisions. A detailed memorandum on the subject was circulated and a substantial majority of those Divisions which replied expressed themselves in favour of the principle of consultation. A report made by the Medico-Political Committee to the Representative Body at Leicester in 1905 was to the effect that opposition to the scheme arose, in the main, from a fear that the suggested consultations might, in the eye of the law, constitute "collusion" between witnesses, or that it would not prove acceptable to parties to the cases or their legal advisers. On these points the opinion expressed by the Committee appears equally applicable to day. After calling attention to the practical success of the Leeds experiment the Committee observed that the term "collusion" is inapplicable to a consultation for the purpose of securing a joint conclusion as to facts, and expressed the belief that "as soon as the more ethical procedure herein indicated has become the recognized practice of the medical profession, any objection which lawyers or their clients might entertain to consultation between their medical witnesses would tend to be regarded as an indication that there was some element in the case which would not bear unbiased examination. Consequently the practice of raising such objections would prejudice the case of the party objecting, and in a short time would cease."

MEDICAL INSURANCE AGENCY.

A MEETING of the Committee of Management of the Medical Insurance Agency was held on Thursday, December 14th, 1922, at the offices, 429, Strand. Dr. G. E. Haslip, the Chairman of the Committee, presided, and the members present were Sir Squire Spriggo, Sir Dawson Williams, Dr. E. Weaver Adams, Dr. H. A. Des Vœux, Dr. R. A. Gibbons, Dr. Langdon-Down, Dr. Alfred Cox, and Mr. W. E. Warner. The Chairman presented an interim report from which it appears that the Agency continues to progress and to flourish. That those who have taken policies of assurance and insurance through the medium of the Agency are well satisfied is amply demonstrated by the renewals no less than by the expansion of the business, largely through recommendations. During the nine months ending September 30th, 1922, new life contracts to the number of 114, representing £94,023, were negotiated, bringing the total of life assurances effected through the Agency to over £600,000. The renewals of motor car insurances also have been well maintained; during the period under review there was an increase of 80 new policies. It is hoped that the advantages to be derived from utilizing the services of the Agency will be even more effectively placed before the profession in 1923. Other branches of insurance show an equally satisfactory state of affairs. The subcommittee which was appointed in June last to consider the means whereby such funds as might be made available could be best applied to the educational benefit of the children of medical practitioners presented a report showing that consideration had been given to the position of the daughters of deceased or disabled medical men. Dr. Louisa Martindale had consented to assist, and her special knowledge and sympathetic understanding of the problems of female education had been of great assistance. After full consideration the Committee came to the conclusion that the best thing to do at the present stage was to select girls of about 12 to 14 years of age and to defray the cost of their education and, where necessary, their maintenance at school until about the age of 18 years; the subcommittee was invited to submit a detailed scheme to the next meeting. The Secretary (Mr. Ferris-Scott) announced that the sum of £265 was available for distribution to the medical charities, and it was resolved to allot £400 to the Royal Medical Benevolent Fund Guild, £210 to the Royal Medical Benevolent Fund, £105 to the Epsom College Benevolent Fund, and to reserve £250 for the proposed educational grants to girls. At its last meeting the Committee allotted 200 guineas to each of the first three charities mentioned. As the result of the distribution now to be made the total sum subscribed to medical charities by the Medical Insurance Agency since 1910 exceeds £10,000.

LIFE AT HIGH ALTITUDES.

MOUNTAINEERS and airmen combined in a discussion on the medical aspects of life at high altitudes at the meeting of the Section of Medicine of the Royal Society of Medicine on December 15th. Dr. T. G. Longstaff, a member of the most recent expedition whose object was to reach the summit of Everest, gave an interesting account of the experiences of himself and his colleagues, and showed some striking photographs. One of the greatest difficulties encountered by the party was, he said, excessive thirst, for at very high altitudes snow and ice did not melt into water, but went straight into watery vapour. Oxygen was, he believed, the best protection against frostbite. Of two parties ascending Everest one used oxygen and the other did not; in the first frostbite was only very superficial, whereas the other suffered severely. The party using oxygen ascended more quickly than the other, but was slower in the descent. Remarkable personal variations were observed; one member of the party became so acclimatized that he was able to spend three nights and four days consecutively and comfortably at a height of 23,000 feet. Mr. T. H. Somervell, another member of the Everest expedition, stated that for several successive evenings, at 16,500 feet, he had Choyno-Stokes breathing when lying down to sleep, but it passed off. At 27,000 feet his breathing was much deeper than at sea-level, and the rate was 55 to 60; during the climb his pulse rate varied between 180 and 200. Mr. J. Barcroft, speaking of the experiences of the recent expedition to the high Andes, said that the response to high altitudes included vomiting, headache, occasionally epistaxis, and some difficulty with vision and hearing; also among various people irritability of temper, trouble with the appetite, and some difficulty about doing work. The normal saturation of arterial blood with oxygen was at sea-level 96 per cent. of the possible; at high altitudes it ranged between 82 and 91 per cent., and the arterial blood was practically as dark as the normal venous blood. The oxygen pressure in the blood was also deficient in these cases, being 60 mm. only, as against the normal 100 at sea-level. Yet there was more oxygen in each cubic centimetre of blood at high altitudes than at sea-level, the reason being that there so much more haemoglobin was present. The climatic conditions were found to produce hypertrophy of the bone marrow. The blood of each member of the Andes party was so altered in its chemical properties that at any given oxygen pressure it combined with more oxygen than it had done at sea-level. Professor J. C. Meakins, who was also a member of the Andes expedition, said that to him the striking feature resulting from the stay of the party in the high Andes was the development of cyanosis; it resembled that seen usually in a bad case of pneumonia, and the violet hue persisted during the whole time. Among the natives of these Peruvian mountains club-fingers were common, quite apart from cardiac or pulmonary lesions. Among them also there was a distinct increase in the width of the chest in comparison with its height. After the eighth day of residence an examination of the party showed that the heart had become smaller, but this was less noticeable in those who did not stand the altitude well. Wing Commander Martin Flack, Director of Medical Research, R.A.F., said that in the case of the airman the change of altitude was very sudden, and his stay in the high altitudes brief; there was no increase in haemoglobin, and no increase of corpuscles even with diminished haemoglobin content. There might be a certain amount of acclimatization of the lung epithelium, by which, after a time, the aviator was able to get an extra amount of oxygen into his blood. It was to be remembered that the aviator sat in his machine, whereas the mountain climber trudged up steep inclines. The first effect of high flying was deepened breathing, and in some cases this amounted to real distress. The pulse rate usually rose, and the blood pressure also in a high flight, though if the blood pressure subsequently fell it never, in the fit man, sank below the normal unless the altitude flight was very prolonged. Muscular weakness was pronounced; even the working of the camera shutter seemed to call for enormous effort. Judge-

ment and perception also were impaired, and in a prolonged flight the respiratory capacity became lessened. Oxygen tended to abolish the effects due to defective circulation and nervous instability. Flight Lieutenant W. D. Faringdon said that at 18,000 feet an appreciable effort was needed even to pick up a map from the cockpit of the machine. At that height the impairment of judgment was apt to be marked, and special care had to be taken over the movements, otherwise almost automatic, involved in taking a photograph. When a height of 18,000 feet was rapidly attained the distress was at first very great, but it passed off in fifteen minutes; it was less pronounced if from two to two and a half hours were occupied in reaching this altitude. Mr. Malcolm Hepburn, F.R.C.S., a member of the Alpine Club, considered acclimatization to be a question of the oxygen-carrying capacity of the blood. If the persons doing such a great climb as that of Mount Everest could accustom themselves to doing with a smaller supply of oxygen than the normal they need not despair of being able to accomplish this supreme feat. But definite training should be undertaken, suitable food supplied, and the ascent should be slow. Dr. J. S. Haldane said that his experience confirmed nearly all the statements other speakers had made as to the effects of high altitudes. He still adhered to the conclusions he arrived at as a result of the Pike's Peak experience. The pressure of oxygen in the arterial blood was not normally in equilibrium with the pressure of the oxygen in the alveolar air, and by all sorts of modifications in the breathing it was rendered far from equal. The account of the experiences on Everest given by Dr. Longstaff was made more vivid by some remarkable photographs, which were shown to the Section.

AN OUTBREAK OF DYSENTERY IN WALES.

Dr. T. W. Wade's report to the Welsh Board of Health on the occurrence of bacillary dysentery in the Ogmore and Garw Urban District, in the county of Glamorgan, has been issued by the Ministry of Health, with a prefatory note by Sir George Newman.¹ It is the record of a very thorough investigation. Ogmore, a district in the South Wales coalfield, is a narrow valley running north and south; flat-topped hills on either side prevent much lateral communication, and the only outlet is at the southern end. The outbreak began suddenly about May 11th, 1921, with explosive intensity and without the occurrence of previous cases to give warning. On May 18th Dr. Anderson, who is in practice in the valley, reported a serious prevalence of diarrhoea, with fever, tenesmus, and blood-stained and slimy evacuations, among the children in one district in this valley. The medical officer of health, Dr. Murphy, found that, besides young children, older children and adults were suffering in the same way. All the signs pointed to a water-borne infection. During the outbreak, which lasted until the end of August, the total number of deaths was 12; the infection was thus comparatively mild. The cases seen by doctors numbered 548 (a case mortality of 22 per cent.); but from house-to-house inquiry it appeared that the total number of diarrhoeal cases had been somewhere about 1,100. The causative organism of the disease was proved to be *B. dysenteriae* Flexner (strain W). The outbreak was limited at first to a defined area supplied by water from a particular main and the houses nearest the source of supply were those most seriously affected. A group of houses supplied with water from a private source, though situated near the middle of the invaded district, escaped almost wholly. Exhaustive inquiry failed to show how the water became contaminated by the specific organism. The Fronwen brook (which fed the contaminated area) was supplementary to the main water supply of the district. While the Fronwen gathering ground was good, and its water chemically and bacteriologically fairly good, yet in its course to the main it was open to contamination by wayfarers. No rain fell from the 1st to the 7th of May

¹ Reports on Public Health and Medical Subjects. No. 14. H.M. Stationer's Office, 1922. (Price, post free, 1s. 1d.)

On May 7th there was 0.86 inch of rain; on May 8th 0.51 inch, and slight rain fell on May 9th, 10th, and 11th. The epidemic first noted on May 11th was at its height on May 13th. The inference that the dejecta of a dysentery carrier was washed into the Fronwen brook and that this caused the epidemic seems reasonable. That the carrier may have acquired his organism in the trenches of the western front is an attractive speculation, based on the fact that very many of the 38th Welsh Division now live in the district and bacillary dysentery was prevalent in their part of the line. Three ex-soldiers, discharged from the army with dysentery, were found, but although two of these lived near the source of this water supply no connexion could be traced between them and the outbreak. Dr. Wade remarks, however, that this organism may probably be a commoner inhabitant of the human intestine in this country than is generally supposed. The epidemic, having started from the definite water source, spread later by case-to-case infection, but not to any great extent. The measures taken were as follows: the water in the main has been chlorinated, and the Fronwen water is now piped for such a distance that casual contamination is unlikely.

SOCIÉTÉ INTERNATIONALE DE CHIRURGIE.

The sixth triennial Congress of this society will be held in London from July 17th to 20th, 1923, under the patronage of His Majesty the King and the presidency of Sir William MacEwen, C.B., F.R.S. The meetings will be held at the Royal Society of Medicine, 1, Wimpole Street, W.1. The subjects chosen for discussion are: (1) The surgery of the endocrine glands with the exception of the thyroid; (2) Arthroplasty; (3) The late results of surgical intervention in traumatic lesions of the peripheral nerves; (4) Serum and vaccine therapy of surgical infection with the exception of tetanus; (5) Operative shock. According to the provisional programme the inaugural meeting will take place on Tuesday, July 17th, at 11 a.m., when H.R.H. the Prince of Wales has graciously consented to open the Congress. Scientific sessions will be held on Tuesday afternoon and on Wednesday, Thursday, and Friday mornings. Operations and demonstrations will be arranged at the various hospitals on the last three days of the Congress. A collection of pathological specimens illustrating diseases of the endocrine glands will be on view at the Royal Society of Medicine. Hospitality will be extended to members of the Congress by His Majesty's Government, the Lord Mayor of London, the Royal College of Surgeons, the University of London, and the Barbers' Company. The organizing secretaries are Sir D'Arcy Power, K.B.E., and Mr. J. E. H. Roberts, O.B.E. The British secretariat is at 26, Harley Street, W.

MEDICAL GOLFING SOCIETY.

The second annual dinner of the Medical Golfing Society was held at the Grand Hotel, London, on December 14th, and was followed by the annual general meeting. The President, Dr. Rolf Creasy, occupied the chair. The rules of the Society were revised so as to provide for the annual election of the officers, and for the continuance in office of the committee for three years, a third of their number to retire annually. A general discussion of the Society's business took place and the following officers and committee were elected for the ensuing year: President, Dr. Percy Kidd; Past-President, Dr. Rolf Creasy; Captain, Mr. H. D. Gillies; Match Secretary, Dr. H. Gardiner Hill; Secretary and Treasurer, Dr. Rolf Creasy, jun.; Committee: Dr. J. Clarke, Dr. R. Creasy, Mr. G. Dawson, Sir K. Goadby, Dr. G. E. Haslip, Mr. T. P. Kolesar, Dr. G. Norman, Sir M. Rees, Mr. J. Swan. Two successful golfing meetings have been held during the past year. The summer meeting took place at Stoke Poges, and the autumn meeting at Littlestone; the results of the various competitions were briefly reported in our columns. Owing to the reconstitution of the Club it was not possible to hold many matches in 1922, but Captain, Sir Milsom Rees, was able to arrange matches

against Royal Wimbledon, Sideup, and the Stago Golfing Society, the two former being lost and the latter won. It was decided that the subscription should remain at 10s. The interest taken in golf by members of the medical profession is at least as great as that of any other calling, and the Medical Golfing Society may well look forward to a future of increasing prosperity.

THE FIRST WOMAN VETERINARY SURGEON.

THE Royal College of Veterinary Surgeons, which is the only body empowered to grant a diploma in veterinary medicine and surgery, has hitherto refused to admit women. The Sex Disqualification (Removal) Act has settled the question of the admission of women to the professions, and on Wednesday last Miss Alcon Cust was admitted a Member of the Royal College of Veterinary Surgeons. She is the first woman to obtain the diploma. Miss Cust, who is the daughter of the late Sir Leopold Cust, Bt., and the sister of Sir Charles Cust, equerry to the King, decided while still a girl to devote herself to veterinary work. She passed through the full curriculum of four years at the Edinburgh Veterinary College with distinction. Although the Royal College of Veterinary Surgeons refused, on the ground of sex, to grant her its diploma, Miss Cust determined to follow her vocation; she established an extensive veterinary practice in the West of Ireland, and was for ten years veterinary inspector under the Galway County Council and the Department of Agriculture in Ireland. During the war she volunteered for service overseas and was appointed by the War Office to a responsible position in the bacteriological laboratory of a veterinary hospital in France. So far as we are aware there are very few, if any, women veterinary surgeons in other countries; we are told that some twenty-five years ago two Russian women attended the Alfort (Paris) Veterinary School, and were subsequently admitted to the Russian State Veterinary Service. Since the Sex Disqualification (Removal) Act was passed the possibilities of the veterinary profession as a calling for women have been perceived by a few, and at the present time there are, we believe, two women students attending the veterinary department of the University of Liverpool, two at the Veterinary College of Ireland (Dublin), and one in Edinburgh. The veterinary profession has been rather a long time following the example of the medical profession in admitting women, but we have no doubt that there is a considerable opening for them, both in practice and in research. The importance of the scientific investigation of diseases of animals, and the light that the study of disease in animals can throw on pathology in general, are now far more fully appreciated than ever before.

DOCTORS IN RUSSIA: A CHRISTMAS APPEAL.

WE commend to the sympathetic notice of every reader of THE BRITISH MEDICAL JOURNAL the appeal, signed by the four officers of the Association and printed at p. 1228, on behalf of the starving doctors, and their families in Russia. At this season the claims upon the generosity of a generous profession are many. But this second appeal for help for our Russian colleagues in distress is one that will surely find a response. What better relish for a Christmas dinner could be imagined than the knowledge that a gift has been willingly made towards the sending of a food parcel to some famine-stricken medical household in Russia? Subscriptions of 5s. or multiples of 5s. should be sent to Mr. L. Ferris-Scott, Financial Secretary of the British Medical Association, 429, Strand, W.C.2.

A GIFT of two sums of 100,000 francs has been made to the University of Paris by Madame Edouard Nathan. The first of these is intended by the donor to be applied to the improvement of the scientific laboratories of the University, and to the promotion of research work. The second is to be set apart for the purpose of making loans to impecunious students of the University to enable them to continue their studies.

SIR EDWARD SHARPEY SCHAFER, F.R.S.

Some time ago the suggestion was made that the meeting of the British Association in Edinburgh in 1921 would form a fitting occasion for the presentation to Sir Edward Sharpey Schafer of some token of their esteem from his present and past demonstrators and fellow research workers first in London and afterwards in Edinburgh.

As so many of those who had been trained under him now occupy posts in distant lands it was found impossible to make the necessary arrangements for a presentation at that early date, but Professor Halliburton made a statement at one of the largely attended meetings of the Physiology Section, expressing the desire of all who had been associated with their old master at the prosecution of physiological

research to present him with some mark of their esteem and affection, and indicating the form it would probably take. It was appropriate that the announcement should be made in Edinburgh, for Sir Edward Sharpey Schafer has been Professor of Physiology there since 1899.

It was decided that the presentation should consist of a life-size portrait plaque, and that a medal reproducing the portrait and inscription should be offered to each of the many subscribers. The plaque and the medal are the work of Mr. C. D'O. Pilkington Jackson, A.R.B.A., and the portrait is

excellent. From the photograph of the medal here reproduced it will be seen that the obverse bears in bold relief the bust of Sir Edward Sharpey Schafer and that the reverse contains a dedicatory inscription. The plaque itself is of bronze and has been mounted on stone with the inscription shown on the reverse of the medal underneath it. At Sir Edward Sharpey Schafer's desire it will eventually be placed within the University of Edinburgh, but at present it remains in the sculptor's studio, as he wishes to exhibit it at the Royal Scottish Academy.

The long list of subscribers includes many of the leaders in physiology and other branches of medical science in this and other lands: a few of them may be named—Bayliss, Rose Bradford, Halliburton, L. Hill, MacWilliam, Mott, Starling, in this country; and Hunter and Tait (Canada), Jolly (S. Africa), Malcolm

and Mackenzie (New Zealand), Addis and S. Simpson (U.S.A.), Row (India), Itagaki and others (Japan). Among the original subscribers were two of great distinction who have unfortunately passed away—Augustus Waller and Benjamin Moore.

The profession will join in congratulating Sir Edward Sharpey Schafer on this spontaneous tribute from his old pupils and fellow workers to his eminence as a physiologist, and to the inspiration of his teaching, and also in the hope that he still has before him many years of successful work.

The profession will join in congratulating Sir Edward Sharpey Schafer on this spontaneous tribute from his old pupils and fellow workers to his eminence as a physiologist, and to the inspiration of his teaching, and also in the hope that he still has before him many years of successful work.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

Prorogation.

Parliament was prorogued by Royal Commission on Friday, December 15th, after the Royal assent had been given to several measures, including the Importation of Cattle Bill. The new Session will open on Tuesday, February 13th.

Insulin for Diabetes.—Sir William Bull asked, on December 15th, whether the Medical Research Council was throwing obstacles in the way of the general production of insulin as a remedy for diabetes; if, as knowledge of the remedy had passed the experimental stage, the Minister of Health could arrange that the manufacture should be left to private enterprise; and whether the system of licences granted by the Medical Research Council to authorized persons would afford ample protection to the public and make the remedy available much sooner than by keeping it a Government monopoly. Sir M. Barlow said that the Medical Research Council was doing everything in its power to accelerate the production and use of insulin. The assertion that the remedy had passed the experimental stage was not in accord with the experience of other countries or the best scientific opinion here. There was no question of any Government monopoly and the suggestion as to manufacture was on the line which the Council had been diligently pursuing for some time past.

Medical Department, Ministry of Pensions.—Major Tryon has stated that local practitioners serving on medical boards received the following fees: Chairman, £1 11s. 6d. (for a session of 2½ hours); specialists, £2 2s.; ordinary members or assessors, £1 6s. 3d. Considerable assistance is now given by full-time medical officers of the Ministry, of whom some 200 are liable for his service. The average salaries of these officers is approximately £324 per annum. The total expenditure on payment to sessional members of the boards was, in 1921, £627,795. The corresponding figure for the current year will be more than one-third less, owing to a reduction of the sessional fees payable, and of the number of members of ordinary boards from three to two. Major Tryon has also explained that when whole-time medical officers of the Ministry were not available local practitioners were employed to examine and make detailed reports on pensioners accommodated in institutions not under the control of the Ministry. These medical men received a fee of £1 1s. for one case, and £1 11s. 6d. for two or more cases. No higher fee than £1 11s. 6d. was paid for visit to any one institution whatever the number of pensioners examined and reported upon.

Vaccine Lymph.—Captain Bowyer asked, on December 14th, why it was that private practitioners were unable to obtain Government lymph. Sir M. Barlow said that the obligations of the Government were limited to the supply of lymph for public vaccination and at present it was not practicable to extend the supply to private practitioners.

Small-pox.—In reply to Mr. T. Thomson, Sir M. Barlow said that the total number of deaths from small-pox in the first eleven months of this year was 27. Twelve of these cases had been vaccinated, 11 were unvaccinated, 3 showed no evidence of vaccination, and one was vaccinated during the incubation period of small-pox. The total number of cases of small-pox occurring in vaccinated persons during the eleven months was 271, and the percentage rate of deaths to cases in this class, irrespective of age, was 4.4. The total number of unvaccinated cases, including those which showed no evidence of vaccination, or were vaccinated only during the incubation period of small-pox, was 625, and the percentage rate of deaths to cases in this class, irrespective of age, was 2.4. In 6 cases no information was available as to vaccination. There were no fatal cases among vaccinated persons under 35 years of age.

Insurance Medical Services.—Sir Montague Barlow informed Mr. Gould, on December 13th, that no medical practitioner working single-handed under national insurance might have more than 3,000 persons on his list, and in a considerable number of areas a lower maximum of 2,500 or 2,000 had been fixed. Taking the country as a whole the average number of insured persons per doctor was approximately 1,000, and the corresponding remuneration, including mileage payment, would be slightly less than £500 a year. On a question as to the procedure, if an insured person desired attention from his own private doctor, Sir Montague said that an insured person wishing to be treated by a practitioner not under an agreement with an Insurance Committee might apply to the local committee for permission to make his own arrangements. If it were granted a contribution would be given by the committee towards the cost of the treatment. The committee had full discretion in considering applications of this nature. There was no provision in the Acts for any reduction in the contribution on the ground that the insured person did not take up the benefits of the Act.

Surplus of Approved Societies.—At the instance of Viscount Ednam, on December 13th, Sir M. Barlow stated that the total disposable surplus of approved societies and branches in England on the first valuation was about £3,000,000, the major portion of which the members elected to take in the form of an increase of the ordinary cash benefits. Of the balance a sum of £950,595 had been allocated by certain societies for payment to hospitals and convalescent homes during the period from July, 1921, to July, 1926.

KING EDWARD'S HOSPITAL FUND FOR LONDON.

A MEETING of the President and General Council of King Edward's Hospital Fund for London, for the purpose of awarding grants to the hospitals and convalescent homes for the present year, was held on December 13th, with H.R.H. the Prince of Wales in the chair. A resolution was passed expressing deep regret at the death of Mr. John G. Griffiths, who since 1902 had rendered invaluable service to the Fund and to the hospitals.

Financial Statement.

LORD REVELSTOKE (honorary treasurer) said that the sum to be distributed would be £220,000, the same amount as last year. The net income for 1922 was almost exactly £220,000. This estimated total included an anonymous donation of £10,000 given to the Combined Appeal, but earmarked by the donor for the King's Fund, and a sum of about £13,000, representing one-fourth of a full year's interest from the legacies of Lord Mount Stephen and Sir Thomas Sutherland; a full year's interest on these bequests would probably approach £50,000. It had always been realized that the special distributions of the last few years—the National Relief Fund, the King's Fund Emergency Distribution, the Government grants administered by the Voluntary Hospitals Commission, and the Combined Appeal—had been only temporary expedients to tide over a particular crisis and to allow time for developing permanent increases in income. Now that the time had come for concentrating on permanent remedies he submitted that the policy should be to endeavour to increase the annual distribution and therefore the power to encourage and assist the hospitals to develop new sources of income and new methods of controlling expenditure.

SIR WILLIAM COLLINS, in making the annual statement on behalf of the League of Mercy, said that it was practically certain that the League would give not less than the £15,000 given last year to the King's Fund; he hoped it would be more. The total which the League had contributed to the King's Fund would then amount to £339,000, besides £49,065 to extra-metropolitan hospitals.

Grants to Hospitals.

SIR COOPER PERRY presented the report of the Distribution Committee. This stated that the amount now for allocation amongst hospitals was £215,000. The Committee had been concerned again this year, not only with the ordinary distribution, but also with special distributions, to assist the hospitals to tide over the period needed for reorganization of their finances after the war. In March, July, and November of the present year the Committee made recommendations to the Voluntary Hospitals Commission covering in all a total of £147,100, the balance of the sum of £225,000 provisionally allocated to London out of the total of £500,000 voted by Parliament for the whole of Great Britain. In August and October the Committee carried out two distributions on account of the proceeds of the Hospitals of London Combined Appeal—£150,000 in August and £100,000 in October. These were not made on the same basis as the ordinary distributions of the King's Fund, but on a basis announced to the participating hospitals when they were invited to suspend their own special appeals in order to co-operate. The number of hospitals applying for grants out of the ordinary distribution was 112, as against 110 in 1921. In view of the urgent need of maintenance grants, the Distribution Committee had again adopted the principle that grants in aid of schemes of capital expenditure should be limited to cases where the work was particularly urgent and was within a reasonable distance of being carried out. The number of schemes which had reached this stage was larger than last year, and consequently the total amount of the grants recommended in aid of schemes of capital expenditure was larger.

Grants to Convalescent Homes.

SIR ALAN ANDERSON (honorary secretary) presented the schedule of awards to convalescent homes. This year the sum fixed for distribution amongst convalescent homes was £5,000; the amount in 1921 was £3,930, besides £6,070 to consumption sanatoriums; but for reasons set out in last year's report grants were now no longer made to sanatoriums. In distributing the increased amount available for convalescent homes, the Committee gave preference to institutions directly connected with London hospitals, and in dealing with the applications it gave special attention to the question of comparative urgency of need, as shown by audited accounts and balance sheets.

The Hospitals' Combined Appeal.

In regard to the present position of the Combined Appeal, SIR ALAN ANDERSON said that no precise figure of results to date could be given, because a good deal of the moneys collected had not yet been paid over, but the grand total

of the Appeal Fund was estimated at £435,000. The intention was to close down the general appeal by December 31st, and to leave in activity only one or two specific appeals which would not be concluded by then. They were now devoting thought to permanent methods of increasing the income of hospitals; one of these was the obtaining of increased support from domestic workers, and the other direction was that of the organization of contributions from wage-earners generally.

Growth of the King's Fund.

THE PRINCE OF WALES said that it was exactly twenty-five years since the King's Fund made its first distribution. On December 14th, 1897, the Executive Committee met under the chairmanship of Lord Lister to settle the first distribution report to the Council. The amount distributed in 1897 was £34,000 from the special efforts of the first year, and £22,000 from the estimated annual income. This year £250,000 had already been distributed from the special Combined Appeal, and the amount now being distributed out of ordinary income was £220,000.

Financial Problems of the Hospitals.

THE financial problem facing the hospitals and the Fund had enormously increased. The King's Fund was founded to meet a crisis; the hospitals of London had then a deficit of £70,000 on a turnover of £700,000. The King's Fund now distributed £220,000 a year, and yet there was a deficit of £210,000. Had the income of the hospitals fallen off? Were voluntary contributions drying out? Quite the contrary. Hospital income was more than three times what it was. Voluntary contributions continued to increase, and were 50 per cent. more than before the war. The present difficulties were due to the fact that hospital expenditure had increased since 1897 nearly fourfold. There were three causes for this: the increased number of patients, needing more hospitals and bigger hospitals; the developments of medical and surgical science, all costing money; and the rise in the price of everything since the war. The result was that, in spite of the great increase in the King's Fund distribution, there was still a deficit of £210,000. The hospital problem was thus much bigger than it was twenty-five years ago, but, fortunately, the means of dealing with it had also grown. They had, in the report of Lord Cavo's Committee, a programme based largely on two things: one was the success of many of the provincial hospitals in organizing workshop contributions; the other was the growth of the King's Fund from a mere collecting and distributing agency into a central administrative body, which, being itself voluntary, respected the independence of the voluntary hospitals. The King's Fund had become the local committee for London, and local voluntary committees had been set up all over the country to do the same kind of work. Moreover (His Royal Highness concluded) the Order of St. John and the British Red Cross Society, through their Joint Council, were now assisting in the solution of voluntary hospital problems.

ROYAL MEDICAL BENEVOLENT FUND.

At the meeting of the Committee held on November 11th, 1922, 24 cases were considered and £389 10s. voted to 23 applicants. The following is a summary of some of the cases relieved:

Homes to make about £10 12s. 11d. in December. Daughters, aged 58 and 50, of L.S.A. Lond., who died in 1915. OWING to chronic ill health they find it extremely difficult to manage on a joint income of £101; the rent amounts to £34. Relieved fourteen times £189. On the recommendation of the Fund's visitor the grant of £18 was raised to £25 in twelve instalments.

Widow, aged 80, of L.R.C.P. Edin., L.S.A. Lond., who died in 1883. She is now left with a total income of £45, out of which she has to pay rent and buy food. The Guild sent her an emergency grant of £3 and £1 for coal, and the Fund voted £18 in twelve instalments, and a special grant of £7 10s.

Subscriptions may be sent to the Honorary Treasurer, Sir Charles Symonds, K.B.E., M.S., F.R.C.S., at 11, Chandos Street, Cavendish Square, London, W.1.

The Royal Medical Benevolent Fund Guild is overwhelmed with applications for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. The Guild appeals for second-hand clothes and household articles for the benefit of the widows and children who in happier times would not have needed assistance. The gifts should be sent to the Secretary of the Guild, 43, Bolsover Street, W.1.

England and Wales.

NEWCASTLE-UPON-TYNE AND NORTHERN COUNTIES MEDICAL SOCIETY.

The annual address of the Society was delivered on December 7th by Sir Humphry Rolleston, President of the Royal College of Physicians of London. The President, Professor Stuart McDonald, occupied the chair. An audience of over two hundred listened with the greatest interest to Sir Humphry's "Reflections on high arterial blood pressure." The lecturer outlined the history of observations on blood pressure from the earliest records to the present time, and then passed on to a critical analysis of the causes and treatment of raised blood pressure. The address will be published in full in the journal of the Society. Professor Drummond proposed a hearty vote of thanks to Sir Humphry Rolleston, which was seconded by Dr. Andrew Smith and carried with acclamation. In the evening the annual dinner took place, at which Sir Humphry Rolleston was the principal guest; 130 members and guests were present. The health of "The Guest" was proposed by Professor T. Beattie, and Sir Humphry Rolleston replied. In his speech he referred to several famous medical men who had originated in the Newcastle district, including Akenside, Addison, and Snow. "The Society" was proposed by Professor Arthur Robinson, Vice-Chancellor of Durham University, and responded to by the President. Dr. R. A. Bolam proposed the health of the other guests of the Society—namely, Professor Drummond, Admiral Slayter, and Mr. S. Dunstan. Admiral Slayter replied.

THE GRADING OF MILK.

The Minister of Health has made an order entitled the Milk (Special Designations) Order, 1922, prescribing the conditions subject to which licences may be granted for the sale of milk as "Certified," "Grade A (tuberculin tested)," "Grade A," or "Pasteurized." The order comes into operation on January 1st, 1923, and copies may be obtained from the Stationary Office either directly or through any bookseller. The principal conditions laid down in the Order are as follows:

Certified milk must be produced from healthy cows which have passed the tuberculin test. It must be bottled on the farm, and must satisfy a somewhat severe bacteriological test.

Grade A (tuberculin tested) milk must be produced from healthy cows which have passed the tuberculin test. It must be bottled before distribution, and must satisfy a bacteriological test less severe than that for certified milk.

Grade A conditions as Grade A (tuberculin tested) of the tuberculin test.

Pasteurized milk must have been held at a temperature of 145° to 150° F. for at least half an hour, and then cooled to 55°, and it must satisfy a prescribed bacteriological test.

The Order proscribes the fees payable for licences; these have been fixed at such amounts as are estimated to recompense the licensing authorities for their expenditure under the scheme, but the fees are open to revision in the light of experience. An amending Order, dated December 18th, has since been issued, relaxing for a period of six months so much of the principal Order as limits the use of the designation "Pasteurized" to milk which has been treated by the process specified in paragraph (1) of Part IV of the third schedule to that Order.

SMALL POX IN LONDON AND THE PROVINCES.

Confidence that the outbreak of small-pox in London had been overcome has been shaken by the occurrence of two fresh cases in Southwark on December 20th. At the beginning of the present week only 15 cases remained in hospital, and there had been no fresh admissions since November 24th. In an interesting report Dr. F. W. Alexander, M.O.H. Poplar, gives an account of the action taken in that borough. The outstanding fact is the vigour and concentration of effort devoted to the stamping out of the infection. The danger of the pestilence was at once realized, and a wholesale immunization by vaccination of the inmates and staff of the Poplar workhouse was undertaken and overtaken without delay, so that only those who were already infected or whose infection was too far advanced to be forestalled by vaccination developed the disease. At the same time search for and surveillance of contacts was carried out. The Ministry of Health, the County Council, the borough health authority, and the guardians all shared in the crusade, and all have to be congratulated on the action taken. In the provinces the position is more doubtful. Cases are

reported from Nottinghamshire and Jarrow, and also from South Wales. It will be important to know whether these cases are of the mild or American type which has been the general character of variola in recent years, and also in the present year, or whether the disease in any of the affected areas is of the severe strain, with its 30 per cent. of fatality which has been experienced in London. It is too soon to go into details of the Asylums Board's cases, but a provisional report by the Chairman of the Infectious Hospitals Committee states that from July 25th to December 6th 69 cases of small-pox were admitted. Of these, 23 had died and 15 remained under treatment. Of the cases admitted none showed evidence of vaccination or revaccination within the preceding seventeen years; 12 of the 21 cases with no evidence of vaccination at any period had died; whilst of 48 cases that had been vaccinated in infancy but not since only 11 had died.

Scotland.

CHAIR OF PUBLIC HEALTH IN GLASGOW.

Mr. HENRY MECHAN, one of the leaders in industry in Glasgow, has presented a sum of £25,000 to the University of Glasgow, for the establishment and equipment of a chair of public health. Hitherto the two departments of forensic medicine and public health have been combined, but Dr. Glaister, the Regius Professor of these subjects, recently reported to the University Court that there had been an enormous increase in the work of the two departments. At the examination last September there were no fewer than 295 candidates. Professor Glaister went on to represent that the time had come when, in the interests of the University, the two subjects should be separated and that an appointment should be made exclusively to the department of public health, leaving him to devote himself to forensic medicine. It was no doubt in consequence of this representation that Mr. Mechan has made his munificent donation. He has left all the details to be settled by the University authorities. The Principal, Sir Donald MacAlister, in making the announcement to the University Court on December 14th, said that the necessary steps to obtain a new ordinance establishing the professorship would be taken immediately. At the same meeting of the Court it was announced that the sum of £20,000 bequeathed by Mr. William Gemmell for the foundation of a chair in the faculty of medicine or of science, in memory of his brother, the late Dr. Samson Gemmell, Regius Professor of the Practice of Medicine in the University, had been received. The Principal remarked that these two chairs raised the number founded in the past fifteen years to seventeen. Even during the last few months four chairs have been founded: physiological chemistry, bacteriology, organic chemistry, and applied physics. The *Glasgow Herald*, in commenting on the most recent gifts, says, speaking of Sir Donald MacAlister, "We shall not go wrong in assuming that his striking personality and high service to the University have some relation to these munificent gifts by the grateful and far-seeing sons of the city."

ST. ANDREWS UNIVERSITY AND DUNDEE ROYAL INFIRMARY.

At a meeting of the governors of Dundee Royal Infirmary on December 11th the announcement was made that a joint committee of the University Court of St. Andrews and of the Royal Infirmary governors had recommended, among other things, that in the event of a vacancy occurring in one of the professorships of medicine, surgery, pathology, or obstetrics the joint committee should recommend to the University Court one or more persons in order that the Court might appoint one of these to the vacant professorship, and the person so appointed should thereafter be elected to the staff of the Infirmary by the directors. It was also recommended that the joint committee should be retained as a standing committee, with the function of harmonizing the activities of the University and the Infirmary in matters common to both organizations. These recommendations had been approved by the directors and sanctioned by the University Court.

TREATMENT OF CRIMINALS.

The last present occupier of the Glasgow Medical Lunch Club for the year 1922, Dr. John Henderson, Dr. James Devon, Prison Surgeon, was present as the guest of

After lunch Dr. Devon addressed the members on the treatment of criminals. He began by stating that from the purely medical standpoint the first consideration is the welfare of the patient, that the primary duty is the saving of life, without regard to the possible value of the life saved. In the treatment of criminals this principle could not be carried out, as the safety of the public must be considered, and to ensure this a suitable line of action must be adopted towards the offender. The proper care of the criminal was a considerable expense to the country, appreciably greater in England than in Scotland, and any scheme of reform seemed only to result in increased financial outlay, without any corresponding certainty as to improvement. Dr. Devon quoted figures illustrative of the annual cost of upkeep for each inmate in a Borstal institution and in prison. He emphasized the fact that the first consideration should not be the comfort of the offender, but the safety and comfort of other people. The world could not be altered to suit the criminal, but the offender must be made to realize that, to remain a member of a community, he or she must conform to its rules. Various classes of offender were cited, and the lecturer emphasized the point that often the so-called political offender was a greater nuisance and danger to the community than those who commit crime under the influence of passion. The latter, after a term of punishment, were not likely to repeat the offence, but the former could not be trusted to refrain. He or she would not obey the laws of a community, whose constitution they were determined to alter by any means, regular or irregular. With regard to the education of the criminal while under restraint, the lecturer expressed his conviction that this should be directed along some line by which on his release the offender might be able to earn a living honestly. The sort of higher education which was attempted in some quarters was unnecessary, and in most cases futile. The address was much enjoyed by the large attendance of members present, whose thanks were expressed by Dr. D. McKail.

CENTRAL MIDWIVES BOARD FOR SCOTLAND.

At a special meeting of the Central Midwives Board for Scotland for the hearing of penal cases, when Dr. James Haig Ferguson was in the chair, the certificates of two midwives were directed to be cancelled and their names removed from the roll. In one instance judgement had been deferred for further reports from the local supervising authority; these were unfavourable. In the other case charges with regard to failure to take and record pulse and temperature, to keep a register of cases, to send for medical assistance in a case of emergency, and of being generally incapable of carrying out the rules were found to be proved. This woman was further prohibited from attending women in childbirth in any other capacity.

Ireland.

BELFAST TEACHERS IN AMERICA.

At a meeting of the Ulster Medical Society held in the Medical Institute, Belfast, on December 7th, with the President, Mr. R. J. Johnston, in the chair, Mr. Andrew Fullerton read "Notes on a visit to hospitals in Canada and in the United States." His visit embraced Montreal, Toronto, Chicago, the Mayo Clinic of Rochester, Baltimore, New York, Boston, and Harvard University. Mr. Fullerton described the warm hospitality of both the Canadian and the United States surgeons, and the most pleasant reunions with those with whom he had worked in France. The essential points of difference between the American hospitals and those at home were the endless wealth that was showered by the rich in the former continent on their institutions; the readiness of both medical men and laymen to pick up, test, and, if found useful, adopt new ideas and suggestions, no matter from what source; the employment of large staffs of young ladies to keep indexes, records, and generally to facilitate looking up past histories and making references; the administration of anaesthetics by specially trained nurses instead of by medical men; the wonderful and very complete general organization; the provision of special pavilions for the middle classes in connexion with the general hospital, so that many surgeons practically spent their whole day at the institution, and the

patient might have his own medical attendant, these patients having thus all the benefits at present conferred only on the poor or on the very rich in this country; the large amount of radium; and the sizes and completeness of the dental clinics. Mr. Fullerton gave very vivid and often humorous details of his interviews and adventures, and described the impressive ceremony of his admission as Honorary Fellow of the American College of Surgeons. He said, once more, that nothing could exceed the kindness and thoughtfulness of those whom he met, some of them complete strangers. The President proposed, and Professor Sinclair seconded, the following resolution, which was carried with acclamation:

"That the Ulster Medical Society congratulates Colonel A. Fullerton, C.B., C.M.G., on his election as an Honorary Fellow of the American College of Surgeons. Not only is this distinction a fitting recognition of Fullerton's eminence as a surgeon and of his wide fame as an urologist, but it reflects honour on the Belfast School of Surgery, of which he is so distinguished a member."

Professor MacIlwaino followed with his account of a "Holiday visit to Montreal, Toronto, and the Mayo Clinic." He described the charming site of the university at each of these Canadian cities, and spoke of the wealth at the disposal of American institutions. His chief interest lay in the pharmacological teaching of the student and in the research, and every step and all equipment were most kindly explained to him. The metabolic clinic with its special little hospital and its special kitchen was a great advance and its study very instructive. The various clinics at Rochester were described and his experiences in each. Everywhere he was struck with the immense amount of trouble taken and the immense amount of work. The indexing and reference staff of young ladies was most complete; in no other way could so much be got through. The kindness of everyone and the amount of trouble taken to show the visitor everything were beyond all praise. Dr. Dempsey and Dr. Gardner Robb spoke of their experiences in America; the latter said that the Rockefeller Institute sent him the anticerobrospinal serum free for the town. The President conveyed to both the readers the very hearty thanks of the meeting for their most interesting and instructive papers.

TYPHUS IN COUNTY MAYO.

The typhus outbreak in the Barony of Erris on the West Mayo coast, about which alarming reports were circulated, is now well under control. When the first outbreak occurred in June the Public Health Department of the Irish Free State Government sent medical and nursing staffs with full equipment to the area. Since then there have been sporadic cases, but with the measures taken by the Public Health Department the serious danger which threatened the inhabitants is practically at an end; the number of deaths recorded is three. The two local medical officers were so unremitting in their attention to the patients that both were prestrated with fatigue and overwork, but neither contracted the fever. One of them has already resumed duty. Dr. McHale, the other medical officer, who was recuperating in Dublin, has returned to Belmullet, and it is expected that he will resume his duties in a few days.

Mr. Blythe, Minister of Local Government, in reply to a question, at a recent sitting of Dail Eireann, stated that in the middle of June cases of typhus fever were reported to the Minister of Local Government by the medical officers of the health in Belmullet, and had continued at intervals over the intervening period. In all about 20 cases had come under notice, including the sanitary subofficer, who contracted the infection in the discharge of his duties, and one of the nursing sisters of the local hospital. The disease had been attributed to crowding in a disused coastguard station in which families who had deserted their homes took up their abode. Belmullet had long been recognized as a district in which typhus fever might be said to be endemic. The population was very poor, living in small and congested homes, with primitive habits, and the practice of housing animals in dwellings still existed. The normal disadvantages of the district had been aggravated by the unsettled conditions, and the sanitary administration was being carried out in the area under the gravest disadvantages. An inspector of the Ministry had reported on the immediate needs of the situation. A medical inspector had since been sent to the district and other action taken. The most recent information received by the Ministry was that there were no fever cases at present in the district, excepting two contacts in hospital under observation.

India.

RESEARCH IN MALARIA.

The Indian Research Fund Association is instituting an investigation into the treatment of malaria, with the object of finding improved methods of coping with that disease. Major J. A. Sinton, V.C., I.M.S., has been placed on special duty for the purpose, and is to carry out his inquiries at Nagpur and Lahore.

AN IMPERIAL RESEARCH INSTITUTE FOR INDIA.

The Indian Legislative Assembly has approved of the proposal of the governing body of the Indian Research Fund Association to devote the capital fund at disposal to the creation of an Imperial Research Institute, and of the proposal of the governing body to devote two and a half lakhs of rupees to the purpose of the institute so long as they receive a sum of five lakhs from the Government. The offer of anonymous contributions, amounting to one and a half lakhs of rupees yearly for ten years, has been accepted towards the maintenance of a clinical unit based on the institute, provided that the Government of India, as funds permitted, would bring the total income of the institute up to five lakhs. The scheme has been promoted on the basis of a report by Professor Starling, and has been accepted by the finance committee. It is stated that the new institute is to be established in Delhi.

HOOKWORM INVESTIGATIONS IN INDIA.

Investigations into hookworm disease have been carried out by the Indian Research Fund Association in two selected tea gardens in Southern India by Dr. Mhaskar and Dr. J. F. Kendrick, the services of the latter being lent by the Rockefeller Foundation. It is stated that on an average 92.9 worms were found in each of the coolies examined on tea plantations. Thymol and beta-naphthol were employed in treating the disease, the latter being found to be the more effective as well as the cheaper. It is reported that while before the treatment was applied deaths on one of the estates from various forms of disease, including pneumonia, were very frequent—the effect of hookworm infestation being to set up a low standard of resistance to disease—after treatment an unprecedentedly clean bill of health was shown, attributable to the marked decrease in morbidity brought about by the elimination of the hookworm.

MATERNAL MORTALITY IN INDIA.

A discussion took place in the Indian Legislative Assembly on September 25th, on the proposal by Mr. Balkrishnan Lal, to refer to a select committee his bill for raising the age of consent in India to 14. Mr. B. C. Allen, a member from Assam, supported the bill strongly as a measure of social reform. He quoted Indian medical opinion as proof of the fact that the early marriage of Indian women was responsible for an appalling amount of infant mortality, maternal mortality, and female suffering. It was stated that the mortality of Indian mothers, so far as the imperfect statistics allowed an estimate to be made, was anything from 16 to 60 per thousand, which meant that in one generation three millions of mothers died in giving birth to children. The proposal to refer the bill to a select committee was rejected.

UNIVERSITY OF LUCKNOW.

The first Convocation of the University of Lucknow was held on October 30th, in the grounds of King George's Medical College. Among the graduates who were presented fourteen received the degrees of M.B., B.S., and five the Diploma in Public Health. Sir Harcourt Butler, Chancellor of the University, received the honorary degree of D.Litt., and, in addressing the assembly, congratulated the university authorities on the progress made since the foundation stone of the university was laid little more than eighteen months before. The university buildings, designed by Sir Edwin Lutyens, would, he believed, outshine all such buildings in India.

SCHOLARSHIPS FOR INDIAN MEDICAL WOMEN.

The Council of the Countess of Dufferin's Fund has decided to offer to Indian medical women scholarships for further study in the United Kingdom to the value of £200 per annum each. Applicants must satisfy the Council that they possess sufficient means to meet the passage money and additional expenses, which will amount at least to £150 per annum. All

applicants must have had some general or hospital experience since qualifying. The present honorary secretary of the Countess of Dufferin's Fund is Lieut.-Colonel T. J. Carey Evans, I.M.S., Simla.

Correspondence.

INSULIN.

SIR,—Dr. F. Roberts introduces his letter on insulin, published in your issue of December 16th (p. 1193), by the statement that it is "perhaps not out of place to review the stops which have led up to the production of this new remedy." Dr. Roberts's "review" takes the form of a destructive and somewhat conspurious criticism, and its publication by him appears to me to be "out of place" for more than one reason. It is, of course, the right and the duty of every scientific worker to sift the evidence presented to him on any subject, and to accept only conclusions which he finds well founded. So far as the public exercise of our critical function is concerned, most of us find ample scope for its activity in dealing with the work of others in the field of our own investigations, whose destruction may be necessary to clear the ground for our own building. Armchair criticism is, I believe, in general, "out of place." It seldom leads to anything but verbal controversy. The proper antidote to bad evidence is good evidence, and not judicial censure. I doubt the right, and cannot understand the desire, of anyone to assume the rôle of independent critic, unless he has private knowledge of facts, which convince him that the scientific world is being misled by fraud, or the innocent public by pretentious humbug.

Now Dr. Roberts's letter is not aimed at anything of that kind. He takes the simple, honest record of experiments, which are doubtless not free from defects, and denounces them as "wrongly conceived, wrongly conducted, and wrongly interpreted." Dr. Roberts has no knowledge of the circumstances in which the work was done, though he could easily have obtained such knowledge. If he had done so, his letter would probably not have been written. He did not know that the work he attacks was the first, unaided attempt at research by two young enthusiasts; that one spent half the war as a combatant, and the rest, after being seriously wounded, as a medical officer in England, while the other has not even yet completed his student course. He had no conception of the personal sacrifice and the heroic labour in which their enterprise involved them. Working things on their own initiative, without the invaluable help and co-operation, given later by the head of the laboratory, who happened to be in Europe when the earlier work was done, they may have wandered along a wrong trail for a time, though this has yet to be proved. It may be that they made an unnecessary detour, before finding themselves at the point where E. L. Scott had stopped. The important point is that Scott did stop, and that Dr. Roberts would not be writing about his work now if Banting and Best and the other Toronto workers had not gone much further. I know that Dr. Scott would be the first to recognize this. It may be that the enthusiasm, which carried them further, was fired by an imperfect interpretation of their earlier results. If so, the mistake will be cleared up in time by others working more calmly and with more experience, and the truth will emerge.

There is nothing to prevent Dr. Roberts from putting his own theories to the test of experiment. Nobody can deny that a discovery of first-rate importance has been made, and, if it proves to have resulted from a stumble into the right road, where it crossed the course laid down by a faulty conception, surely the case is not unique in the history of science. The world could afford to exchange a whole library of criticism for one such productive blunder, and it is a poor thing to attempt belittlement of a great achievement by scornful exposure of errors in its inception.—I am, etc.,

National Institute for Medical Research,
London, N.W., Dec. 18th.

H. H. DALE.

TREATMENT OF FEVER.

SIR,—May I thank Surgeon Commander Bastian, Captain Gelston Atkins, and Dr. Buchanan for their letters? With other medical men I am making immense claims for a line of treatment and research which is founded on a theory of recovery and immunity other than that generally accepted.

Very naturally and properly, medical men, with their unhappy experience of 'mare's nests, tend to be sceptical. With this difficulty in view, I appealed in my original communication² for independent evidence. The truth of a hypothesis is best demonstrated when it confers powers of prediction. We prophesied³ that it is possible to reduce the severity of small-pox. Captain Golston Atkins supplies unexpected and very welcome confirmation, though unfortunately in only one case. May we renew our appeal to such of our readers as have opportunities of treating this disease? Personally I am confident that it may be rounded little more dangerous than measles, or even chicken-pox.

That the treatment we suggest is not merely palliative is sufficiently demonstrated by the numerous febrile cases of unknown origin—disease aborted before recognizable—which are not when it is employed. The curious ring of retreating and diminishing inflammation seen in erysipelas is even more decisive. May I quote an instructive case?

A boy was admitted to hospital with cellulitis and apparently peritonitis of the leg. Immediate operation was considered necessary; there was, however, unavoidable delay, so he was put under treatment with "triple powder" as a palliative measure, and the leg was prepared for operation. He was anaesthetized ten hours later and laid on the table. When the dressings were removed the surgeon declared that the wrong leg had been prepared. The other leg was normal. Complete recovery.

In this hospital one of the lieut.-surgeons, founding his opinion on the fall of temperature, declared that the treatment produced great shock. I took him to see various persons who, delighted with repeated shocks, were doing very well. A mile or so distant is another hospital where the treatment had "no effect," which I daresay was true in a sense. Two miles distant was yet another where the treatment has had so much effect that it has become the routine.

The treatment is not empirical. As indicated by Commander Bastian, it is founded on the belief that the human being, physically and mentally the educable animal, may be trained to tolerate many (not all) poisons; that recovery and immunity from acute disease imply this habituation; that habituation is more easily and safely attained by a succession of small doses than by the huge continuous dose which is experienced in disease; that toxins are eliminated in the sweat (hence the improvement in the crisis of pneumonia, the cool stage of malaria, and the moist skin which commonly accompanies recovery from most fevers); that toxins tend to paralyse the sweat centre, and so, by bottling themselves up, to place the intrusive bacteria in a position of advantage; that it is possible by means of this treatment to restore the centre to action, and thus produce a series of artificial crises which enables the sufferer to experience a number of small losses with intervals between, whereby opportunity is afforded for his cells to attack and destroy the bacteria and attenuate their toxins. A scale of toxins, attenuated in varying degrees, is thus produced, and recovery and immunity are achieved by reacting up this scale. In vaccination against small-pox attenuated toxin is provided by passing the virus through the calf; in rabies by drying the cords of infected rabbits; in diphtheria by digestion in the tissues of the horse; in snake poisoning by gastric digestion antecedent to snake bite, and so on. Presumably an antitoxic serum provides attenuated toxins together with the enzymes which digested them. Vaccination provides bacteria which themselves provide attenuated toxins. Presumably, also, the enzymes are the same in all diseases, but the toxins and therefore the habituations to them are specific.

This theory of habituation, though published as long ago as 1897,⁴ has never achieved popularity among medical men, who have preferred to believe in specific antitoxins and antibodies—complex chemical substances which in some way neutralize those other complex chemicals, the toxins. Probably there are some thousands of animal and vegetable poisons (including the bacterial toxins) against each of which may be acquired powers of resistance that do not avail against any other poison. In other words, the human body is supposed to be a sort of magic bottle which is able, at short notice, to produce any one of an endless number of chemicals which counteract other chemicals of which, in many cases, the race has had no antecedent experience. Biologically speaking, we have here a supposition founded not on solid science but on miracle. We know that the human being is educable. By means of his educability we can explain much

—for example, increased powers of resisting fatigue, poisons, and the like. The theory of neutralization goes farther—it explains educability on what seems to me an impossible chemical basis. However, this by the way; habituation there is, no matter what the machinery. Meanwhile, may I remind your readers that we cannot hope to establish the truth about this treatment unless there be publication of results? May I also suggest its trial in the case of snake bites, insect stings, and perhaps other forms of poisoning?—I am, etc.,

Southsea, Dec. 6th.

G. ARCHDALL REID.

SIR,—I notice with much interest that several medical men have recently made the discovery that diaphoretics are of great service in the early stages of febrile disorders; the further interesting observation that a purge, such as calomel gr. iv, may also be usefully employed is, if possible, even more epoch-making.

It seems strange that our predecessors never thought of these measures, but they of course had not the exact and intimate knowledge of toxins and their nature and composition that we have, though they did have, I believe, some vague notion of purifying the blood.—I am, etc.,

December 3rd.

W. B.

X RAYS IN HYPERTRICHOSIS OF THE FACE.

SIR,—I have read Dr. Semon's courteous rejoinder to my criticism of his previous letter. I have unfortunately had a long and close contact with the dangerous side of x-ray therapy, and have seen every class of case from an x-ray burn to a chronic x-ray dermatitis. (His case was the latter, not the former.) It is therefore with a full sense of responsibility that I express the opinion that the matter is still one for careful research and careful feeling of the way. We all, of course, know that developmentally and anatomically the root bulb of a hair follicle and the rete Malpighii are closely related and pass insensibly one into the other. But is it not begging the question to assume that they are therefore equally sensitive to irradiation? Many different tissues in the body are of epiblastic origin, and yet vary largely in their reaction to x-rays. Do we not get frequent illustrations of the greater susceptibility of the Malpighian contents of the hair follicles than of the rete Malpighii itself? In alopecia Celsi we have at times complete atrophy of the hair follicles with comparatively few changes in the skin itself. I have under my care at the present moment a girl of about 14 suffering from universal alopecia of eight years' standing but with no apparent atrophy of the epidermis itself. In symptomatic and senile alopecia we have no evidence of the great sensitiveness of the hair follicles? Dr. Semon "finds it particularly hard to give credence" to some of my statements. Dr. Thurstan Holland (*Archives of Radiology and Electrotherapy*, p. 203, December, 1920) records a case of hypertrichosis treated by x-rays, which was a tremendous and complete success. The hairs fell out and did not grow again; no unfortunate after-effects occurred. As I stated before, Dr. Holland now refuses to treat such cases. But the fact remains that he had one success. If possible once it must be possible again. I know it is taking great risks, but to progress risks must be taken. A suitable technique may yet be found. Do not other medical men take risks? How many surgical methods have begun in disaster and ended in success? It is unfortunately the fact that when a radiologist makes an error of judgement all the world can see it and recognize it. It is not always so in other walks of medical science. Dr. Semon accuses me of "discrepancy" and "inconsistency." I am sure if he will read my letter again he will find neither.—I am, etc.,

Bradford, Dec. 10th.

WILLIAM MITCHELL.

SMALL-POX AND VACCINATION.

SIR,—Of course I agree with Dr. C. S. Thomson that cases of unmodified small-pox may walk about—for a time. I can match the case he quotes from Dr. McVail by one which occurred in my own experience in Leicester. A tramp dangerously ill and with the eruption out visited a public-house three days before he died. His condition at once aroused suspicion, we were communicated with, and fortunately no further cases arose. Another case was "spotted" walking and down one of our main thoroughfares, "rounded up," and brought to the Health Department. In my experience cases of this description which are soon recognized are less potent

² BRITISH MEDICAL JOURNAL, June 4th, 1921.

³ Ibid., November 18th, 1922, p. 1300.

⁴ *Lancet*, September 11th.

mischievous than modified cases which are entirely overlooked until serious cases occur.

Dr. Thomson goes on to say: "If Dr. Millard's suggestion is followed [that is, the abandonment of compulsory infant vaccination], then we would witness a repetition of the Gloucester disaster whenever small-pox commenced." This begging the whole question. It is just because I think it is insufficient justification for this assertion that I have ventured to challenge the orthodox teaching about infant vaccination. (I can assure Dr. Thomson that to do this is not the "easy" or "popular" thing which he suggests, though possibly it is less difficult for me than for most health officers.)

All medical heresies, heresy on the subject of vaccination is surely the most heinous! Anyone who studies the Gloucester epidemic in an unbiased spirit must admit that there were ample reasons, apart altogether from the neglect of infant vaccination, to account for the débâcle which there ensued. The whole handling of the epidemic, from an administrative point of view (I am not blaming the unfortunate officials) was a glaring example of how not to control small-pox. Such an occurrence ought not to happen again, and, as a matter of fact, has never happened since, although a quarter of a century has elapsed. During this time our methods of controlling small-pox have greatly improved, and, although the disease has been repeatedly introduced into the country, appears to be finding increasing difficulty in gaining a foothold, in spite of the fact that infant vaccination is falling more and more into disuse. Small-pox has now become one of the rarest of our zymotic diseases, and for the past decade the mortality caused by it has been almost negligible, in spite of the large proportion of children which is vaccinated.

Moreover, as a set-off against Gloucester, we must remember that even the best vaccinated towns, such as Warrington and Middlesbrough, have had very serious and very fatal epidemics, though it is not the fashion to talk much about them. In Middlesbrough, in 1897, where the M.O.H. estimated the proportion of unvaccinated at only 2 per cent., over 1,400 cases occurred, and 108 vaccinated persons lost their lives. Of course, in every epidemic the case mortality is higher amongst the unvaccinated, but this is no evidence of the efficacy of infant vaccination in keeping small-pox at bay, though many people argue as if it were so.

Dr. Thomson asks what I should answer to bereaved Gloucester fathers whose children might lose their lives through taking my advice, "should the long prophesied conflagration occur. I do not wish to seem to disclaim responsibility, but let me say that I have never advised parents not to have their children vaccinated. I quite admit, however, that I have not attempted to tell them that they are exposing their children to grave risk by not having them vaccinated, because I do not believe that they are. Let me say further that if the people of Leicester follow my advice, should the need for vaccination ever really arise, there need never be a serious conflagration in Leicester at all comparable with what happened in Gloucester or Middlesbrough. I quite recognize that it is conceivable that the time may arise when I shall add it my duty to advise universal vaccination of the entire population. The only real difficulty in the way of such a step is the unfortunate prejudice against vaccination (largely engendered by compulsory infant vaccination), and I contend that I have done more to allay this prejudice by my moderate attitude towards vaccination than if I had been an ardent revaccinist like Dr. Thomson. Moreover, I flatter myself that should a real need for universal vaccination ever arise the people of Leicester will be all the more ready to follow my advice just because I have never cried "wolf" when there has been no wolf. The people of Leicester know full well not only that I am not an antivaccinist but that I have a profound faith in the efficacy of recent vaccination. I gave them tangible proof of this by taking my wife and young family, recently vaccinated, to visit the patients in our small-pox hospital and photographing them by the bedside.

Dr. Thomson says that not one medical man in a thousand shares my views. It may be so; I cannot say; though I would suggest the possibility of there being more prophets in Israel than he suspects. I can say, however, that in 1915 he State of New York, acting on the advice of their health officer, Dr. Herman Biggs, virtually abolished compulsory vaccination by repealing the regulation under which all children had to produce evidence of vaccination before being admitted to school. Dr. Herman Biggs, who is one of the most experienced and distinguished members of the Public Health Service in the States, gave this advice, I understand,

because he had come to believe that the disadvantages, in the way of injury to health caused by child vaccination, more than outweighed the advantages to be gained by immunization against a rare disease like small-pox.—I am, etc.,

Leicester, Dec. 16th.

G. KILLICK MILLARD.

PSYCHO-ANALYSIS.

SIR,—I note that there are still some in our profession who remain out of sympathy with the psychological theory of mental disorder. Further, these gentlemen attempt by argument in your pages to overcome what they consider the foolishness of the adherents of this theory. But what, put into plain English, is the great psychological discovery of our day? Simply that most cases of mental disorder are cases of extreme foolishness. Adherents of the physiological theory of mind are, then, themselves psychotherapists without knowing it. They do not attempt to prove their point by the application of physiological or anatomical methods to their opponents' skulls—experience proves that there is a better way, namely, by argument, rhetoric, and so forth. Well, so also with the extreme degrees of mental perturbation which are known as insanity. Whether or not this method be "scientific" depends on the meaning we attach to such words. The main point is, it works.—I am, etc.,

Edinburgh, Dec. 16th.

A. J. BROCK.

SIR,—The correspondence upon this topic has at last focused upon a definite issue. Does the psychological interpretation of mental disease involve the denial of its physical basis? Sir Clifford Allbutt (to whose address to St. George's Hospital this narrowing of issues, I think, is due) has assumed that it does, and along with his followers has concluded that scientific psychiatry must be "physiological." On both points they are wrong.

In its most general statement the method of psychopathology is to seek the explanation of certain behaviour (abnormal) in the special circumstances of the patient's life history. It aims at a direct correlation between types of upbringing and types of reaction. Of course "cerebral dispositions" are the link between the two; psychology does not, and has no need to, question their existence. But it holds:

1. That these abnormalities are not necessarily determined by toxins, lesions, or germinal variations affecting (directly or "externally") the integrity of the nerve tissue, but may be due to unusual patterns, sequences, intensities, etc., of the afferent (formative) stimuli. If this should be so, the methods of general pathology are inapplicable.

2. That in any case a physico-chemical formulation of the neural substrate of thought is at present unattainable. Wild conjectures such as Dr. Berry mistakes for facts ("remember that dreams are merely impulses," etc.) are, from the psychological as from the practical point of view, worse than worthless.

Dealing with this second point first, it is surely obvious that the "engrams," "dispositions," etc., are known wholly through the behaviour, memories, etc., they occasion. We do not increase or improve this knowledge by adulterating it with physiological imagery. On this point the physiological school of psychiatry is at variance with behaviourists and psychologists alike. These latter schools differ as to the necessity of "subjective interpretations," but this is a different question and cannot be discussed here. Both agree in correlating conduct and speech-reaction (memory) with each other and directly with the life history of the organism, without interpolating detailed physiological hypotheses. In thus dispensing with physiological explanations, it must be noticed that it is their adequacy and not their possibility that is challenged, and moreover that we are not forced back upon "subjective interpretations" as the sole alternative. Sir Clifford Allbutt and his followers are wrong, therefore, in supposing that psychopathology implies an animistic denial of the physical basis of thought, and also in claiming for physiological psychiatry the monopoly of objective method.

Space does not permit me to "counter-attack" the neuro-pathologists' position or to show how so gross and widespread a misunderstanding arose. Apart, however, from all their positive errors, they have confused the animist, psychological, and behaviourist positions, and the issues that divide these schools—so much for their knowledge of what they criticize! They have assumed that the denial of a pathological basis is tantamount to a denial of the existence of a physical basis—so much for their logic and "thoroughness." They quote

extensively (at least Dr. Borry does) from popular drivel. This reflects either upon their sincerity or upon their learning.—I am, etc.,

Perth, Dec. 12th.

IAN D. SUTTIE.

SIR,—Would it not be as well to ask ourselves what the word "psychology" means? If it has a meaning it would appear to be "the study of the psyche," and we can amuse ourselves finding varying translations for the Greek $\psi\chi\eta$. One fact would seem fairly clear, that it cannot by hook or crook be adequately translated by any physiological term. This being the case, I suppose a psychologist, being a person who studies the psyche, has no part in medicine, which studies physiology. "If we believe the dictum of Cabanis that 'nerves make the man,' we have no real necessity of making the vastly difficult postulate that a human psychology exists," writes Dr. Maurice Nicoll. Further, if we do hold this theory we should obviously not call ourselves psychologists nor profess the study of a subject we consider a myth. Further still, we had better hold aloof altogether from the "wanderings" of those deluded unfortunates who believe in such a phantasm.

But surely the proof of the pudding is still in the eating? I have not yet found it any help to a psychopath haunted by nocturnal dream terrors to know that "dreams are merely afferent impulses from exteroceptive, proprioceptive, and exteroceptive sources running riot amongst the cells of a brain where control has been removed by sleep . . ." but I have found amazing and speedy relief follow treatment based on the belief in a hypothetical psyche.

As a matter of fact, the neurological pronouncement I have quoted is just as hypothetical; no one has seen it happen, and neurologists are by no means in accord on the matter. It seems possible, in view of the experimental data, is about the best we can say. It is merely the present neurological theory, which, like all theories, is, in its day, the only correct one. I would not be understood to represent the psychological theory as correct; it probably is not. But it works, and when I can find another to work better I will gladly give it up. I am prepared to believe that neurology can tell us how we dream, by what mechanism the effect is produced, but to the "Why?" neurology gives no satisfactory answer. If Dr. R. J. A. Berry had not "suspected" a meaning in day-dreams, though doubtless understanding their mechanism, one would expect him to rejoice at hearing a theory which offered an explanation of what must have been an otherwise irritatingly meaningless phenomenon.

However, I quote Nicoll again: "By insisting on a human neurology we can thus, at first sight, prevent the existence of a human psychology. This is the attitude of many physicians at the moment." And, it would seem, *mirabile dictu*, of not a few professors and teachers of psychology.—I am, etc.,

Netley, Dec. 16th.

JOHN A. TIERRE, M.R.C.S.

HOSPITAL POLICY: THE REPORT OF THE COUNCIL.

SIR,—The letter of Dr. Garratt, dated December 2nd (p. 1196), shows a great advance upon the previous attitude taken up by him. At last he declares freely and frankly that the Leicester resolution is "entirely suitable" for hospitals in the great industrial areas. That is an immense concession on his part. Once controversialists can see the other side there is reasonable hope of an acceptable accommodation.

Dr. Garratt's reading of the history of the Leicester resolution is less happy. That resolution was fairly and fully discussed at hospital staff conferences, at Divisional meetings, and at the Annual Representative Meeting, 1921. The case presented by the hospital staffs from the industrial areas was so strong that it carried conviction and secured the acceptance of that resolution. Later those whose lines are fallen to them in pleasant places began to reflect on the possible reaction of the resolution on their own practice, and the reaction of their fears was seen in the Annual Representative Meeting at Glasgow. They secured the rejection of an amendment to the Leicester resolution, but dared not push the attack to the length of attempting its repeal. Following Glasgow, the Council has considered the situation in all its bearings, and has put forward an amendment to the Leicester resolution which forms a bridge that can be used with comfort and safety by both parties, and I am hopeful the amendment will receive the blessing and whole-hearted support of Dr. Garratt.

I would urge all interested in hospital work to read the report of the Council which was published in the SUPPLEMENT of November 18th, 1922 (p. 186); it gives the terms of the new resolution and a short explanatory statement. So far as I can hear, the report is being received with a remarkable degree of unanimity.—I am, etc.,

London, W., Dec. 16th.

N. BISHOP HARMAN.

DIPHTHERIA PROPHYLACTIC AND IMMUNITY.

SIR,—Nurse H. is one of two nurses among those on duty in the diphtheria wards of Tolworth Isolation Hospital who were positive to the Schick test in June, 1922. She was given three doses, 1 c.c.m. in each, of diphtheria prophylactic (toxin-antitoxin mixture), the last of the three on July 11th. On November 18th she complained of sore throat and had a temperature of 101° F.; the left tonsil was enlarged and capped by a patch of white exudation about the size of a threepenny piece which was easily wiped off; a swab from the throat, on culture, showed a growth of Klebs-Loeffler bacilli and micrococci. On November 21st she felt quite well and on November 23rd the tonsil was clean; cultures from the throat continued positive on November 23rd and 26th but were negative on December 1st.

If this attack was diphtheria it would tend to awaken some distrust of the efficacy of prophylactic inoculations, for the patient was one of two nurses who had received the inoculations four months previously; in other words, 50 per cent. failure, a very different result to that shown by some American figures, according to which 95 per cent. of 201 children who had had three prophylactic inoculations were immune three months afterwards. I think, however, that there is another possible explanation of her attack.

She may have been a "carrier" (so far as I know prophylactic inoculations do not prevent this); nurses in the diphtheria wards have not infrequently been found to be "carriers" when, prior to any one of them being transferred to the scarlet fever wards, a swab from the throat has been examined; and while being a "carrier" she may have contracted a mild sore throat with a follicular exudation due to some other organism. This was the view I took; but if she had not previously had the prophylactic inoculations I should certainly have labelled her attack mild diphtheria.—I am, etc.,

Surbiton, Dec. 5th.

HARRY COOPER, M.D.Oxon.

EXPERT WITNESSES: SURGICAL AND MEDICAL.

[In our issue of September 16th (p. 531) we published a letter from Mr. C. H. Fagge, in the course of which he criticized the method in which, in the courts, medical evidence is called for the plaintiff and for the defendant, and urged that it should be discontinued. This drew from Sir John Lynn-Thomas a letter, published on September 30th (p. 614), in which he described the course of action he came to adopt when asked to give expert evidence. He consented to see the patient, took full notes of the case, and when his examination was finished said: "I will send a copy of the notes I have taken to your doctor, and will ask him to come and discuss your case with me, so that I shall have full inside knowledge before deciding whether I can support your claim." From the next sentence of his letter we gather that after he took this course he was not very frequently invited to act as a medical expert witness. Shortly afterwards Sir Clifford Allbutt addressed a letter to Sir John Lynn-Thomas, and has now been kind enough to consent to its publication. It is as follows:—]

St. Radegund's, Cambridge,
November 24th, 1922.

DEAR SIR JOHN,

In my early days in Leeds these cases were very many; then there were few of the modern developments for the security of railway passengers; also more sources of lead poisoning, etc., etc. In Leeds the profession was not infected by any spirit of jealousy; we were all brothers—and I think, to there, things are still on this co-operative footing. Due to the concentration of hospital work all in one large institution? So we soon gained a reputation for fairness as medical witnesses. But you ask for more than this:—We soon felt a grave objection to setting medical men as fighting cocks one against another; it led to some partisanship if not direct advocacy; and to unbecoming differences of statement—over as to facts. So we held a meeting, and decided that we would combine to refuse to give evidence in legal cases unless a consultation of both sides were arranged before the case came on in court; even if this were—as often it was—very shortly before. Many witnesses came from a distance, an

so on. I do not say that those consultations put an end to all differences between experts on the two sides, but many of these were apparent rather than real, and mostly cleared up by consultation. In the witness-box we often differed in opinion, but not much on the facts. Moreover, our differences were clean cut and intelligible to the court.

We met at first with bitter opposition from the lawyers—open from the solicitors, covert from the Bar, because it tended to cut down fees, or to show less for them! Moreover, they naturally feared our making pies of our own—that we might be too compromising, etc. But some of the larger legal firms approved our ruling, and even applauded it; so did gradually the leading counsel. The amendment became apparent to all, and ere long we had all cordially with us. The evidence was immensely improved in both quality and consistency; now facts or now interpretations came out; and doctors of less experience were not sorry to accept a more adequate diagnosis, or partial modifications. I will give an instance: A consultation was arranged between two of us and a doctor from a distance in a case of railway injury—the top of shoulder bruise which you know so well. Unfortunately the patient's doctor missed his train and didn't appear at the consultation. He was a very honest fellow, and had assured the patient that his complaints were due to transitory if not imaginary causes. We "experts" examined him just before the court sat—and found under some fat layers (electro tests, etc.) decided atrophy of the right shoulder girdle. With us was an expert for the patient, and he quite agreed. The case proceeded, and the patient's doctor came in, hot from his journey, and rather gave his patient away of course. Then the counsel for the railway company arose and explained to the judge that, on the contrary, the railway company was prepared to accept the patient's story, and to give referee's damages. Then said the judge: During the lunch interval I walked to the window of my room with a sandwich and glass of sherry and saw the plaintiff walk out with his wife, also to lunch. I saw him put up his umbrella under his right arm; it fell to the ground. He picked it up again, and again it fell to the ground. Then his wife picked it up, and he put it under the other arm, successfully. Now if the case had gone forward I intended to set this evidence of mine against the "transitory neurosis," and I should have summed up against you. He then complimented the railway people on their correct attitude.

Well, in this sort of way we got credit, so that from the vulgar point of view we made even more fees; people trusted us, and cases came (when possible) to the Leeds Assizes. It was before this little story that Fitzjames Stephen had paid a formal compliment to the Leeds medical evidence. He said from the Bench how different was the Leeds evidence to that of too many other places, and he could not speak too highly of the temper and consistency of the Leeds evidence. He had attended the Leeds Assizes rather frequently. I may add that the official medical officers of the railway company were included in our *both sides* consultation rule always, and although one or two of them were disposed to take very sceptical views of all their cases, yet they took a loyal part in the discussions.

Very sincerely yours,
(Signed) CLIFFORD ALBUTT.

[The observations by Mr. Justice Stephen to which Sir Clifford Allbutt refers were noticed in a paragraph published in our issue of August 28th, 1880 (p. 354), as follows:

MR. JUSTICE STEPHEN AND THE LEADERS OF THE MEDICAL PROFESSION IN LEEDS.

DR. CLIFFORD ALBUTT (Leeds) and Mr. W. A. Statter (Wakefield) gave evidence, at Leeds Assizes, before Mr. Justice Stephen, relative to the injuries which a young lady had received in a railway accident on the Lancashire and Yorkshire Railway. At the close of the case, says the *Yorkshire Post*, his lordship paid a very high compliment to those gentlemen, and to the leaders of the medical profession in Leeds generally. He said the medical evidence by Mr. Statter and Dr. Clifford Allbutt was a pattern of what such evidence should be. He was in the habit of hearing medical evidence in all parts of the country, and Leeds was the only town where he never heard those unseemly disputes between the legal and medical professions which occurred at other places. Here there was a certain number of gentlemen, the leaders of the medical profession in the great School of Medicine in Leeds, who had set an admirable example for many years past of truth and candour and straightforwardness in the witness-box, and he was happy to see that their example was being followed by the younger members of the profession. When a man really tried to tell the truth, the whole truth, and nothing but the truth, in plain and simple language, notwithstanding what consequences might be

drawn from it, and whether he was called on the one side or the other, bullying in court and things of that kind ceased at once. Alluding to Mr. C. G. Wheelhouse, surgeon, of Leeds, who had seen the plaintiff on behalf of the company, his lordship said that although there was another eminent gentleman present to give evidence, the defendants had not found it necessary to call him. He hoped that such a state of things might long continue in Leeds, and be imitated in other towns.]

Universities and Colleges.

UNIVERSITY OF OXFORD.

The following candidates have been approved at the final examinations for medical degrees:

Forensic Medicine and Public Health: R. V. Facey, R. F. Johnston, T. L. Omerod, J. P. Shaw, A. L. B. Stevens, E. H. Watkins, A. Q. Wells, Norah E. Boddin, Dorothy D. Crook, Sibyl R. Eastwood, Katharine M. H. Midwinter, W. R. Braln, E. J. G. Johnston, C. R. Lan.

Robertson, A. W. L. Row, A. Slovens, E. B. Strauss, T. S. T. Allee E. Harding, Cecily Williams.

At a congregation held on December 16th the following medical degrees were conferred:

D.M.—W. Burridge.
B.M.—H. A. Gilkes, R. F. Johnston, W. R. Braln, C. W. O. Bain, J. G. Johnston. *Women:* D. W. Crook, K. M. Hodgkinson, D. J. Collier, C. M. Otley.

UNIVERSITY OF LIVERPOOL.

The following candidates have been approved at the examinations indicated:

FINAL M.B., Ch.B.—Part I: B. E. Acland, Grace A. Austin, †C. B. Bamford, R. S. Brock, Helen S. H. Brown, A. A. Cooke, J. W. Cohen, W. D. Cr., M. Davies, Eileen N. Deane, W. T. Donovan, J. C. Drummond, H. Duff, H. W. Fell, H. J. Fisher, G. A. Fu too, J. Gauchman, Clara M. V. Glens, H. Gobie, T. A. Griffiths, D. C. G. Hanlon, Dorothy M. Hanson, Fannie S. Holt, J. E. Howie, G. P. Huys, C. P. Jones, A. L. Kerr, n. G. A. Lowe, G. A. Lington, Robert, J. A. L. Jorie A. Wrenno, Cooke, N. D. Hawe, Phyllis Marsh, Margaret D. T. Rogers, J. F. D. Shrovesbury, canor E. ion, R. L. C. Evans, es, Hilda Mary E. Sparring, Weisberg, D.T.M.—M. J. Cohen, A. C. Crawford, C. M. Gracias, W. A. Lethem, M.C., S. D. Rieley.

* Distinction in Surgery. † Distinction in Pathology.

UNIVERSITY OF EDINBURGH.

A GRADUATION ceremony was held on December 15th in the McEwan Hall, Edinburgh, under the presidency of the Principal, Sir Alfred Ewing. The following were among the degrees conferred:

M.D.—D. Aiken, J. Brander, *De Pury Casalis, †J. H. Crawford, *B. V. Dunn, J. D. Ingram, J. Mackenzie, †D. M. Morrison, T. C. St. C. Morton, R. J. Parish, *G. S. Bowden, *J. Walker, L. H. Warden.
M.B., Ch.B.—M. S. Abaza, S. A. Acland, Isabelle E. Allen, W. Anderson, Jean Y. Andrew, Margat Austin, L. C. L. Averill, F. E. A. H., Irene Dick, Easor, Grace, Hamilton, H. Hastings, H. D. Hayes, Flora M. Hogg, C. F. W. Logan, D. B. McFarlane, M. Mackay, F. Macleod, A. T. Martin, V. Pietersen, om, Isabel S. Rutherford, R. M. Stewart, Flora M. Stewart, Thompson, Eliza, Isabella du Telt, Hazel H. F. Wai Wilson, M. Witkin, W. S. Woodburn.
The Freehand Barbour Fellowship has been awarded to Jessie Eeles.
M.B., Ch.B.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

An ordinary Council was held on December 14th, when Sir Anthony Bowlby, President, was in the chair.

Diplomas of Fellowship were granted to the following twenty-three candidates found qualified at the recent examination:

A. Goodwin, N. P. L. Lamb, C. L. Gimblett, J. L. Davies, J. F. H. Stalman, A. C. Ainley, S. D. Lodge, R. S. Woods, A. C. Hackett, C. O. Davies, E. C. B. Lindon, V. Wilkinson, H. L. Sackett, * Mildred Ward, A. D. Wright, R. B. Chandrachud, R. A. H. Fulton, I. B. Jose, N. J. Judah, G. C. Wellish, J. G. Whitaker, H. P. W. White, D. Whyte.

* Under the Medical Act, 1876

A further candidate was found qualified, but has not yet complied with the regulations.

Dental Surgery.—Diplomas in Dental Surgery have been granted to eighty-four candidates found qualified at the recent examination.

A report from the examiners in dental surgery was received. Certain new regulations were adopted, which apply to all candidates who pass the preliminary examination in general education on or after January 1st, 1923. Information may be obtained from Mr. F. G. Hallett, O.B.E., Examination Hall, Queen Square, Bloomsbury, London, W.C.1.

Delivery of Lectures.—Owing to Sir Arthur Keith's illness, his lectures, arranged for January, 1923, have been postponed to March or later.

LONDON SCHOOL OF TROPICAL MEDICINE.

The following students have passed the examination of this school held at the termination of the seventieth session (September to December, 1922):

*†Major T. L. Bam'orl (I.M.S.), *Dr. W. T. Benson, *Captain G. Covell (I.M.S.), *Lieut.-Col. el W. H. Hamilton (M.S.), Miss B. Richardson, Miss H. Gregg, C. J. H. Sharp, Squadron Leader H. A. Hewat (R.A.F.), C. J. Pandit, Captain H. Chaud (I.M.S.), W. O. Karandikar, K. Nain, P. W. O'Connor, W. P. H. Lightbody, Major M. J. Holcote (I.M.S.), Captain P. R. Vakil (I.M.S.), B. C. Dasgupta, C. A. Calder, H. T. Le Vieux, J. Cauchi, J. M. Survevor, Captain R. A. Warters (I.M.S.), R. D. Whitelaw, P. W. Lamb, C. T. Nain, A. S. Macfie, B. C. D. S. Rupasinha, Captain H. I. Murray (I.M.S.), H. J. J. Garrod, H. E. Varlava, O. T. Brosius, J. M. Sornasundrum, Captain W. J. S. Ingram (I.M.S.), A. C. A. Fernando, D. Bulos.

* With distinction.

† Awarded the Duncan Medal.

Obituary.

KENNETH MACLEOD, M.D. EDIN., F.R.C.S. ENG., LL.D. ABERD.,
Colonel I.M.S. (ret.); Honorary Physician to the King.

We regret to announce the death, on December 17th, at Southampton, of Colonel Kenneth Macleod, I.M.S. (ret.). He was born in Trumisgarry manse, in the island of North Uist, one of the Outer Hebrides, in the county of Inverness, on July 23rd, 1840, the eldest son of the Rev. Norman Macleod, minister of that parish. At the early age of 3 he played an involuntary part in a striking episode of Scottish history, for his father was one of the ministers who succeeded from the Church of Scotland over the question of patronage, and "went out" in the Disruption of 1843. His father remained in North Uist as minister of the new body, the Free Church. Kenneth was sent to Marischal College, Aberdeen, in 1853, at the age of 13, and graduated there as M.A. in 1857. In the same year he entered on the study of medicine in Edinburgh University, and, after taking first prizes in surgery, medicine, midwifery, and medical jurisprudence, graduated as M.D., with honours, in 1861. For the next three and a half years he served as assistant medical officer in the Durham County Asylum, taking the L.R.C.S. Edin. in 1864; and in February, 1865, when competition for the Indian Medical Service was reopened, after being closed for four and a half years, he passed first for that service, being commissioned as assistant surgeon from April 1st, 1865. Three future directors-general went through the Netley course in the same term: James Cleghorn was second, and Robert Harvey third, for the I.M.S., while Sir William Taylor was among the M.D. men of the term.

His first appointment in India was that of civil surgeon of Jessore, in Bengal, where he served for two years. In October, 1868, he became medical officer of the 6th Bengal Infantry at Jalpaiguri, and in December, 1869, was appointed a member of the Cattle Plague Commission. He had thus had less than four years of the ordinary routine work of officers of the I.M.S., that of regimental medical officer or civil surgeon of a district, and never again served in such posts. In January, 1871, he was appointed secretary to the Inspector-General of Hospitals, I.M.S. (The title of this appointment was changed to surgeon-general in 1873; and to director-general in 1895.) This post he held for eight years, with an interval of fifteen months in 1874-75, when he acted

as professor of anatomy in the Calcutta Medical College and second surgeon to the college hospital. He was appointed substantively to this professorship in April, 1879, but on December 31st of the same year was promoted professor of surgery and first surgeon. These posts he retained till he retired on April 15th, 1892. He had reached the rank of brigade surgeon on June 26th, 1888.

After his retirement from the service he was appointed a member of the Medical Board of the India Office, and served in that capacity first under Sir Joseph Fayer, then under Sir William Hooper, till he was appointed professor of military medicine at the Army Medical School, Netley, on May 29th, 1897. This post he held until the Netley school was closed in 1905, when it was transferred to Millbank. In 1880 he was elected F.R.C.S. Edin.; in 1892 Aberdeen University conferred upon him the honorary degree of LL.D.; in 1900 he was made an honorary F.R.C.S. Eng.; and on May 2nd, 1906, was appointed honorary physician to the King, with the rank of colonel.

In addition to his professional duties, Colonel Macleod found time for a large amount of public work. His service on the Cattle Plague Commission in 1870 has already been mentioned. In 1879 he was appointed consulting health officer of Calcutta, and, after resigning this post in 1884, was in 1885 elected a municipal commissioner for Park Street Ward, the chief European ward of Calcutta. In January, 1880, he founded the Calcutta Medical Society, of which he was afterwards president. He was also at different times president of the Calcutta Public Health Society, vice-president of the Bengal Social Science Association, vice president of the National Indian Association, Bengal Branch, president of a committee to consider the establishment of a veterinary school in Calcutta, and secretary and medical officer of the Martinière schools in Calcutta. After retirement he succeeded Sir Joseph Fayer as president of the Sanitary Assurance Association in 1894, and was a vice-president of the Medical Graduates' College and Polytechnic.

He took much interest in the affairs of the British Medical Association. He was President of the Section of Tropical Diseases at the Annual Meeting at Ipswich in 1900, and Vice-President of the Southern Branch.

His chief works were: *Manual of Diseases of Cattle*, 1869; *Sanitary Treatment of Epizootics*, 1869; *Report on Medico-Legal Returns of 1868 and 1869*, 1870, expanded into *Medico-Legal Experiences in the Bengal Presidency*, 1875; *History of the Medical Schools of the Bengal Presidency*, 1872; *Report on Establishment of a Veterinary School in Bengal*, 1883; *Operative Surgery in the Calcutta Medical College Hospital*, 1885; articles on Delhi boil and Scrofula elephantiasis in *Health's Dictionary of Surgery*, 1886; articles on Cholera and Epidemic dropsy in *Albatt's System of Medicine*, 1896-99; articles on Cholera, Choleraic diarrhoea, Sunstroke, and Epidemic dropsy in *Quain's Dictionary of Medicine* (third edition), 1932; and *Indian Medical Memories*, 1909, originally contributed to the *Caledonian Medical Journal*. He edited the *Indian Medical Gazette* for twenty years, 1871-91, and after his return to this country was a frequent contributor to our columns.

Colonel Macleod was twice married, first in 1865 to Jamima Isabella MacDonald, who died in 1874. She had two sons, both of whom died in infancy, and three daughters. In 1877 he married Jane Christie Aitken, who had three daughters and four sons. One son served in Paget's Horse in the South African war, and three in the war of 1914-18: Commander Kenneth Macleod, R.N., Major Torquil Macleod, R.A., and Lieutenant Alastair Macleod, 1/5 Hampshire Regiment. Major Macleod was severely wounded at Contalmaison in July, 1916, and on rejoining duty, after a long stay in hospital, was sent to Palestine, and on the way out was twice torpedoed in one day, near Alexandria. A grandson, Lieutenant Kenneth Carnduff, R.E., was killed in France on January 12th, 1916.

Colonel Macleod was a man of fine stature and physique. Only a man of perfect physical health and strong constitution could have got through the immenso amount of work, professional and public, which he did for twenty years in Calcutta. He was a bold and skilful surgeon, and for many years had a large private practice in Calcutta in addition to his work in the medical college hospital and the duties of his chair. He was somewhat brusque in manner, and did not suffer fools gladly. But he was a good friend, officially and privately, to junior officers who served under him, and in all respects was an excellent representative of the great service in which he served so long.

R. J. RYLE, M.A., M.D. OXON.

DR. REGINALD JOHN RYLE, who died on December 4th, aged 68, was the son of the late Bishop of Liverpool and a brother of Bishop Ryle, Dean of Westminster. He was educated at Ropton School and Trinity College, Oxford, and received his medical training at Guy's Hospital Medical School. He graduated B.A. Oxon. in 1877, M.A., M.B. in 1884, and M.D. in 1894, and took the diploma of M.R.C.S. in 1883. After practising at Barnet for some ten years he removed to Brighton, where he continued to practise until recently, when he retired and went to live near Pangbourne. Dr. Ryle took great interest in local public affairs and social service. He served for two years as the representative of the Pier Ward on the Brighton Town Council; he felt compelled to resign his seat owing to his inability to give to the work the time and attention which he considered it should receive. He was a justice of the peace for the county borough of Brighton, and his professional knowledge was of great assistance to the Bench. He married in 1885 the daughter of Mr. S. K. Scott, surgeon, of Brighton, and a member of a well-known medical family. He leaves five sons, one of whom is now assistant physician at Guy's Hospital, and five daughters.

Dr. Ryle's interest in social medicine was shown in many ways. He had, for example, studied closely the question of feeble-mindedness, and to the conference held at Brighton in 1911 under the auspices of the Association for the Feeble-minded he read a paper on the origin of feeble-mindedness, an abstract of which was published in our columns at the time; subsequently the full text appeared in the report of the Conference. At the Annual Meeting of the British Medical Association in Brighton in 1913 he was President of the Section of Medical Sociology. In a brief address he adopted the definition of sociology that it is "the scientific study of society and of all the phenomena it exhibits, including the various forces and processes at work within and upon it."

We are indebted to Dr. L. A. PARRY of Brighton for the following brief tribute: The profession has sustained a great loss by the death of Dr. R. J. Ryle. We in Brighton, where he practised for so many years, especially feel this, for we knew him well as a man absolutely upright and straightforward, one who always thought of the good of others rather than of his own. His professional, scientific, public, and social work were all of the highest character. Whatever he did, he did well, and with the sole object of doing his best for others. We have lost a good man and a good friend. We could always rely on his advice and assistance in any matter, and we knew it would be freely and willingly given.

JOHN MAGEE FINNY, M.D.,

Consulting Physician, Sir Patrick Dun's Hospital, Dublin.

DR. JOHN MAGEE FINNY, formerly of 36, Merrion Square, Dublin, passed away at his residence, Erith Lodge, Sandymount, on December 7th, at the age of 81, and was interred at Mount Jerome Cemetery, Dublin, after a service in Christ Church, Leeson Park, where he had been a member of the congregation for over fifty years.

Dr. Finny was a distinguished scholar of Dublin University; in 1864 he obtained the medical scholarship and became the senior exhibitor, and also took the M.B. degree. In 1868 he became a Fellow of the Royal College of Physicians of Ireland, of which he was elected President, 1890 to 1892. In 1882 he was appointed King's Professor of Medicine in Trinity College, Dublin, and physician to Sir Patrick Dun's Hospital, where his teaching of medicine attracted large numbers of pupils to his lectures and his clinics. He was chairman of the Academy of Medicine, consulting physician to Mercer's Hospital, Dublin, member of the Senate of Trinity College, Dublin, and a member of the Board of Superintendence of the Dublin Hospitals, and H.M. Visitor in Lunacy. He was also for a considerable time an examiner in medicine at the army medical examinations in London.

Dr. Finny was a son of Rev. Thomas Henry Cotter Finny of Cork, by his second wife, Frances, daughter of William Magee, D.D., Archbishop of Dublin, and grandson of William Finny, Commissary-General for Ireland. He leaves a widow and four sons, two of whom are members of the medical profession.

THE late Professor J. K. A. Wertheim Salomonson has bequeathed his instruments and books on medical electricity and roentgenology to the University of Amsterdam.

Medical News.

THE annual dinner of the Royal College of Physicians of Edinburgh will be held in the Hall of the College on January 26th, 1923.

THE first two ceremonies in honour of Pasteur's centenary will be held in Paris on December 26th at the Académie de Médecine, and on December 27th at the Institut Pasteur, when there will be an exhibition of the instruments and apparatus used by Pasteur. The French Government has decided to issue an international stamp bearing a portrait of Pasteur.

THE annual dinner of the Epsomian Club was held at the Trocadero Restaurant, London, on December 14th, with Dr. H. F. Ealand in the chair. In proposing the toast of "Floreat Epsomia," Dr. Ealand, in the course of a witty speech, remarked that to his mind the disadvantage of Epsom was that it had been a "class" school, in that most of the boys—in his time, at least—were sons of doctors. He hoped that in future this would not be so, and that the boys would come from every walk in life. After the school song had been sung with much enthusiasm, Mr. Powell, the new headmaster, gave a brief review of the school's activities. A new chemical laboratory was in course of preparation, and work upon the chapel—the war memorial—was to begin as soon as possible. The school had had eleven successes in the first medical professional examination, and the sports successes had also been notable. Mr. Powell emphasized the place in the body corporate that the old boys held, and invited them to make more use of the playing fields. The toast of "The Visitors" was proposed by Mr. Mackay, and Lord Dawson of Penn, in responding, made a plea for the broadening of interests at Epsom. The medical profession, he said, had not had that influence upon the general culture that it ought to have had. The health of the new headmaster was proposed by Dr. Stillwell, and that of the chairman by Mr. Maynard Smith.

AT the social evening of the Royal Society of Medicine on December 13th a wireless concert was given. It was arranged by the Electric Light Insurance and Maintenance Company and the society's electricians, in conjunction with the Mareconi Company. The President, Sir William Hale-White, in addressing the large company which had assembled in the Robert Barnes Hall, said that the music would be received from the London broadcasting station in the Strand a mile away. The music was quite clearly heard, and the demonstration was much appreciated. A vote of thanks to those who had taken the pains to arrange the concert and to the Mareconi operator was passed by acclamation. Afterwards Dr. Arnold Chaplin gave a short lecture on engraved portraits of medical men, a subject upon which he is one of the chief living authorities in this country.

A COURSE of twelve lectures on the management and feeding of infants and young children will be given by Dr. Eric Pritchard (medical director of the hospital) to qualified practitioners, at the Infants' Hospital, Vincent Square, S.W., at 6 o'clock on Mondays and Thursdays from January 15th to February 22nd, 1923. Further information may be had from the secretary of the hospital.

THE Women Sanitary Inspectors' and Health Visitors' Association is holding its second winter school for health visitors and school nurses at King's College, Strand, W.C., from December 28th to January 11th, when a course of lectures will be given by Lady Barrett, Dr. Eric Pritchard, Dr. A. F. Tredgold, and others. The full programme of lectures may be obtained from the secretary of the Association, 5, York Buildings, Adelphi, W.C.2.

THE annual report of the Officers' Families' Fund shows that valuable work continues to be done by this organization, particularly in connexion with education. During the past year the committee dealt with 3,338 new applications and 2,516 renewed applications for assistance, and over £17,800 was distributed in grants and loans.

A SPECIAL intensive post-graduate course in cardiology will be given at the National Hospital for Diseases of the Heart, Westmoreland Street, W.1, from January 8th to January 20th, 1923, inclusive. The fee for the course is £7 7s. Inquiries should be addressed to the Dean at the hospital. Further particulars will be found in our advertisement pages.

THE Walker-Gordon Laboratories were established twenty-seven years ago chiefly for the purpose of preparing modified milk on prescription, and the supply of unpasteurized cream of any desired percentage of butter fat. The company ceased its operations during the war (1916); it has now re-established its farm, and its offices at 54, Weymouth Street, London, W.1.

THE French medical journal, *Progrès médical*, founded by Dr. Bonneville, has recently celebrated its fiftieth anniversary.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Attitology, Westrand, London*; telephone, 2630, Gorrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate, Westrand, London*; telephone, 2630, Gorrard.
3. MEDICAL SECRETARY, *Medisecra, Westrand, London*; telephone, 2630, Gorrard. The address of the Irish Office of the British Medical Association *Pacillus, Dublin*; tel 6, Rutland Square, telephone, 4561, Central.

QUERIES AND ANSWERS.

INCOME TAX.

"P." pays £95 a year interest on money borrowed to buy a practice.

* If the interest is paid to a bank the amount can be deducted as a professional expense, otherwise "P." is entitled to deduct tax at the standard rate from the interest as and when he pays it, and must include the interest in the profits on which he pays tax.

"S. J. H." replaced a second-hand Ford car by a new car costing £445. The Inspector has allowed £150, the estimated cost of replacing the Ford car by a similar one, less £30 deducted therefrom for private use of the car.

* So far as the £150 is concerned the inspector seems to be right; the additional expenditure was incurred in the improvement of the professional equipment and not in its mere maintenance. If the private use of the car shortened its working life so far as "S. J. H." was concerned, or reduced the amount allowed to him when he sold it, some deduction is reasonable, but unless it has been used in that way more than is ordinarily the case we doubt whether that sum would have increased at all the expense incurred in replacing it, and in that case the full £150 should be allowed. Our correspondent has a right of appeal to the District Commissioners or to the Commissioners for Special Purposes from the Inspector's decision.

"X. Y." purchased in 1914 a Wolseley Innuletto for £600, supplementing it in 1916 with an 8-h.p. Renault costing £300. In 1922 the former was sold for £280 and the latter for £150, and a 11.9-h.p. Calcott coupé purchased for £595.

* We advise our correspondent to regard the Calcott car as a replacement of the Wolseley and to claim £595 - £280 = £315 as a professional expense of the year 1922. When he purchases a second car he will have a valid claim to the allowance of the cost thereof up to a maximum of £300 - £150 = £150 as a replacement of the Renault.

LETTERS, NOTES, ETC.

THE PAST, PRESENT AND FUTURE OF MIDWIFERY.

DR. C. LUNDIE (Thaba-Nebu, O.F.S., South Africa) writes: After reading Professor Watson's excellent inaugural address at Edinburgh University (BRITISH MEDICAL JOURNAL, October 21st, p. 712), it occurs to me that in order to attain to his very lofty and praiseworthy ideals in midwifery a very drastic change in the present methods is necessary, the chief thing to be done being intensive organization and team work among members of the profession. The various branches of the profession have become such wide subjects in themselves that specialization is essential, yet few who can afford an ordinary medical curriculum can afford the further expense and delay in earning power involved in a specialist's course after taking the ordinary medical degree. Hence there are not enough specialists to go round if every one is to have their aid within their means, yet there is an immense superfluity of general practitioners, many of whom find it difficult to make a living.

The only reasonable hope of providing efficient service to all, rich and poor, and at the same time using all the qualified men to the full seems to be a modified form of state medical service, which it should not be beyond the genius of man to evolve free from the numerous objections to it that have been pointed out at different times. The newly qualified men would have to serve

a sort of apprenticeship in the hospitals and later in general practice under supervision of older and more experienced men. Patients would be allowed to choose their doctors, and fees according to the means of the patients would be collected by the State and salaries proportionate to the amount and nature of the work done paid to the doctor, who would be promoted for efficiency to higher grades of work and so to higher rates of fees. There would thus be no resting on one's oars when one got to a high rank because the salary would depend on the amount of work done as well as on the rank attained—specialist general practitioner or professor. Only by some such scheme, which would have to be introduced gradually, can proper team work be organized in the profession. Facilities for specialization and further study would be provided for the keen and ambitious.

RADICAL PREVENTION OF VENEREAL DISEASE.

MISS ETTIE ROUL (London, W.), in the course of a letter on this subject, writes: Dr. Gerald Garry's letter from Cairo regarding the onthrecks of venereal disease there in the early days of the war should be read in conjunction with the opinions expressed by Colonel Sir James Barrett, the first A.D.M.S. of the Australian Forces in Egypt then (1915), and later on his return to Egypt after sick leave (1916-1917-1918). Dr. Garry says "there is but one way of dealing with such diseases"—isolation and segregation. These measures are necessary but in themselves of proved insufficiency, even when properly administered. The evil of venereal disease cannot be greatly lessened until all the factors of reduction are brought into play—ethical, social, legal, and medical; to argue in favour of a cure-all is not medicine but quackery. Nor can any headway be made with any sex problem till both men and women turn their minds upon it cleanly and strongly. To state, as Dr. Garry does, that moral plitudes should be ruled out of medical practice is clean and logical; to say immediately afterwards that "Perhaps not the least regrettable fact in connexion with this unsavoury controversy is this prominent part taken in it by women," is unclean and illogical. The fact is that women must step out of their almost incredible ignorance and prejudice, and men must learn to de-Orientalize and dis-Turk their minds. . . . Those who have studied the venereal problem most carefully—historically and personally—know that a prime factor in its solution is the engagement of women's minds and hearts in this very dreadful affliction of modern society—for which women as well as men are responsible. A day will come when all women of courage and sympathy will freely give their services in the great cause of sexual health, but that day will not be hastened by snubbing their early endeavours to gain the knowledge and experience necessary to qualify them as efficient social health workers.

THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

DR. F. W. COLLINGWOOD (London) writes: It seems strange that the Council and Fellows of the Royal College of Surgeons of England should wish to retain rights under a charter granted in 1843, which at the present time are utterly inconsistent with the spirit of the age in which we live. After the annual meeting a member of the press was surprised and could not realize the attitude of the Council towards the request of the Members to participate in the administration of the College. I do trust that the British Medical Association will show sympathy and take steps to induce the Privy Council to amend the charter of this College and bring its constitution into keeping with the atmosphere of the present day.

A NEW SUBSTITUTE FOR SALYARSAN.

BOOTS PURE DRUG CO., LTD., of Nottingham, inform us that the Ministry of Health has approved of their preparation "Stabilarsan" being placed upon the list of approved substitutes for salvarsan. "Stabilarsan" is stated to be a chemical compound of salvarsan—the original diamminodihydroxyarsenobenzene, not neo-salvarsan—and glucos. It is prepared in solution ready for immediate use, and can be given either intravenously or intramuscularly.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 32, 33, 35, and 36 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 34 and 35.

A short summary of vacant posts notified in this advertisement columns appears in the Supplement at page 232.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

Note.—It is against the rules of the Post Office to receive post restante letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

476. Arterio-sclerosis in Children.

GEORGE EVANS (*Quart. Journ. of Med.*, October, 1922, p. 33) confirms Poynton's statement that arterio-sclerosis in children and adults is identical. He publishes four cases, which not only confirm the previous observations of others, but go farther in exhibiting the identity of a particular type of arterial lesion—diffuse hyperplastic sclerosis in children and adults. This identity is confirmed in detail in the type of arterial lesion, its vascular distribution, its incidence in several organs, and association with a raised blood pressure and left ventricular hypertrophy. Arterio-sclerosis is not uncommon in children; it may result from acute infection, from syphilis, and in the course of renal disease; future observations may determine whether this particular type of arterio-sclerosis occurs in syphilis or in acute infections apart from kidney disease. Possibly by the definition of diffuse hyperplastic sclerosis in children, the association of arterio-sclerosis with chronic nephritis may be explained. The present observations throw no new light on this association. The endothelial proliferation in the arterioles now demonstrated for the first time indicates active inflammation. Further, the active inflammatory changes in the kidneys in all four cases, particularly the epithelial proliferation in Bowman's capsule, indicate a primary disease of the renal parenchyma. Such proliferation would not result from interruption of the glomerular blood supply; it indicates that the renal lesion is primary and not secondary to vascular disease. At present the simplest interpretation is that the vascular and renal lesions are both produced by a single pathogenic agent. Another possibility is that renal disease indirectly causes arterial disease through toxæmia resulting from renal inefficiency. The author cites a remarkable case of Hale-White's (*Guy's Hospital Reports*, lv, 17): a boy, aged 6 months, in whom extensive arterio-sclerosis was associated with bilateral hydronephrosis and extreme renal cirrhosis due to phimosis; in this case it was thought that syphilis was the primary cause and that the kidney disease was contributory. In Evans's four cases there was no evidence of syphilis. Chronic nephritis of this type in children is generally considered non-syphilitic. The author made the autopsies in all four cases, and the records (from dates of admission) are very full. The first three cases belong to the type of chronic nephritis in children termed "renal infantilism"; the fourth case differed in some respects, but the renal and cardio-vascular changes justify its inclusion with the others. All exhibited marked cardiac hypertrophy and very high blood pressure. Evans concludes that (1) diffuse hyperplastic sclerosis is identical in children and adults, and (2) its association with chronic nephritis in children is more significant than in adults because many causes of arterio-sclerosis are excluded in children by reason of their age.

477. Treatment of Typhoid Fever.

P.-E. MICHELEAU (*Gaz. hebdomadaire des Sciences Médicales de Bordeaux*, October 22nd, 1922, p. 506), as the result of twenty years' experience, is inclined to agree with Huchard, who used to say that in typhoid fever the patient was exposed to two dangers—the disease and the treatment—and that the former was not always the more dangerous. He relates two cases which nearly died of collapse as the result of treatment by pyramidal, but were saved by stopping this treatment and substituting a warm bath, which acted as a cardiac tonic. Another patient suffered from post-typhoid asthenia for several months as the result of too energetic treatment. During the day there was barely half an hour in which he did not have some injection, an enema, or a bath; and it was only during the night that he had a few hours' uninterrupted rest. Michéleau's method of treatment is as follows: Patients are allowed to drink as much water as they can in the form of vegetable soup, weak tea or coffee to which a little alcohol is sometimes added, and lemonade made of citric or tartaric acid. Milk is forbidden, as it tends to coat the tongue and favours intestinal fermentation. The bowel is cleared out morning and evening with an enema of boiled water containing one or two tablespoonfuls of glycerin, and three or four cachets, each containing 0.30 g. quinine sulphate and benzonaphthol. Cold baths are not given except in special circumstances. From time to time an injection of camphor oil or a few centigrams of adrenaline, caffeine, or spartein are given as required.

478. The Circulatory System in Tuberculosis.

LIVIERATO (*Rif. Med.*, September 18th, 1922, p. 839) says that tuberculosis may affect the circulatory system in four ways, causing—(1) morphological alteration, (2) trophic changes, (3) functional changes, (4) changes due to localized infections of the vascular organs. The morphological changes constitute the so-called "phthisical habit," comprising dwarfism of the heart and hypoplasia of the aorta and vessels. There is, he declares, no special habit predisposing to phthisis, although it is true certain people contract phthisis more readily than others; the habit, if present, is more often a result than a cause of phthisis; a syphilitic "habit" is not regarded as constituting a predisposition to syphilis. The acquired morphological changes of the heart are the result of profound disturbances of nutrition. Nutritive changes include fatty degeneration of the heart and arterio-sclerosis. The functional disturbances include dilatation of the heart (especially the right ventricle), palpitation, especially after the evening meal, tachycardia (which, when persistent, is often due to pressure on the vagus); bradycardia is more common in mild cases. Low blood pressure is common, and is probably due to an endocrine want of equilibrium. High blood pressure may precede hæmoptysis. The localized infections comprise tuberculous pericarditis (often latent), myocarditis, endocarditis, obliterative arteritis, phlebitis. Lastly, tubercle bacilli may be found in the circulating blood.

479. Late Effects of Injuries to the Nervous System.

V. CHRISTIANSEN (*Ugeskrift for Læger*, October 26th, 1922, p. 1444) deplores the fact that the Danish Workmen's Compensation Act is worded so that every compensation claim must be settled within three years of the accident. During the author's conduct of the Neurological Polyclinic of the Rigshospital in Copenhagen in the past nine years he has seen at least 50 cases in which the symptoms first developed ten to thirty years after an accident. Most of the cases, of which he gives full records, were not complicated by compensation claims, and it was therefore possible to obtain unbiased evidence as to the relation of the accident to the injury. In one case of late traumatic apoplexy, with symptoms of hæmorrhage into the oculo-motor nuclei, the combination of drowsiness and coma with paralyses of the muscles of the eyes led to the mistaken diagnosis of lethargic encephalitis. To enforce his suggestion that the three-year limit of the Workmen's Compensation Act is arbitrary, unfair, and too short, the author points out that in some cases improvement occurs after this interval, and the compensation awarded is, accordingly, too high. Although he records many cases he has not found it necessary to draw on that large class represented by tabes, disseminated or combined sclerosis, syringomyelia, dementia paralytica, or amyotrophic lateral sclerosis. He notes that while late hæmorrhages into the brain long after an accident are now generally recognized little is known as to the late traumatic genesis of hæmorrhages into the spinal cord. He is, however, convinced that such hæmorrhages do occur, and he has seen several cases in which the interval between injury to the cord and hæmorrhage into it was long.

480. Mental Disorders in Epidemic Encephalitis.

ACCORDING TO A. BARBÉ (*Paris Méd.*, October 21st, 1922, p. 349), the mental disturbances following epidemic encephalitis are usually manifested at first by symptoms of confusion, obsessions of guilt and unworthiness, sometimes followed by a period of confusion with stupor, necessitating confinement in an asylum, and accompanied by a slight Parkinsonian condition and disturbance of speech. In children encephalitis may be revealed by a change of character, so that the convalescent presents a striking resemblance to a case of congenital mental deficiency. Strange to say, the patients often retain a consciousness of their morbid state even at a late period of the disease. When the acute stage of epidemic encephalitis has subsided, the patient presents symptoms which vary according to the intensity of the lesions. In some cases there may be a hebephrenic-catatonic syndrome ending in recovery, while in others there may be a mental disturbance of a melancholic type often ending in suicide. The most frequent sequel of epidemic encephalitis is Parkinsonianism, which is often accompanied by mental disturbances, shown by somnolence, change of character, spasmodic laughing and crying, and loss of memory. In rare cases a pseudo-bulbar syndrome may develop. Pierre Kahn claims to have obtained rapid improvement in post-encephalitic mental disturbances by daily hypodermic injections of 0.40 g. of sodium cacodylate.

581. Oculo-motor Lesions in Lethargic Encephalitis.

G. COUSIN (*Paris méd.*, September 2nd, 1922, p. 207) remarks that the oculo-motor changes in lethargic encephalitis vary considerably, and in some cases may constitute the whole clinical picture. The following classification is adopted: (1) Clinical forms differing according to the situation of the lesions. The nuclei of the third nerve are principally affected, the symptoms being as follows: ptosis, especially at the onset, insufficiency or paralysis of the rectus internus with nystagmiform jerking, ophthalmoplegia interna, and paralysis of accommodation either alone or in association with the other symptoms. Paralysis of the sixth nerve is rare and may occur in association with that of the third nerve or alone. Paralysis of the fourth nerve has hardly ever been observed in lethargic encephalitis. (2) Clinical forms varying according to the intensity of the symptoms. Ocular palsies are a constant feature of the disease, whatever the intensity of the symptoms may be, being found alike in the well-marked forms characterized by somnolence and fever, and in the incomplete forms in which they may be the only symptoms, sometimes consisting merely in paralysis of convergence or accommodation. As a rule, progressive improvement occurs and the symptoms completely disappear, except when the Parkinsonian syndrome develops, in which case they may persist in a more or less attenuated state, especially in the form of slight paralysis of convergence. Syphilis and botulism must be excluded in the diagnosis. No special treatment is required.

582. The Auscultation Sign of Richard Karplus.

LUDWIG BRAUN (*Zentralbl. f. Innere Medizin*, July 29th, 1922, p. 489) discusses this phenomenon—a modification of the vocal resonance—in diseases of the lungs and pleurae, which he regards as a definite addition to diagnostic signs. Karplus found that on auscultation over a pleural effusion the vowel "u" is clearly heard as *a*. He recommends that one ear should be applied to the chest wall and the other closed with the finger. Braun discusses in detail the acoustic problems involved; he states that vibrations of the vocal cords give rise to low-pitched harmonic overtones, and that the modification of the vowel sound is heard only over the area of pleural dullness; elsewhere it is normal. With a small pleural effusion *a* is changed into *eo*, and eventually is heard as *ea*. He gives numerous examples of changes in the vowel sound which he has observed, and which are more marked in areas where bronchophony or oegophony is present.

583. Endemic Goitre and Cretinism, and their Prophylaxis.

G. HOTZ (*Klinische Wochenschrift*, October 14th, 1922, p. 2073) describes the recent attempts made in Switzerland to prevent goitre. They are based on the old experience that iodine, administered in small doses for a long period, diminishes the most common forms of goitre. It is now known that only very small doses of iodine are required. It should be given for many years (during the whole period of childhood and in the years of sexual activity). Various conditions of the thyroid gland are found in cretins. The author's observations show that in early childhood the cretinous condition often develops under the influence of a large vascular active goitre, and that by the early resection of most of the goitre the cretinous condition may be arrested; the child then develops in a normal manner and increases in height. In cretinous families usually the mother or father or both parents suffer from goitre. Chemical researches respecting endemic goitre are at present in their early stages. One fact is known with certainty—that the normal thyroid gland substance, iodothyron, iodothyroglobulin, and thyroxin are able to prevent or diminish goitre. The prophylactic iodine treatment shows that potassium iodide has the same action. The iodine prophylaxis is carried out in Switzerland in two ways: (1) Potassium iodide is added to the ordinary cooking salt in the proportion of 0.5 gram of potassium iodide to 100 kg. of ordinary cooking salt. This iodized salt is sold at the same price as ordinary common salt, and can be employed for household use. This prophylaxis is carried out in the cantons Appenzell and Valais. (2) In other districts tablets, each containing 5 mg. of iodine, are given to the children in schools; one is given weekly. The reports of Bayard show a marked diminution of goitre in the districts where the iodized cooking salt is used. The reports of Steinlin and Imhaeh respecting 7,500 school children treated with tablets show a diminution of the number of cases of goitre. The cost of the tablets for each child for a year was one franc. Caution in the treatment is, of course, necessary, as in certain cases of goitre in adults small doses of iodine lead to symptoms of Graves's disease.

SURGERY.**584. Shoulder Pain in Acute Abdominal Disease.**

ZACHARY COPE (*Brit. Journ. of Surgery*, October, 1922, p. 192) shows the great importance of pain referred to the shoulder in acute abdominal disease. By "phrenic" shoulder pain is indicated pain felt in the top of the shoulder in consequence of an irritation of the terminations of the phrenic nerve. This referred pain is felt over the areas of skin supplied by the same spinal segments as the phrenic nerve. Pain is roughly felt in the areas supplied by the descending cutaneous branches of the third and fourth cervical nerves. Any condition causing irritation of the diaphragm may cause this pain, disease of the liver, stomach, duodenum, pancreas, and spleen being most common. The position of the pain varies according to the part of the diaphragm irritated. Irritation of the right side of the diaphragm causes pain in the right shoulder, whilst left shoulder pain results from affection of the left diaphragm. Irritation of the anterior part of the diaphragm causes pain in the clavicular or supraclavicular region, and when the posterior part is irritated pain is felt in the supraspinous fossa. Pain over both shoulders indicates a median irritation. The author finds that gall stones and gall-bladder disease are less commonly the cause of phrenic shoulder pain than are perforated ulcers of the stomach. Cholecystitis does not cause this pain unless there is accompanying local peritonitis. The pain is often a help in making a diagnosis. In perforated duodenal ulcer it is the rule for pain to be felt in the right supraspinous fossa, whilst in appendicitis it is very rare. In acute pancreatitis pain may be experienced in the left supraspinous fossa, associated with the signs of an acute abdominal lesion.

585. Indications for Tonsillectomy.

H. HEIMAN (*Amer. Journ. Dis. Children*, September, 1922, p. 204) inveighs against indiscriminate removal of the tonsils, and urges the substitution of more conservative principles in treatment. From an analysis of 200 cases he formulates the following rational indications for removal of the tonsils and adenoids: Adenoids should be removed in cases presenting obstructive symptoms, mouth breathing, and snoring, without any evidence of these being caused by a high arched palate, and in those with an obstinate nasal discharge without signs of sinusitis. Tonsillectomy is indicated when the tonsils are obviously causing obstruction to breathing or swallowing, are definitely diseased, or present recurrent accumulations of cheesy material with symptoms of toxic absorption; and when tonsillitis is followed by persistent cervical adenitis, whether pyogenic or tuberculous. Each case requires careful consideration on its merits before recommending operation.

586. Papillary Carcinoma of the Kidney.

T. C. STELLWAGEN (*Therapeutic Gazette*, October 15th, 1922, p. 685) points out that these growths are of rare occurrence. They are usually considered to arise within the kidney pelvis; some consider them secondary to vesical papillomata. It is possible that irritation of the renal epithelium in the pelvis plays a definite rôle in their causation; they are found associated with stone in a number of cases. Papillary carcinoma is generally believed to grow from the renal pelvis or epithelial lining of the collecting tubules in the Malpighian pyramids. They may occur as solitary or multiple buds, perhaps filling the whole pelvis and causing obstructive symptoms. They are more common in the male than the female, in the ratio of two to one; and occur between the fifth and sixth decades of life. The diagnosis is seldom made with certainty. Haematuria is the most important symptom, and cystoscopy should be employed to determine the source of the bleeding. Papilloma of the bladder is strong evidence of a growth higher up, especially when associated with renal haemorrhage or the growth involves the ureteral outlet. less haematuria should be suspected. Nephromata are usually more rapid in growth and cachexia is more pronounced; there is usually a dull aching pain in the loin, and sometimes attacks of colicky pain. Treatment depends on early diagnosis; and it becomes essential, if cure is to be effected, to do nephrectomy early, before the change to malignancy has occurred. In doubtful cases an exploratory incision should be made, followed if cases an exploratory incision should be made, followed if necessary by nephrectomy and ureterectomy. The ureter should be removed down to the bladder wall. Operation should be performed in cases where bleeding persists and the patient is losing health rapidly from loss of blood. When all other methods have failed and the haemoglobin has remained in the neighbourhood of 60 per cent., exploration should be carried out.

487. **Pneumoperitoneum in Splenic Tumours.**

F. PARTSCH (*Zentralbl. f. Chir.*, June 24th, 1922, p. 905) draws attention to the value of pneumoperitoneum before attempting to remove splenic tumours. As Helucko has shown, splenectomy in Banti's disease and other chronic disorders of the spleen is often rendered very difficult by adhesions, and most of the fatalities from this operation are to be attributed to this cause, which gives rise to 'secondary' hæmorrhage. Partsch states that during the last six months pneumoperitoneum has been carried out on three occasions at the Rostock University surgical clinic before splenectomy. The first case was one of hydatid disease of the spleen, the second one of splenomegaly with portal thrombosis, and the third one of hæmolytic jaundice. In the first case pneumoperitoneum showed the presence of echinococcus disease of the liver in addition to a large rounded splenic tumour. The liver and spleen were firmly adherent to the diaphragm and did not allow the air to penetrate between them and the diaphragm. An attempt to separate the spleen in spite of these adhesions led to rupture of the diaphragm and pneumothorax. In the second case, after evacuation of 4 litres of ascitic fluid, extensive adhesions to the anterior abdominal wall, due to a previous operation, were shown. The splenic tumour reached three fingerbreadths below the costal margin, the diaphragm was freely movable, the upper pole of the spleen was free from adhesions and the sides were adherent. In the third case adhesions were not shown on pneumoperitoneum and the operation confirmed the x-ray findings. These cases show that pneumoperitoneum, though it cannot exactly take the place of exploratory laparotomy, can nevertheless serve as a guide to the difficulties of splenectomy and is of prognostic value, as in cases of extensive adhesions it may supply a sufficient reason for refusing to operate.

488. **"Thermo-penetration" for Abdominal Pain.**

M. MENARD and S. NEMOURS-AUGUSTE (*Journ. de Radiol. et d'Électrol.*, September, 1922, p. 397) discuss the effects of "thermo-penetration" on the abdominal organs. They use a current of such a strength that the patient feels a sensation of warmth, very slight and not unpleasant; they advise the maximum strength which the patient can bear, and this varies in different cases. They have treated patients suffering from affections of the alimentary canal, both those who have been operated upon without success and others prior to operation—cases of gastric ulcer, vesical calculus, gastritis, and appendicitis. In all cases they carry out a blood examination and test meal of the fasting stomach. Many cases on a screen examination showed evidence of pyloric spasm. The pyloric pain was often relieved without change in the x-ray appearances after treatment. Cases of persistent vomiting and spasmodic pain with hæmatemesis have been greatly improved under the treatment. In cases of dysmenorrhoea the results have been excellent, and the pains have disappeared. The authors conclude that this form of treatment gives good results in certain gastro-intestinal lesions, while for dysmenorrhoea in particular it is the treatment of choice.

489. **Gastric Cancer and Gastric Ulcer.**

F. A. SCHALIJ (*Nederl. Tijdschr. v. Geneesk.*, October 14th, 1922, p. 1726) remarks that whereas it was formerly held that a very large percentage of so-called chronic gastric ulcers ended in cancer, the present view is that this result occurs in only a small proportion of cases. If it is true that a high proportion (50, 60, or 90 per cent.) of chronic gastric ulcers is liable to malignant change, a large number of patients with gastric cancer should give a history of chronic gastric ulcer. Schalij has investigated 200 cases of gastric cancer, 97 of which came to operation and 103 did not. Of the former, 79 had a history of gastric symptoms lasting only from four weeks to eleven months before coming under treatment, and of the remaining 18 only 12 had symptoms suggestive of gastric ulcer. Of 103 patients who were not operated on, 100 had symptoms for less than a year before seeking medical advice, so that out of a total of 200 cases of gastric cancer only 15 had in all probability been suffering from gastric ulcer. This did not, however, imply that the old ulcer had always been transformed into cancer, as Schalij had seen patients who had formerly had gastric ulcer, but in whom the cancer developed in a different part of the stomach from that in which the ulcer had been situated.

490. **Traumatic Rupture of the Biliary Passages.**

H. RUBBERG's study of 41 cases of traumatic rupture of the biliary passages (*Uppsala Läkareförenings Förhandlingar*, August 5th, 1922, p. 223) shows that the structures most often involved are the ductus choledochus, the ductus hepaticus and its chief branches. Occasionally the rent in the biliary passage was complete, but as a rule it was not, and only in two cases was the course of the rent longitudinal; in the

other case it was transverse. Children are said to be more liable to this injury than adults, and among the author's cases there were 12 patients under the age of 15. Only 3 of the patients were females, and the preponderance of males is assumed to be due to their living under less sheltered conditions. The clinical picture was extraordinarily uniform in these cases. Immediately after the injury there were signs of shock, with pain in the abdomen, rapid pulse and pallor, often accompanied by vomiting. The symptoms of shock soon passed off, and many of the patients were able to walk home. During the next few days the abdominal pain diminished, and, apart from slight diffuse abdominal tenderness, there were no signs of peritonitis. The temperature was either normal or only slightly raised. On the third or fourth day the urine contained bile pigments, and jaundice became progressively more severe, and was accompanied by signs of free fluid in the abdominal cavity. In the cases not operated on death occurred in a few weeks or months, during which the patients became emaciated and very weak. In one case as much as 22 litres of bile were found *post mortem* in the peritoneal cavity.

491. **Recurrence in Cancer of the Breast.**

WIART (*Bull. et Mém. Soc. Chir. de Paris*, July 11th, 1922, p. 979) has followed up all the cases of carcinoma of the breast operated upon by himself over six months and under three years previously. The cases operated upon were those which did not show ulceration, which were movable over the chest wall, and were not accompanied by glandular enlargement in the axilla. The operation consisted in removal of a large area of skin and a still more extensive removal of the subcutaneous fatty tissue, removal of the pectoralis major and minor, and a careful dissection of the axilla as high as possible under the clavicle. The number of cases investigated was 26. Of these, 9 are dead—8 during the second year and 1 at the end of two years and a half—from general metastases in the bones, lungs, glands, and opposite breast in the different cases. There was no local recurrence in the scar in these patients at the time of their death, but in 3 there was pain and oedema of the arm, probably due to axillary recurrence; this was perhaps due to an incomplete removal of the fatty tissue in the axilla, and should be avoidable. The 17 remaining patients are all alive; 2, however, show signs of recurrence in a nodule in the region of the scar. The 15 other cases are all in good health and give no evidence of recurrence. Where there is any limitation of abduction due to removal of the pectorals this is too slight to cause any inconvenience. The performance of a radical operation considerably diminishes the number of recurrences, and with careful technique these should be very few. On the other hand, in a certain number of cases this will not prevent the rapid appearance of secondary deposits and death.

OBSTETRICS AND GYNAECOLOGY.

492. **Treatment of Abortion.**

J. A. VAN DONGEN (*Nederl. Tijdschr. v. Geneesk.*, November 4th, 1922, p. 2033) has treated 1,081 cases of abortion in hospital and 112 in private practice since 1914 by curetting. Sixteen deaths occurred among the hospital cases and none among the private cases, so that the total mortality was 1.4 per cent.; 897 cases were afebrile and 296, or 24.8 per cent., were febrile—that is, had an axillary temperature of 100.4° F. or higher before curetting. This figure holds an intermediate position between the statistics of Kermauner-Zelnik, in which 22.4 per cent. of the abortions were febrile, and those of Steffen at Kiel University clinic, in which 400, or 26.1 per cent., of 1,600 abortions were febrile. Of Halban's abortion cases, 28.7 per cent. were febrile, and of Litzko's 33.5 per cent. In 4 of van Dongen's 16 fatal cases the temperature before curetting was normal, or at least below 100.4°. The causes of death in these 4 cases were sublimato poisoning, influenza pneumonia, hæmorrhages, and embolism of the pulmonary artery respectively, and not sepsis, peritonitis, or paraterrine complications, so that death cannot be attributed directly to the curetting. It is therefore clear that in afebrile abortion active treatment is indicated, as the mortality among 897 such cases was only 0.4 per cent. Of the 12 fatal cases of febrile abortion, 9 were complicated by infection of the adnexa or parametrium, and only 3 were uncomplicated, so that the mortality of cases of uncomplicated febrile abortion treated by curetting was only 1.09 per cent.—a far better figure than any hitherto recorded, the next best being that of Halban, who had a mortality of 3.13 per cent. in cases of febrile abortion. The three principal objections to conservative treatment of abortion are the danger of hæmorrhage, the risk of sepsis, and the longer duration of treatment. In almost 80 per cent. of the

uncomplicated febrile cases the temperature became normal two days after curetting. The average duration of treatment was 11.25 days. In a subsequent paper van Dongen proposes to discuss whether instrumental or digital removal of the residues of abortion is better.

493. Stenosis of the Female Urethra.

E. CHOCHOLKA (*Casopis lékařů českých* and *Zentralbl. f. Gynäk.*, October 28th, 1922, p. 1743) records nine cases of stenosis of the female urethra, none of which was of gonorrhoeal origin. Three were cases of syphilitic stricture, and yielded to antisiphilitic medication without other treatment. In five cases the obstruction was due to polypus near the external orifice or in the lower third of the urethra; these cases exhibited symptoms of stricture and of secondary affection of the bladder and upper urinary tract. Cure was effected by destroying the polypus by means of the Paquelin cautery and stretching the scar. In the remaining case the stenosis was caused by a vertical scar left behind by a vaginal tear dating from labour many years back; after internal urethrotomy the vaginal scar was excised, the urethra freed, and the wound sutured in the vertical direction.

494. Uterine Displacements after Childbirth.

F. W. LYNCH (*Amer. Journ. of Obstet. and Gynecol.*, October, 1922) has found a surprising frequency of uterine displacements during the fourth to the twelfth months after childbirth. His records are those of 1,230 among 2,037 women delivered at term in an obstetric clinic, and 505, or 41.1 per cent., of the 1,230 were found to have retroposition of the womb at some time during the twelve months ensuing on labour. Apart from those traced in the systematic "follow up," no fewer than 32 per cent. of the patients with retroposition returned to the clinic on account of pelvic symptoms, and only 10.5 per cent. of the control series with normally placed uterus gave similar complaints, which consisted in bearing-down sensations, a feeling of pressure in the pelvis, or sacral backache. These results are in conflict with the belief which has concluded—largely from the work of Schroeder, who found that one-fourth of women having no pelvic symptoms showed retroposition of the uterus—that uterine displacements are of little importance. From the fact that fewer than 20 per cent. of private patients showed retroposition, it may be argued that insufficient rest after labour is a factor of etiological importance. Of the 505 displacements, 18 per cent. developed between the fifth and eighth months, and 6 per cent. between the ninth and twelfth. Treatment was attempted in all cases, subinvolution being treated by douches and tampons. Not less than five weeks after delivery straightening (without anaesthesia as a rule) and correction by pessary were tried in 281 cases, with 68 per cent. of cures. Cases suitable for operation, pessary treatment having been unsuccessful, or impossible on account of a relaxed condition of the vagina, numbered 47. With regard to retrodisplacement and fecundity, it was found that the percentage of subsequent pregnancies in married subjects was twice as great in those with treated as in those with untreated malpositions, and three times as great as in those without displacements. Emphasis is laid by the author on the importance of examining the uterus at stated periods after childbirth and of early correction of retropositions.

495. Transmission of Placental Tuberculosis.

GEIPEL (*Zentralbl. f. Gynäk.*, September 9th, 1922, p. 1453) was led by an observation of Schmorl—who found a caseous mass in the chorion, breaking through and allowing entrance of detritus and tubercle bacilli into the liquor amnii—to examine liquor amnii from pregnant patients suffering from advanced tuberculosis of the lungs and other organs; the centrifugized fluid was stained and also injected into guinea-pigs. No evidence of the presence of tubercle bacilli was obtained in two cases, in one of which the placenta contained a tubercle with tubercle bacilli; in a third case, in which the chorion contained two tubercles but the amnion was intact, the liquor amnii contained a clump of tubercle bacilli and infected the guinea-pigs into which it was injected. No evidence of tuberculous infection was found in the foetus of the last-named case, but, theoretically at any rate, infection of the gastro-intestinal tract or skin was possible. Geipel, however, is sceptical concerning the occurrence of effective infection; he points out that, although tubercle bacilli have been found in foetal lymph glands and liver, evidence of local reaction has been absent. Similarly the detection of tubercle bacilli in the intervillous placental space in maternal tuberculosis is not evidence of placental tuberculosis unless tubercle formation is histologically proved. A case is recorded by the author, in which, in connexion with a five months' abortion, the placenta presented a condition of pseudo-tuberculosis, with numerous nodules, containing round, epithelioid, and giant cells; no tubercle bacilli or spirochaetes were detected.

PATHOLOGY.

498. Test for Botulinus Poisoning.

V. BURKE and C. W. MAY (*Journ. Amer. Med. Assoc.*, November 11th, 1922, p. 1669) have devised a rapid test for the etiological factor in bacterial food poisoning, for which the claim is made that it can be readily applied by practitioners lacking access to a diagnostic laboratory. The test consists of a rapid, confirmed test for the toxin of *Clostridium botulinum* (*B. botulinus*) combined with a slower presumptive test for organisms of the paratyphoid-enteritidis group. There is also described a rapid presumptive test for the presence of botulinus toxin which may be used when botulinus antitoxin is not available. The application of this test in a recent outbreak of botulism, with the resulting diagnosis and case history, is described. In testing to determine the presence and nature of the poisonous substance in a jar of tinned asparagus, 2 c.c.m. of the unfiltered asparagus liquor was placed in each of five serum tubes. To the asparagus juice in the second tube was added 1 c.c.m. of Type A botulinus antitoxin. To the third tube was added 1 c.c.m. of Type B botulinus antitoxin. The fourth tube was placed in boiling water for ten minutes. To the fifth tube was added 0.5 c.c.m. of a 10 per cent. solution of hydrochloric acid, which was allowed to stand for ten minutes. The contents of all five tubes were then neutralized to litmus with a saturated solution of sodium bicarbonate. The contents of each tube were then injected into the marginal ear vein of a medium-sized rabbit. The results indicated that the asparagus contained a botulinus Type A toxin.

497. Glycaemia in Diphtheria.

P. LEREBOLLETT, P.-L. MARIE, and L. LEPRAT (*Paris méd.*, November 4th, 1922, p. 417) for some months have been carrying out investigations on the presence of glycaemia in diphtheria for the following reasons: (1) because in recent years stress has been laid on the hypoglycaemia which is the rule in suprarenal insufficiency, and (2) because severe forms of diphtheria are often associated with acute suprarenal insufficiency. They found that in three cases of mild diphtheria without much constitutional disturbance or toxic symptoms the blood sugar remained normal, varying between 0.91 and 1.13 gram; while in six cases of severe diphtheria, characterized by extensive membrane, oral fetor, much adenitis, and albuminuria, the glycaemia, with one exception, in which it was normal, was decidedly diminished, the amounts being 0.597, 0.71, 0.77, 0.79, and 0.74 gram respectively. In some of the cases the hypoglycaemia was associated with other signs of suprarenal insufficiency. The authors conclude that if these findings are confirmed by further observations hypoglycaemia in severe diphtheria may be regarded as an indication of suprarenal involvement which is so frequent in diphtheritic intoxication.

496. The Effect of Carbohydrates in the Production of Immune Bodies.

IN view of the beneficial effect which has so frequently been observed to follow the administration of glucose in infective diseases, M. OHZAKI, K. SUREGAWA, and S. SAWAGUCHI (*Japan Med. World*, October 15th, 1922, p. 288) endeavoured to determine the biological effect on the organism of the administration of carbohydrates. For this purpose they made up 1 per cent. solutions of certain sugars—glucose, lactose, saccharose, maltose, dextrin, and glycogen—and injected them intravenously once a week into rabbits. Two animals were used for each sugar. Eight days after the fourth injection they were bled, the serum collected, inactivated by heating at 60° C. for half an hour, and preserved with 0.5 per cent. phenol. Agglutination tests were put up, starting at a dilution of 1 in 20, against heated saline suspensions of typhoid, paratyphoid, colon, dysentery, and cholera bacilli. With the exception of the typhoid strain, all the bacilli gave negative results. The *B. typhosus*, however, was agglutinated up to a titre of 1 in 1280 by the glucose and glycogen serums, and to a lower titre by the others. The ability of this typhoid strain to fix complement in the presence of the various serums was then tested, and was found to be positive in the case of the glucose and glycogen serums. A certain bacteriolytic action in respect to *B. typhosus* was demonstrated with these two serums, though the results were not very convincing. The effect on the cellular constitution of the blood resulting from the injection of 2 per cent. glucose solution was found to be a leucocytosis, while rabbits subjected to the injection of typhoid bacilli developed a leucopenia. The authors find it difficult to draw any definite conclusions from the foregoing experiments. Whether the immune bodies produced are to be considered as specific for *B. typhosus*, or whether they are of a different nature, has not yet been determined.

NINETIETH ANNUAL MEETING

OF THE

British Medical Association.

Held at Glasgow, July, 1922.

PROCEEDINGS OF SECTIONS.

SECTION OF OPHTHALMOLOGY.

A. S. PERCIVAL, M.B., B.Ch.Camb., President.

DISCUSSION ON
THE CLINICAL SIGNIFICANCE AND TREATMENT
OF HETEROPHORIA.

OPENING PAPERS.

I.—ARCHIBALD S. PERCIVAL, M.B., B.Ch.Camb.,
Senior Surgeon, Northumberland and Durham Eye Infirmary.

The name "heterophoria" and the classification of its varieties we owe to George Stevens of New York. Latent deviations differ from manifest deviations or squints in being small enough to be overcome by the superior influence of the higher centres in the effort to maintain single vision. This effort will very probably entail asthenopia, and possibly some other curious symptoms to which I shall cursorily refer later.

In every case of heterophoria the first point is to distinguish between those that are *comitant* and those that are *non-comitant*. Suppose we find with the Maddox rods before the right eye and a green glass before the left eye, when a pea lamp at 6 metres' distance is viewed with the eyes in the primary position, that the red line is seen by the patient 4 centrads to the right of the light, the total esophoria in the primary position is 4 centrads. Now turn the patient's head to the right, so that he has to assume the "eyes left" position in order to view the light. If now the deviation appears to be 8 centrads, the deviation is non-comitant and there is a paresis of the left external rectus. Now turn the patient's head to the left, so that he assumes the "eyes right" position; if the deviation of the red line be more than 4 centrads he must have a paresis of the right external rectus. There is no excuse for our following the lead of some of our confrères in mispronouncing this word as *paresis*, when we all know it is the Greek *πάρεσις*, and the instinct of our language is to throw the accent back; but this is by the way. It is only in such non-comitant deviations as the above that one can justly use such terms as "insufficiency of the externi" or of the interni."

Esophoria or exophoria is only comitant when the deviation in the "eyes right" and in the "eyes left" position is the same as that in the primary position. Comitant heterophoria is due to some supranuclear lesion; non-comitant heterophoria is due to some lesion in the muscles, nerves, or terminal motor nuclei. As Maddox has well pointed out, it is a most important clinical distinction that all affections of the final common paths are non-comitant, while all those of higher structures are comitant. Non-comitant or lower hyperphoria is often overlooked, as many are in the habit of limiting their examination to the heterophoria in the primary position. The diagnosis of parietic muscles is made on the same principle as for paralysis, but in most of the textbooks the diagnosis is a most complicated and difficult affair. Perhaps I may be excused for repeating the extremely simple and accurate method first published by Maddox and which I have been demonstrating at the Newcastle Eye Infirmary for the last sixteen years or so.

Diagnosis of the Paralysed Muscle.

The twelve muscles of the eyes may be divided into three groups of four each, four moving the eyes laterally, four upwards, and four downwards. Each group is divided into two pairs, one muscle of each pair being in the right eye and one in the left eye.

1. Lateral.

- (a) Right turners: Right external rectus and left internal rectus.
(b) Left turners: Left external rectus and right internal rectus.

2. Elevators.

- (a) Eyes right: Right superior rectus and left inferior oblique.
(b) Eyes left: Left superior rectus and right inferior oblique.

3. Depressors.

- (a) Eyes right: Right inferior rectus and left superior oblique.
(b) Eyes left: Left inferior rectus and right superior oblique.

Each of these six pairs of muscles consists of Graefe's "true associates," and are easily remembered by Maddox's mnemonic that their names are the most contrary possible—for example, right external rectus and left internal rectus; or right superior rectus and left inferior oblique. It is clear, then, that if we consider the patient's field of view to be divided into right superior, external and inferior areas, and left superior, external and inferior areas, and if we find the area in which the greatest cardinal diplopia occurs, the condition must be due to the same named muscle, or to the most contrary named muscle. By the term "cardinal diplopia" I mean simply either a vertical diplopia (in the superior or inferior areas) or a lateral diplopia (in the external areas). Thus if the maximum vertical diplopia occurs in the right

LEFT SUPERIOR		RIGHT SUPERIOR
LEFT EXTERNAL		RIGHT EXTERNAL
LEFT INFERIOR		RIGHT INFERIOR

inferior area, the patient must have a paralysis of either the same named muscle (the right inferior rectus) or the most contrary named muscle (the left superior oblique). It only remains to distinguish which eye is affected: cover one eye, and note which image disappears; if the farthest image from the mid-line (in vertical diplopias the horizontal mid-line) disappears, the covered eye is the paralysed eye, and vice versa. In a lateral diplopia the farthest image from the vertical mid-line will be that formed by the paralysed eye. If the diplopia is increased in more than one of the cardinal directions an affection of more than one muscle is indicated.

It will be noticed that no attention whatever is paid to the torsion of the image, or whether the diplopia is homonymous or heteronymous in the diagnosis of an ocular paralysis by this method; these are refinements which may only lead to trouble. For instance, in fourth nerve paralysis the diplopia is usually homonymous, but it may be heteronymous, if any exophoria be present, and the torsion may not be what one would expect owing to an unrecognized cyclophoria, or periphoria as I prefer to call it. It will be found that by this method all difficulties in recognizing an ocular paralysis disappear. Similarly, if both eyes see well, an ocular paresis, however slight, can be discovered with the Maddox rods before one eye and turning the head in the required position, so that the displacement of the red line can be investigated in each of the named areas.

The objection to the Maddox rods is that the test is entirely subjective, and sometimes one may doubt the reliability of a patient's statements, so that it may be necessary to use objective tests. This will be always necessary if there be no diplopia from blindness of one eye, and, if the parietic eye be used for fixing, a difficulty may be introduced. On examining the movements of each eye when the attention is directed to each of the six named areas any gross loss of movement can be easily recognized, and the parietic muscle can be at once named. If, however, the parietic eye fixes, the associate in the other eye will undergo a marked secondary deviation. For instance, last year I had a case of left sixth nerve paralysis; there was marked diplopia in the left external area, at the same time the right eye was seen to turn strongly in. Clearly the left eye was fixing, and I subsequently found an old macular haemorrhage in the right eye. An intelligent student at the time diagnosed the case wrongly as spasm of the right internal rectus. There is another excellent objective test very largely used by the experts in America, but with which I personally am not so familiar—the screen test.

The test object should be a small electric light, such as that on the tangent scales; the patient is placed at a distance of 6 metres, with his head erect and his eyes looking straight forwards. The surgeon now suddenly covers the right eye with a card and notices whether this right eye moves in any direction when covered. If the right eye alone moves when covered, while the left eye remains fixed on the test object, heterophoria is present. If the right eye moves outwards there is exophoria: if inwards, esophoria; if

upwards, right hyperphoria; if downwards, left hyperphoria. If both eyes move when the right eye is covered, the left eye is squinting, or heterotropia is present.

If neither eye moves, either orthophoria is present or the right eye is squinting; in the latter case the deviation is easily seen on covering the left eye.

Now, after holding the screen over the right eye for at least a minute, suddenly remove it, when a corrective movement in the opposite direction will be seen. This movement of "redress" is usually more noticeable than the movement of deviation just described.

Duane has added a refinement to this test by finding the prism which, when held before the right eye in the appropriate position, will prevent the movement taking place.

Finally test for comitancy by repeating the test with the patient's head in different positions.

Symptoms.

The most characteristic symptom (although it is frequently absent) of heterophoria is occasional diplopia. The effort to overcome a heterophoria in the interests of single vision may occasion asthenopia, headache, giddiness, and all the symptoms of depression one finds in neurasthenia. In several cases for which I have ordered prisms I have been told that there has been a remarkable change of disposition; previous ill temper, moroseness, and pessimism have been replaced by geniality and optimism, but I need not say I cannot lay claim to any results as anuizing as those related by Dr. Gould.

When the tired nervous centres give up the effort to maintain single vision, diplopia ensues, and possibly a visible squint, which, however, only lasts a short time, and then single vision is re-established. Patients will often acquire the habit of temporarily closing one eye; indeed, the facial muscles of one side of the face are sometimes affected with nervous twitching movements that are entirely cured by an appropriate prismatic correction. The giddiness due to heterophoria may be at once recognized by this peculiarity—that it ceases as soon as one eye is closed.

In hyperphoria I have often noticed a peculiar symptom—the inability to read near type (J.1) with both eyes, though each eye separately can read J.1 quite easily. It is probably due to the vertical diplopia which frequently recurs; as the angle of separation is so small, the images of the printed letters overlap when close to the eyes, and hence cause great confusion. In reading test types at a distance the vertical separation will be greater, so that less inconvenience will be occasioned, or one image may be suppressed. There is also often a tendency to convergence at a distance, but a tendency to divergence at reading distance. This diminution of the range of convergence entirely disappears on correction of the hyperphoria.

With regard to periphoria, I have noticed one curious symptom which was present in the first case I ever recognized some thirty years ago, and tentatively suggested this name for the affection. It is now recognized under the extraordinary name "cycliphoria," though what the tendency to a circle can mean passes the wit of man; still worse are the bastard terms "excycliphoria" and "incycliphoria," which I would replace by the terms "okperiphoria" and "emperiphoria," which, at any rate, are of legal Greek parantage; however, this is by the way, and those who know most about the subject have given their sanction to the term "cycliphoria." Anyhow, in science technical terms are names arbitrarily assigned, like Christian names to children, on the principle clearly enunciated in Wonderland to Alice by Humpty Dumpty, when he told her apropos of his use of words: "I pay them extra and make them mean what I like" (Whitehead).

In periphoria, or cycliphoria, I have often noticed that patients complain when going into the street that the houses on either side seem to be falling upon them. I should be interested to hear if others have met with this symptom.

Treatment.

In all comitant cases of heterophoria (but not in periphoria), if not of too high a degree, prisms are the ideal treatment, for the deviation produced by a prism is almost the same in whichever direction the eyes range. I think that probably the best way to promote a lively discussion is to state my personal experience, which will no doubt give rise to controversy from which we shall all profit.

In parietic non-comitant heterophoria the authorities on the subject urge exercise of the weak muscles by ordering appropriate prisms for occasional use. I have met with no success by adopting this method. It very possibly may be that I have not had sufficient influence over my patients to get them to persevere with the exercise, but practically I have abandoned the method altogether. At first I always feared

that ordering prisms which would relieve all or nearly all the error would be followed by the error becoming greater and greater, necessitating stronger and stronger prisms. To my surprise and delight I have found that the heterophoria has rather tended to become less. It may be owing to the rest or rather relief from constant effort of the opposing muscle, for whatever prism is worn the muscle is still frequently used.

There are two rules from which I never depart: (1) I never correct any heterophoria, however great it may be, unless it is attended with symptoms. (2) I always let my patients wear trial prismatic corrections for at least half an hour in my waiting room, to judge their effect, before ordering the spectacles for constant use. For comitant hyperphoria I do not hesitate to order the full correction that will relieve the manifest hyperphoria as revealed by the Maddox rods at a distance; this will be a little nuder the manifest error for near work.

I would here point out that non-comitant hyperphoria is far from uncommon, and may be due to a paresis of a depressor on one side, or to a paresis of an elevator on the other side. It will be found that a paresis of a depressor (the inferior rectus or the superior oblique, and which is most manifest when the patient looks down) is far more annoying than a paresis of an elevator. Even for these cases I have so far only ordered a prism base down before the paretic eye, and base up before the sound eye. If this were not successful, I should consider the advisability of operating—an advancement of the inferior rectus if that were at fault and possibly a tenotomy of the inferior rectus in the other eye if the superior oblique were at fault. But I confess that I should do such operations with fear; the inferior rectus is a particularly tricky muscle to interfere with, and the result in my hands has not been what I had hoped for. At first sight it would appear that in a permanent paresis of the superior oblique, as its insertion cannot be reached without seriously damaging other muscles, the most hopeful thing to do would be to induce a similar paresis in its true associate, the inferior rectus of the other eye. This should correct the hyperphoria for distance, but I cannot see that it would be any help when convergence is called into play for reading when the eyes are to a great extent depressed by both superior obliques. I gather that Duane has had extraordinarily good results in paralysis of the superior oblique with secondary deviation of the inferior oblique in the same eye, by a tenotomy of this inferior oblique. The effect will be to diminish the hypertropia and the extension at the cost of inducing a diplopia in a superior region which is of far less consequence.

If there is any hyperphoria I always correct it first with prisms, before examining any lateral defect there may be, as frequently, when the hyperphoria is corrected, the lateral defect disappears. I am never afraid of ordering strong prisms for hyperphoria if they are really called for, provided that the patient obtains relief after wearing them for half an hour on trial in my waiting room.

Comitant Horizontal Deviations: Esophoria and Exophoria.

In these cases, as there is such a wide range of relative convergence at each distance viewed, there must now be a "region of comfort," and so I make no use of the Maddox rods except for hurried hospital work, or as a rough indication whether further examination is required. The principles on which I work were published thirty years ago at the annual meeting of this Section, held at Nottingham. I have never seen any reason to alter my views as expressed then, though I now feel justified in speaking more dogmatically on the subject, and I think I can express my views a little more clearly:

1. Correct accurately all refractive errors for distance, and direct the patient's attention all the time to the smallest type he can read.

2. Find his relative range of convergence (R_c) while he is still keeping his accommodation relaxed—that is, while he can still read the smallest type without its doubling.

Suppose that — 2 ∇ before each eye is the amount of divergence that the patient can just overcome, and that + 4 ∇ is the amount of convergence he can just overcome, his R_c is 6 ∇ for each eye for distance. Then as I find that practically every patient can continuously exercise only the middle third of his relative range without fatigue, he will be able to exercise the range from 0 to + 2 out fatigue, and he will not require any relieving prisms for distance. In this case the Maddox rods would indicate an esophoria of about 2 ∇ , or 1 ∇ for each eye.

Now most patients have a considerable power of adapting themselves to the new conditions caused by a correction of their errors, so that even if the patient's R_c were from 0 to +6 (especially if he were hypermetropic), I should order no relieving prisms, although the vertical line through O, denoting parallelism of the fixation lines, would then be to the left of the region of comfort. If such a patient still had discomfort after wearing the glasses for three weeks, I would again test his relative range R_c , which would almost certainly now show some power of overcoming divergence, and I would order such prisms or decentration as would shift the region of comfort to the left, so as to overlap the point O. It is, of course, quite unnecessary to make a diagram.

Suppose R_c were from -1τ to $+5\tau$ for each eye, or 6τ , when there is Esophoria it is only necessary to add (algebraically) the minimum to one-third of R_c , and the prism for each eye is given at once.

$$\text{Min. } +\frac{1}{3}R_c = -1 + \frac{1}{3}6 = -1 + 2 = +1.$$

So that 1τ prism (base out) is required for each eye in order to give relief from discomfort.

Just the same principle is used when there is discomfort in reading, the only difference being that the relative range at reading distance is found when the appropriate correction is worn.

Suppose that the R_c at $\frac{1}{2}$ m. were 12 for each eye, ranging from -2 to $+10$. The point R indicates the convergence required

at this distance; R is seen to lie 2 units to the left of the region of comfort, so if a 2τ prism (base out) be given for each eye in addition all the reading trouble should disappear.

It will be noticed that the formula given above gives the required prism at once:

$$\text{Min. } +\frac{1}{3}R_c = -2 + \frac{1}{3}12 = -2 + 4 = +2.$$

I may state that this case had been to many experts all over the country, and though her refractive errors had been accurately corrected by most of them they had all failed to give her relief. Her relative range was excellent, but it was in the wrong place. I may point out that esophoria for reading usually gives rise to much more trouble than exophoria, which would appear to be exceedingly common as tested by Maddox's ingenious instrument, and usually gives rise to no symptoms of discomfort.

Exophoria.

In this condition the position of parallelism for distance, and of convergence for reading, lies to the right of the region of comfort, and all that is necessary is to shift the region of comfort so that its right edge just touches the point O or R as the case may be.

Suppose that R_c for distance when the correction is worn is 6, ranging from -6 to 0, his region of comfort must range from -4 to -2 , hence he must have a -2τ prism (base in) before each eye to ensure comfort for distance.

Suppose that when the appropriate correction is worn his R_c at reading distance is 12, ranging from $-9\frac{1}{2}$ to $+2\frac{1}{2}$, the weakest prism that will ensure comfort is $-1\frac{1}{2}\tau$ (base in) before each eye.

My formula for all cases of exophoria is $\text{Max. } -\frac{1}{3}R_c$; in this case:

$$\text{Max. } -\frac{1}{3}R_c = 2\frac{1}{2} - \frac{1}{3}12 = 2\frac{1}{2} - 4 = -1\frac{1}{2};$$

for all cases of exophoria is $\text{Min. } +\frac{1}{3}R_c$.

I should not hesitate to operate in any case that required a high prismatic correction for symptoms of exophoria or esophoria. It is necessary in all cases for operation to distinguish between an overaction of the externi or interni, and a weakness of their opponents; the distinction is easy, as will be seen from the following table:

	At a Distance.	Near.
Exophoria—		
Diverging power in excess...	Great	Slight
Converging power weak ...	Slight	Great
Esophoria—		
Converging power in excess...	Slight	Great
Diverging power weak ...	Great	Slight

If in exophoria the diverging power is in excess, the exophoria will be greater at a distance than near, and so on. In cases of excessive diverging or converging power I should recommend a tenotomy of the externi or interni as the case may be; but in weakness of these muscles I should recommend their advancement if really necessary. At the

same time I must admit that as a rule I am not satisfied with a simple advancement. If the advanced muscle is left stretched it always eventually atrophies, I think.

Periphoria.

I have had no success with exercises by the use of two rotating Maddox rods; the only successes I can claim are those obtained in oblique astigmatism by slightly rotating the axes of the cylinders to a wrong position, and this is not a scientific way of dealing with the condition. Possibly a marginal tenotomy on a superior or inferior rectus might do good, but I should like to see the after-results of others who have operated for this condition before attempting to operate myself. Any suggestions for this rare and troublesome condition would be most helpful. It is most important to remember that most people have a small amount of periphoria when converging and looking down without any discomfort arising.

It is far the simplest way to discover what prisms are required when the patient is wearing his refractive correction, in all horizontal deviations at any rate; the frames I use are 60 mm. from centre to centre; knowing this there is no necessity to waste any time in centring the glasses or in calculating the correction that must be made when the prisms are combined with lenses. As I always when possible order decentred lenses rather than prisms, on finding the decentration required that will be equivalent to the prism, I have only to add this to 30 and I get at once the distance of the optical centre of each glass from the mid-nasal line.

Decentration.

If L denote the decentration in millimetres, and N the number of centads required, and D with its appropriate sign the dioptric strength of the lens,

$$L = \frac{10N}{D}.$$

When D is positive, L is positive, and the direction of decentration is that of the base of the relieving prism. When D is negative L is negative, which reminds one that the direction of decentration is opposite to that of the base of the relieving prism. For instance, for esophoria the relieving prism is base out, and when L is positive the decentration is outwards, when L is negative the decentration is inwards.

Sphero-cylinders present some difficulty, which is easily surmounted when it is remembered that an oblique cylinder C with its plane axis at an angle θ with the horizontal, in the horizontal meridian acts as a spherical lens of power $C \sin^2 \theta$, while in the vertical meridian it acts as a spherical lens of power $C \cos^2 \theta$.

$$\text{As } C \sin^2 \theta = \frac{C}{2} (1 - \cos 2\theta), \text{ and } C \cos^2 \theta = \frac{C}{2} (1 + \cos 2\theta).$$

This is an easy-form to read off from the tables. For instance, suppose we have a sphero-cylinder $-5D - 4D \text{ cyl. ax. } 15^\circ$:

$$\begin{aligned} \text{Horizontally, } -4 \text{ cyl. ax. } 15^\circ \text{ acts as } -4 \sin^2 15^\circ &= -2 (1 - \cos 30^\circ) \\ &= -2 (1 - 0.866) = -0.268; \\ \text{Vertically the cylinder acts as } -4 \cos^2 15^\circ &= -2 (1 + \cos 30^\circ) \\ &= -2 (1 + 0.866) = -3.732; \end{aligned}$$

so that the sphero-cylinder acts horizontally as $-5.268D$ lens and vertically as $-8.732D$ lens.

II.—L. WEBSTER FOX, M.D., LL.D.,

Professor of Ophthalmology, Graduate School of Medicine, University of Pennsylvania, Philadelphia, U.S.A.

WHEN the array of phenomena incidental to inco-ordination of the extraocular muscles was presented to the medical profession under the term "heterophoria," there was opened up a field for discussion and speculation the limit to which seems nowhere in sight. Like Mark Twain's remark concerning the weather—"a lot has been said, but nothing done about it!" As we all know, it is to the late Dr. George Stevens of New York City that we owe a debt of gratitude for this term and the others of the phoria group, for it is by reason of this nomenclature that a proper appreciation of these functional disturbances was obtained. The previously existing chaos of terms naturally led to a chaos of understanding. Unquestionably the condition had been recognized and treated successfully in individual cases, but the problem of disseminating this information was complicated by the fact that no one observer knew what the other one was talking about.

To the physiologist the problem of the two images seen by the two eyes appears to be settled. It may be, as Hering long ago said, the eyes are a single organ with two limbs, and also that the duality of the eyes is necessary for stereoscopic vision.

but at the same time the philosophic sceptic marvels at the absence of double vision and stereoscopic vision when the extraocular muscle balance is disturbed in any given patient. The patient suffers instead from dizziness, nausea, and vomiting. Binocular single vision in the presence of orthophoria is difficult enough to explain properly, but binocular single vision in the presence of heterophoria requires all the attention of the physiopsychologist to elucidate. The creation of these reflex symptoms, already referred to, in the presence of heterophoria argues for a closer association of the extraocular muscles system with the entire physiology than is generally admitted even among the most zealous exponents of this relationship. It is conceded that the nervous system, and especially the sympathetic, is directly involved, but from then on the relationship of heterophoria to the general human physiology is left to take its own course.

The unlimited variety of terms coined in connexion with the transitory impairment of function of the extraocular muscles, and the muscle inco-ordination that accompanies such changes, and the still greater—if such were possible—explanations of the phenomena brought out by the countless precision tests in this connexion, leave the poor searcher after truth in a bewildering maze—and still heterophoria continues to develop, and even persist in the patients that have been the subject of these tests and observations.

In the Oxford Ophthalmological Congress of 1921, Ernest E. Maddox in the course of the Doane Memorial Lecture elucidates the condition, in the manner of the master that he is, and doubtless will be unconsciously quoted from time to time in this paper. Buried in a maze of physiological data, he casually mentions the fact that the link between convergence and accommodation enables us to influence its slackness (called "exophoria") by spherical lenses, a treatment that next to constitutional measures is the best. For esophoria he uses full correction of hypermetropia; for exophoria, partial correction; but not always, for in neurasthenia a full correction may be the best. For many years he has treated exophoria in healthy young people by concave lenses so as to stimulate accommodation and create better convergence.

Herein lies the entire subject of heterophoria. The diagnosis is fairly well worked out—the explanation never will be (there are too many explainers)—but the treatment can be, as the very complexity of the condition speaks for its close relationship to the general health. It may be regarded as a form of neurasthenia.

One cannot help being impressed by the statement that however great the postural defect may be, if compensatory hypertrophy has made the fusion reflex great enough to overcome it easily, the heterophoria may be regarded rather as a harmless anomaly than as a pathological symptom. The trouble begins when compensation fails to be completely obtained. There are many psychic factors that effect fusion. Sir James W. Barrett¹ reports a case in which there was voluntary control of fusion. The patient could move either eye outwards separately or together, but he could not effect vertical disassociation. W. Rumbaur² reports a girl who could squint voluntarily. She could adduct each eye separately, and again she could fix one eye in adduction and then turn the other horizontally. With this remarkable accomplishment she showed two degrees of exophoria compensated for by glasses. Why should she have had any? This case points not to an abnormally strong innervation impulse, but rather to a voluntary inhibition of normally associated innervation. Another example may be mentioned of the popular moving picture actor, Ben Turpin, who has capitalized his ability to rotate one of his eyes at will while the other remains fixed.

Coming back to the original thought, when the images seen by each eye are alike in shape fusion is facilitated, but with the Maddox rod, for instance, diplopia will be developed that probably did not exist for practical visual purposes. Again, with the Maddox rod in the horizontal position the line of light will not only be to one side of the light but may be above or below the light, yet when the rod is turned so that the streak is in the horizontal plane, it will be found to be in the same plane as the light. Also, in the measurement of the strength of the muscles with prisms before one eye, it will be repeatedly found the muscles will overcome a stronger prism base down before the right eye than base up before the left eye, and that nearly always the left eye will overcome a stronger prism base

down than base up, yet orthophoria will be found with the Maddox rod in a whole group of cases showing varying peculiarities of this character. Doubtless many explanations can be advanced for these phenomena, nearly all of which will be correct depending upon how far we go into the subject. The shorter the distance we go, the better able are we to grasp the big comprehending truth that the compensation is effected by a host of factors embracing the whole domain of human physiology, and that it is never constant or static.

Maddox very nicely sums up the treatment of heterophoria. He advises first discovery of the cause and its removal. Then examination of the refraction and the correction of ametropia. If lateral and vertical deviation exist together, which they frequently do, he corrects the vertical and ignores the lateral. Next he prescribes muscle training and prism exercise, and last of all muscle operation (graduated tenotomies).

Since heterophoria is, after all, only the latent disturbance of the extraocular muscle co-ordination it is well to refer to the work done in recording the movements of the eye in the discharge of their normal function of reading. C. Sheard, in the *American Journal of Physiological Optics* (April, 1921), reviews the work in this phase of muscle physiology, and it is well worth a pause to relate some of the facts that he has brought together. Thus the fact—first brought to the attention of ophthalmologists by Javal about 1879, that eye movement, as in the act of reading, is not continuous but rather discontinuous. While many of his inferences drawn from his experiments to prove the above have since been shown to lack substantiation, the principal point, that the eyes steady themselves for each completely focused picture, remains accepted. Landolt concluded after working on this basis that 1.5 words on the average were read at each fixation. Delabarre, of Brown University, in 1898, attached a recording apparatus to the cornea and secured tracings of the ocular movements. Later Huey, of Clark University, attached a very light plaster-of-Paris cup directly to the cornea and recorded the eye movements by a system of light beams which were so arranged in conjunction with suitable electrical devices as to provide a measurement, in very small fractions of a second, of the time used up by an eye in the movements of reading. Quoting Sheard's abstract of this work, the results obtained by Huey showed: (1) In reading relatively long lines of magazines, the average number of fixations is about 4.5 a line. (2) Doubling the distance from the eye to the page does not affect the number of fixations. (3) Minor modifications in the size of type do not affect the number of fixations. (4) The duration of the reading pauses, although extremely variable, averages about 0.19 second. (5) Fast reading entails fewer and shorter stops or pauses but not faster movements. (6) A short line—for example, about 60 mm.—makes possible fewer pauses relatively, so that more is read with a single pause. (7) The movements forward—that is, from left to right—are quite constant at 0.042 to 0.048 second. (8) The movements of return—that is, from the right end of the line to the left end of the next line—are quite constant at 0.051 to 0.058 second. Sheard adds the comment that these generalizations are incorrect in that they are too low. Our comment would be that they seem to indicate that accommodation has little or nothing to do with binocular fixation and binocular fusion.

Erdman and Dodge in 1908 added some observations on this subject and among their conclusions is the statement that of the entire time spent in reading, from 12/13 to 23/24 is devoted to pauses and the remainder to reading, and that during those pauses it is extremely doubtful if anything is perceived.

Dodge in 1900, at Wesleyan University, had perfected a method of recording the eye movements by which he showed that the speed of the forward movements averaged about 1/25000 of a second, while the speed of the return movements was³ of the order of 1/40000.

Dearborn, using Dodge's method at the Columbia University in 1906, further substantiates his observations and adds some of his own which constitute perhaps the latest information on the subject. It is of interest to know that the duration of the fixation pause is, roughly speaking, one-fifth of a second; thus, in reading a newspaper column, four readers averaged 161, 216, 255, and 402 thousandths of a second, respectively. The duration is therefore different with different readers, as would naturally be expected. Again, fixation is not absolute and constant, but only approximate—in other words, the eye often makes slow

changes of position during a fixation. If these physiologists are correct, then heterophoria is more or less constant in every individual during reading, although its quantity is extremely variable within short ranges of time. Again, its degree must vary with each of these fixation pauses, yet our means of determination and expressing heterophoria have to do with the eye in repose and fixed at a distant point of no practical importance or occasionally at some definite target at a definite close point, in neither case approaching the practical conditions under which the eyes are used day in and day out. It is most remarkable in the circumstances that we do as well as we do in the handling of the treatment of heterophoria.

These observations of Dearborn, ably interpreted by Whipple of Cornell University, prove conclusively that we have far to go in the subject of heterophoria before we can reduce the phenomena to hard and fast rules of practice. Fixation pauses were shown, for instance, to be more frequent than is needed for clear seeing of the stretches read, as is shown by the fact that they remain the same in number when the print is removed to a double distance from the eye. This would seem to belittle our time-hallowed belief in the accommodation-convergence relationship. Fatigue, Dearborn insists, causes a slower rate of reading and a gradual decrease in the velocity of the eye movements. We venture the inquiry as to whether the multiplicity of the steps and the readjustments is not the cause of the fatigue, not the prolonged accommodative effort.

If fixation is so frequent, then must our observation be made with greater frequency in order to determine what the normal average variation is for each patient. Many careful examiners now do, and all should, measure the so-called muscle balance of every patient at each examination of the refraction, retaining such records for such time when symptoms of muscle asthenopia appear. In passing, comment is made of the term "extraocular muscle balance"; there is no such isolated condition—the intraocular and extraocular muscles at all times have an interlocking relationship.

The recitation of these points may impose on the good nature and patience of the members, but they are mentioned in order to prepare you for the reception of the writer's own views a trifle later on.

Now in order further to confuse our knowledge of ocular movements, E. Ruggeri¹ gives us tracings showing the marked effect under certain conditions of extreme convergence. The reclining patient is made to gaze at the forefinger held 1 cm. from the tip of the nose, and then tracings of the pulse are taken. In the numerous normal subjects it was not disturbed, as would naturally be expected. In multiple neuritis, from malaria, diphtheria, or influenza, the pulse ran up at once from 20 to 30 beats; in thyroid dysfunction from 25 to 30. In other cases it was negative. By strange coincidence it is in these latter groups of patients who have recently had these conditions that our heterophoria patients occur.

The great criticism that obtains in all our work is the scarcity of observations made upon healthy normal individuals without symptoms. The late war afforded much material for such valuable observation. James N. Buchanan of Freeport, Illinois,² while working in the Medical Research Laboratory, Hazelhurst Field, Mineola, Long Island, N.Y., made a detailed study of the examination of the extraocular muscles in fifty-one air pilots and observers, and three non-fliers who had served successfully as airmen overseas. Seven of these subjects, of whom five were fliers, were found to have qualifying heterophoria. The tabulation of these results and the method of examination is worth reading. One of his observations is notable—that with two exceptions every determination of convergence, divergence, and sursumduction by the descending method of using prisms is less than the corresponding one taken by the ascending method. This is to be expected, as the individual has been accustomed to fusion since childhood and tends to retain it as long as possible in the ascending method. On the other hand diplopia is produced early, and in the absence of encouragement it is more difficult to regain fusion.

A pertinent inquiry arises as to whether the heterophoria is to be accounted for before or after these well-known phenomena are produced. There is certainly a marked variation in the degree present before diplopia has been artificially produced, and after the same has been taken place.

The conclusion to be drawn from these apparently disconnected observations is that heterophoria is a constant accompaniment

of binocular single vision, although not always symptom producing, and that even though constantly present varies considerably in each individual patient and is extremely fluctuating in amount.

The question naturally arises as to what factors are necessary to cause the more or less constant heterophoria to assume a pathological significance, or, in other words, When is it symptom producing? We may quote from many authorities or fall back on our own experience for the answer, and state that such conditions as devitalize the muscles and nerves in general are responsible, and then under this head fatigue and exhaustion in general; and then fatigue and exhaustion of the eye muscles from overwork in the presence of an insufficiently corrected ametropia—anaemia, nervous prostration, malaria, influenza, diphtheria, typhoid fever, nephritis, diabetes, and similar disturbances. All these will assist materially in expressing a pathological heterophoria. Faulty attachment of the muscles and congenitally weak muscles may cause heterophoria, but it is doubtful—heterotropia results therefrom as soon as the eyes are used to any extent in efforts at binocular single vision. In point of fact heterophoria, being latent, is always overcome; therefore congenitally weak muscles, being present from the very beginning, are compensated for at the start, if at all, and the patient is adapted to the change from the very start of binocular single vision in infancy. Consequently we cannot accept such causes as refer to anatomical distribution, disturbance of innervation, spasm or paresis of the muscles. If these causes have failed to produce heterotropia, they are of no moment. It is, rather, an effort to maintain a physiological process in the presence of exhaustion of the parts concerned that induces the symptoms.

These symptoms are never constant and continuous; they are always periodic, depending upon the patient and the circumstances of his or her work. Therefore we cannot help but assume that the cause is likewise of a periodic character.

To Stevens and to Maddox and Duane we are indebted for most of the tests and determination of the varieties of the condition, and these are well known to every practising ophthalmologist. The symptoms given in the books are correctly stated, and when in the course of routine examination of the refraction we discover heterophoria its treatment should be considered, but not necessarily by the use of prisms and graduated tenotomies.

In a recent number of the *American Journal of Physiological Optics* (April, 1922) it is refreshing to read the views of a veteran in the matter of prisms and their uses. Charles F. Prentice, in an article in this number on the "Lateral adaptability of the extrinsic muscles in ametropia," gives us considerable practical advice as the results of his long experience in the use of prisms in heterophoria. One of his conclusions was that most persons for whom lateral prisms had been prescribed did not usually revisit him, whereas those patients who had been given vertical prisms did return for subsequent examinations and commonly expressed great satisfaction respecting the comfort they had derived from them. It is therefore his opinion, on an experience of forty years' practice, that the use of prisms for the attempted correction of lateral muscle imbalances only retards recovery. This, it will be noticed, corresponds in large part to the statement of Maddox, quoted again in this article: "If lateral deviations are complicated by hyperphoria, correct the vertical deviation first and the lateral will very likely correct itself."

Returning to the symptomatology of heterophoria, one of the greatest symptoms of the condition is a failure of the patient to obtain perfect comfort and relief from glasses recently prescribed for asthenopic phenomena, that are to all intents and purposes correctly prescribed. The great cause of uncomfortable glasses is an uncorrected heterophoria, usually a hyperphoria, or an artificially created heterophoria as the result of imperfectly centred lenses or overcorrection. This is more especially true when bifocal lenses have been ordered. Many older people have corrected their own heterophoria by grotesque twistings of their reading glasses, causing much mirth and merriment to the onlookers, and evoking pity that they should be ruining their eyes in this manner. Such persons have greater difficulty in wearing the correcting lenses properly centred if the heterophoria correction is not incorporated in them.

De Schweinitz and others have emphasized the point, with which I agree, that the measurement of the relative weakness should be made after the correction of the refractive error has

he also includes in his series of cases those of heterophoria, and there can be no clear line of demarcation between the two. He has found a connexion between these cases and a personal and family history of left-handedness, and so far as definite cases of strabismus are concerned I can confirm these observations. Inman has now collected 700 cases and he is not only able to point to an arbitrary connexion between two symptoms which have no relation to one another, but he has been able to show that both of these conditions are associated with emotional conflicts and particularly with some form of parental complex. Another writer on psychology in its relation to visual abnormalities is Dr. Freeland Fergus, whose absence on account of illness we regret. He has given much attention to the subject of binocular vision and the mechanism by which this is secured, and the muscular co-ordination with which we are dealing is a part of this and should always be considered in this connexion. If heterophoria is present when tested by Maddox rods one of three conditions must result. Either there must be diplopia, or the heterophoria must be corrected by muscular effort, or the image of one eye must be suppressed. Probably the second of these alternatives is the most common. This would probably involve some muscular stress with corresponding symptoms of discomfort. It is, however, possible that the mental distress may be the cause of the heterophoria.

I have recently learnt that in the Royal Air Force the existence of heterophoria is usually found when pilots have made bad landings. I would suggest that the muscular imbalance is due to some condition of fear, and that in most cases mind training is more important than muscle training. Nothing could be worse than to call attention to the condition. This condition is so similar to the visual judgement which is necessary in athletics that I would suggest that good training in cricket or tennis, or similar exercises involving the training of the judgement, would be the best safeguard against crashing in flying. Auto-suggestion might be of great benefit in these cases, and might be tried. I have only recently begun to experiment in this direction, but I may say that the basis of the system on which I am working rests on the following beliefs: (1) That the controlling influence of the mind which regulates all our vital processes, including complicated muscular actions, is adapted for normal use. (2) That it is our phobias and minor mental conflicts which upset this normal action. (3) That auto-suggestion based on these principles has in it possibilities of the utmost interest.

Mr. INGLIS POLLOCK (Glasgow) stated that he found many cases improved by the use of prism exercises in parietic non-comitant heterophoria. It was a condition which was not often understood by the patients' doctors, and many of them did not seem to realize the necessity for continuous treatment. The important thing was to persevere with the treatment, backed up by rest, as many of the patients had been overworked or run down by some intercurrent trouble. If they did not improve with the prism exercises then he advised operation, and it should always be advancement, and not tenotomy. The operation was not so difficult as had been suggested, but care should be taken to make sure that the stitches were inserted into the sclera, and not to put too great a strain upon the sutures, otherwise they were liable to cut out, and the muscle slipped back and was worse than before. Mr. Inglis Pollock also stated that there was no doubt that there was a psychological element in every case, and every means of treatment should be employed in each individual case to make sure of a good result.

Mr. N. BISHOP HARMAN (London) thought that there was no more complex subject in the whole range of medicine than defects of muscle balance, nor was there any matter in which rule of thumb methods of treatment were more unreliable. Since his own apprenticeship was served in anatomy, it was natural that he should look to defects in the anatomical arrangements of the tendons as the primary cause of defect of balance in action. The variation in tendon insertions was very striking when the eyes of fishes were examined. The insertions of superior rectus and obliquus in fishes were usually symmetrically disposed as a complete Y, but the limbs might be slightly separated or actually crossed; so also with the inferior pair. The internal and external rectus might vary: the internal might fail to reach round the globe, and be inserted close to the optic nerve, as in the common herring and some salmon; and the external rectus might be much

diminished in size, as in most pleuronectids or flat-fish. In those flat-fish, as it were at one bound, and in the life of one fish, a very complex superior oblique capable of producing rotation of the eye was developed, and the degree of this development differed in different species; it was highest in the flounder and least in the halibut.

Those anatomical facts in fishes (Mr. Harman continued) led him to think that there might be similar differences in man, though of lesser degree, and indeed gross cases of muscle defect were known which were hereditary for several generations. A defect bad enough to cause constant squint caused no trouble other than loss of binocular vision and loss of good appearance. A small defect might make life a burden, yet many patients showed defects with no certain symptoms. Diagnosis was full of pitfalls. For himself he was not content unless he got conformable results by three tests—in distance with the Maddox rod, in a near vision test, and, finally, by the actual observation of the resultant alternation of distance fixation when one or other eye was covered and uncovered. The last test he considered absolutely necessary.

In correction by prisms he was an unblushing opportunist. Attempts at precision—so much deviation, therefore so much correction—were, in his experience, generally failures. A little correction, with the promise of more at a later date, and a full explanation to the patient, was better practice than precision. With a gradual adjustment of the correction it was surprising what success could be obtained in the relief of symptoms. Operation was needed in high degrees of defect where prisms did not give sufficient relief or would not be worn. He had had some gratifying successes with his subconjunctival reefing operations, both in his own cases and in cases operated upon at the request of other surgeons. The value of the method lay in the ease of gradation of the adjustment of the tendon and in the comparative absence of risk of making conditions worse than before operation—which was no small matter.

Dr. J. GRAY CLEGG (Manchester) said that in regard to the voluntary control of the extrinsic muscles he would mention the case of a man seen a week ago who could at will bring on a most marked nystagmus of the circumductory type. It was undoubtedly important in every case to estimate the phoria for distance and near. In a series of cases the percentage of heterophoria was about 40, but very few required any treatment. The degree of exophoria varied in the same patient at different distances and was not necessarily increased on convergence; indeed, it might be less. Esophoria was usually of less degree for near, but in some cases it was increased. Insufficient convergence even up to 12 centrad did not necessarily require any treatment. Concave or weaker convex lenses than the refraction required were sometimes useful in stimulating convergence. Undoubtedly prism exercises practised at home by the patient were of distinct service, the discomfort disappearing even though the measurement of the degree of heterophoria remained the same. If overaction of any particular muscle was found, tinctura belladonnae tended to relieve the spasm; on the other hand, tinctura nucis vomicae helped to stimulate muscles which showed atony. In a few cases relief was obtained by the use of drops of 1/2 per cent. solution of homatropin hydrobromide, instilled the last thing at night for some days or weeks. By this method the activities of the patient were not interfered with, as would be the case with atropine.

Dr. HERBERT CAIGER (Sheffield), speaking from personal experience of hyperphoria in his own case, emphasized that hyperphoria certainly was capable of causing mental distress—depression without any apparent cause and a sense of fatigue—in the complete absence of headache. He called attention to "latent hyperphoria"—a term used by the late Dr. Wendell Reber in 1914 at Oxford, and also by Dr. Webster Fox in his opening paper here. Cases occurred in which the Maddox rod test showed little or no error, while fusion tests with prisms showed marked difference in hypervergence in the two eyes. He raised the question of the connexion between hyperphoria and astigmatism: Did astigmatism ever lead to hyperphoria or vice versa? The point deserved investigation.

Mr. J. J. HEALY (Llanelli) emphasized the occurrence of latent exophoria in cases of low myopia of -0.25 sph. to -1.00 sph. These cases came complaining of headache on doing close work, and not for distance. The sufferers were usually young adolescents or adults, school children or clerks.

No exophoria or other phoria could be demonstrated by the usual tests, but correction of their simple spherical myopic error for use when doing close work relieved their symptoms. This was contrary to the usual textbook teaching, therefore he wished to emphasize it.

Dr. G. M. HARSTON (Hong-Kong) said that there seemed to be a general consensus of opinion that muscle tone must necessarily be a predominant factor in muscular imbalance. Situated as he was in his practice, geographically midway between the American and British schools of thought in ophthalmology, he saw the results of both, and he paid the greatest tribute of admiration to the former. He specially wished, however, to emphasize the point that any correction prescribed should be accompanied by the advice that in the case of any patient proceeding to a tropical or subtropical region that patient should place him or herself under the care of a competent ophthalmologist so that any loss of tone following upon malaria or prolonged residence in the tropics might be suitably corrected.

Dr. T. STEWART BARRIE (Glasgow) said that it was most important that the glasses supplied to the patient should be exactly according to the ophthalmic surgeon's prescription, especially when prisms were necessary. This meant that the ophthalmic surgeon should specify the pupillary distance when prescribing prisms, otherwise the lenses supplied in the spectacle frame might have their prismatic effect neutralized, if not actually reversed, by decentration outwards or inwards. He followed the practice of stating essential facts concisely and checking the glasses supplied to the patient. Cases could be cited in which considerable errors were present; this was hardly avoidable at times, for something must always be left to the optician, such as the width of bridge, etc., and he deserved credit for the manner in which he interpreted ophthalmic prescriptions.

Dr. LINDSAY REA (London) said that in every case he put down the result of his tests for distance and for near vision. In 90 per cent. of his cases there was exophoria when tested with the Maddox ring test. In such cases he usually found that the glasses which had been worn for proximal vision had been too weak, so that an effort of accommodation had been produced. This in turn produced the exophoria at the near test. These heterophorias cleared up by the accurate correction of their refractions. The full correction for minute amounts of astigmatism would do more than prisms would do. He had found this by removing prisms which had been prescribed, correcting the refraction most carefully, and in no case had he been disappointed. The surgeon should see the result of his prescribing by examining the spectacles made, if possible on the patient's face.

Dr. JOHN ROWAN (Glasgow) wished to emphasize the importance of the insertion and the size of the muscles; this was found when cases came to operation, for it was never known what a muscle would be until it was seen. He was glad that all were agreed that treatment was only necessary when there were symptoms.

Mr. PERCEVAL, in reply, thanked Mr. Bishop Harman for his very interesting account of the ocular muscles in flatfishes of various kinds. Mr. Harman considered that anatomical peculiarities were the cause of practically all cases of heterophoria. Mr. Perceval had only rarely found anomalous insertions of the ocular muscles, even in the cases of squint on which he had operated. He was quite unable to answer Mr. Caiger's question about the relation between hyperphoria and astigmatism.

Dr. WEBSTER FOX, in reply, said that with regard to the questions, he would answer them in brief by giving his method of treatment of heterophoria patients:

(1) Distant vision was recorded, adduction and abduction of each eye. Muscle imbalance was tested, and if right or left hyperphoria was present this was recorded and corrected by prism or partial tenotomy. Full correction of ametropia was made according to age.

(2) After a few weeks' trial with glasses as prescribed and found unsatisfactory a re-examination was made, and if hyperphoria still existed a partial tenotomy of the offending muscle was made. In this way muscle balance was attained.

A CASE OF OPHTHALMIC MIGRAINE WITH UNUSUAL SYMPTOMS.

BY

A. R. MOODIE, M.D., F.R.C.S. EDIN.,
Dundee.

THE following case of ophthalmic migraine seems worthy of record because of the unusual symptoms.

The patient was seen by me in private on August 16th, 1921. He was a business man, 52 years of age, and complained that during the previous week he had been troubled with frequent attacks of headache and with flashes of light in front of his eyes, which interfered with his sight. In 1915 he had had a serious illness, which, among other symptoms, exhibited hemiparesis, hemianopia, and fits. He was still taking luminal to control the fits. By the courtesy of Dr. J. Mackie Whyte, his family physician, I am able to submit the following notes of the clinical condition during this illness.

On July 15th the patient complained of headache. The eyes were said to be inflamed. Next day, after golf, he was very tired and yawned a great deal. During the night he was delirious. Two days later there was headache and vomiting. The temperature was 100°. On July 5th pain was complained of at the back of the head. There was complete motor paralysis of the right arm and leg, with impaired sensation over the same area. The temperature was normal and the pulse 60. The pupils reacted to light. On the following day paralysis of the lower part of the right side of the face was noticed, and thickening of the arteries was recorded.

On July 12th sensibility had returned. Right hemianopia was discovered, and the patient wandered in his speech a little. Two days later there was another delirious interval. Thereafter the patient mended, for on August 2nd, one month after the onset of the illness, he began to move his fingers, and it was noted that he had been mentally clear for a fortnight. On August 20th there was an epileptic fit. Later he came to know when a fit was imminent, because he felt himself unable to express what he wanted to say and got confused. At this date pus and blood appeared in the urine.

On August 27th the hemianopia was still present. The hearing was poor on both sides. The glycosuria persisted till the middle of the following year, and the hemianopia was absent in December, 1916. In February, 1916, there was a second fit, and others occurred at intervals. The last fit occurred in September, 1920, when he was put on luminal.

In September, 1917, the systolic blood pressure was 150 mm. of mercury. The patient had returned to work, but his memory was still poor for recent events. He informed me that this illness followed on several years of great worry in business.

When seen in August, 1921, he said he had again been subject to worry, and gave a description of his symptoms. He had gone to St. Andrews on holiday, and had again been playing much golf. After a game on August 8th he noticed a coloured light in front of the eyes. It began as a spot of light a little to his right side. The circle enlarged and "took on all the colours of the rainbow." No headache followed the first attack. The flashes of light recurred at frequent intervals—"every five or ten minutes"—and these recurrences were followed by headache. They left him "not seeing properly." The headache began over the left eye, and involved the left side of the head. Thinking the trouble would soon pass off, he continued to play golf, and he found that the balls "tended to go to the right." He was unable to judge distances on his right side. "People seemed to be sometimes nearer, and sometimes farther away."

There was no family history bearing on the condition. He seemed to be of a highly strung disposition. The expression was anxious, and he apparently dreaded a return of his 1915 illness. On examination there was some photophobia. Vision in both eyes was 6/6 partly. There was one diopter of hypermetropia. The conjunctivae were not injected. The pupils were small and equal; they reacted to light. Nothing abnormal was seen in the media or fundi. There was no ophthalmoplegia.

The fields were taken with a McHardy's perimeter with a 5 mm. white object, and showed a partial right hemianopia. The scotoma was complete in the right lower quadrant, and involved the peripheral to the 40 circle. It appeared the fixation point. The outline of the field was slightly irregular and convex in general contour. Pilocarpine drops were prescribed, and also aspirin internally.

There was another attack that day, and one on the following day of a slighter nature. Since then the attacks have ceased. About two months later, perimetry showed that the fields were normal. The Wassermann test with blood serum was reported by Professor Talloch as definitely negative.

This description is unfortunately not so complete as one would have wished. The tension was not measured. The fields for colours were not taken. A more exact picture might have been obtained by the use of a Bjerrum screen, and it would have been interesting to have observed the date when the scotoma disappeared. These things were precluded by the condition of the patient and the circumstances.

The case is apparently one of the ophthalmic type of migraine, with scintillating scotoma. The association with

epileptic fits is uncommon. Dr. Mackie Whyte and Professor Ashley MacIntosh, who saw the case in May, 1916, were of opinion that the illness at that time was most probably due to a thrombotic lesion affecting the left cortex. If this were the case, it does not seem unreasonable to assume that some permanent damage of the cortex took place, which provided the focus of irritation for the epileptic fits. The recent migrainous attack would seem to have been due also to vascular disturbance in the left cortex, but of milder degree and more limited distribution. It would therefore seem that the association with the migrainous of epileptic fits in this case is based on a pathological relationship.

The conclusions reached by Gordon Holmes and Sir William Lister,¹ as the result of their investigations in cases of war injuries involving the occipital lobes, indicate that the visual cortex can be mapped out according to the retinal areas with which it is connected. The hemianopia here would be traceable to temporary interruption of the branches of the left posterior cerebral artery which supply the upper lip of the calcarine fissure and the anterior part of the lower lip.

Regarding the etiology, there is a distinct record of worry having preceded each attack. The arteries were thickened, but the blood pressure was not raised, and the Wassermann reaction was negative.

EDUCATION OF PARTIALLY BLIND CHILDREN IN MYOPE CLASSES.

H. WRIGHT THOMSON, D.S.O., M.D.,

Surgeon, Glasgow Ophthalmic Institution.

It has been suggested to me that it might be of interest to this Section to hear something of the myope classes in the schools in Glasgow. I do not propose to submit to you any details of an administrative nature, nor do I wish to discuss the question of the degree or kind of myopia which warrants admission to such special classes, but I should like to say something concerning children who are visually defective from causes other than myopia and who are being educated in myope classes.

Prior to the establishment of such classes children of low visual acuteness had either to attend ordinary classes, severely handicapped and learning next to nothing, or be relegated to the Braille class among the blind; but with the advent of the myope class, which, I think, would be much better named the sight-saving class, we have been provided with a form of schooling which we as ophthalmologists can recommend in many such cases.

The essence of the myope class is that all print to be read, writing to be done, and illustrations to be seen are on such a large scale as to require only a low visual acuteness, and to obviate the necessity for a high degree of convergence. Under such conditions it is easy for the child with, say, visual acuteness 6/60 and J. 10 or 12 to take a good place in the class and yet be doing nothing to the detriment of his eyes. Further, he is free of the stigma of having been at a blind school, and he enjoys the educative advantage of being constantly associated in play hours and in certain class work with normal children. It is true that his future sphere of usefulness in the industrial world is somewhat limited, but experience has taught that, given a moderate amount of will power and intelligence, the prospect of earning a living for a person with very defective sight is much greater if he has cultivated the methods of the seeing than if he is dependent on, and limited by, the acquired attributes of the blind.

In 1907 I published a paper on "The eyesight of the poorer city children,"¹ in which I was able to demonstrate the visual superiority for distant objects of country children over city children, and how the inferiority of the city children was greater in the central closely built regions than in the outskirts. Errors of refraction and disease or abnormality were, of course, excluded, and the explanation seemed to be found in the greater or less development of the power of interpretation by the higher brain centres of the images formed on the retina. Such a power is greater the more spacious the child's

It is this same power of interpreting what his eyes see

that is of so much importance to the partially blind child. The degree to which he possesses it is a weighty factor in the decision as to whether he shall be educated in a myope or a Braille class. In illustration let me quote a case.

A boy, aged 7, had had ophthalmia neonatorum. There was a leucoma adhaerens, right, with a cataractous lens. The left eye had corneal nebulae, anterior polar cataract, and 4 D. of irregular myopia. Vision < 6/50 and J. 8. He was sent for trial to a myope class on January 25th, 1920, and on June 8th, 1920, the headmaster of the school reported: "His progress has been most satisfactory. His writing is as good as that of the average infant, and in reading he has gone over the *First Infant Reader*. So far as can be seen he seems to have no difficulty whatever in doing any work required of him in the myope class; indeed, he seems to do it with the greatest ease and without straining his eyes."

That boy would be practically unteachable as one of an ordinary large class, and I think it may be claimed that his progress in the myope class fully justifies the continuance of his education as a seeing child.

When examining a child for the purpose of advising as to how he can best be educated it is not enough, especially in young children, to register the vision in the usual way by the reading of letters or the recognition of objects. One must also make an estimate of his intelligence, both from personal observation and from the accounts of his parents or guardians. Then, of course, the prognosis as regards the condition of the eyes is of very great importance. It is manifestly necessary to feel assured that the vision is not likely to become worse in the future. Also, one must bear in mind the time of onset of the visual difficulty. If it was congenital or nearly so the faculty of cerebral vision must, from the lack of the normal amount of exercise, be below the average standard. I am quite satisfied that this faculty is capable of great improvement under the encouraging stimulus of constant practice in looking at enlarged objects, and this improvement, moreover, not infrequently expresses itself in an increase in visual acuteness, as tested by Snellen's types.

Coming now to the cases on the experience of which these remarks are based, they may be conveniently arranged in two groups. Group I includes (a) the cases in which the cause of the visual defect was congenital, and (b) those in which it was the result of ophthalmia neonatorum. Group II is made up of those whose defect is due to disease acquired some time after birth.

There are 13 cases which I have not included in the list because their presence in the myope classes is due partly to myopia and partly to conditions "other than myopia." Four of them are myopic albinos, and nine are myopes with extensive corneal opacities, which have resulted from strumous ophthalmia. These latter are liable to recurrences of their corneal ulceration, and consequent further deterioration of vision, if they are sent to an ordinary sighted school. Their circumstances are such that they cannot be sent to live in the country, and I find that they do well under the curriculum of the myope class, which includes supervision by the teachers of the hygiene not only of the eyes but also of the body generally.

GROUP I.—Congenital Defects, including the Effects of Ophthalmia Neonatorum.

This group comprises 48 cases, and it is, perhaps, to them specially that my introductory remarks may be applied. In many cases their age or lack of training precluded any exact register of their visual acuteness, and one's judgement was influenced by considerations along the lines which I have indicated. They may be tabulated thus:

Congenital cataract ...	15
Nystagmus, apart from albinism, and with no history of ophthalmia neonatorum ...	9
Albinism, with hypermetropia ...	2
Coloboma of iris and choroid ...	5
Ectopia lentis ...	2
Aniridia ...	3
Microphthalmos ...	1
High hypermetropia (vision 6/36 and J. 10) ...	1
Ophthalmia neonatorum (after-effects of) ...	10

The cases of congenital cataract include some whose surgical treatment is not yet complete in both eyes and who are likely to finish their education in ordinary classes. Most of the others have good surgical results (aphakia or optical coloboma iridis) but low visual acuteness. The ophthalmia neonatorum cases have all got corneal opacities and most of them have nystagmus and anterior polar cataract.

GROUP II.—*Acquired Defects.*

This group comprises 18 cases, as follows:

Cberoiditis and choroido-iritis	5
Sympathetic ophthalmia	1
Corneal opacities from interstitial keratitis	8
Partial optic atrophy	1
Choroido-retinitis	2
Disseminated choroiditis	1

The interstitial keratitis cases are all of long standing, and in some instances are still receiving treatment in the hope of further clearing of the cornea. All the other cases have been judged to be beyond the stage of active disease and not likely to suffer further depreciation of vision.

These two lists show the cases which are at present in actual attendance in myopia classes and they are of all school ages. They are examined at regular intervals, and, according as improvement justifies or necessity demands, they may be transferred to ordinary or Braille classes. In doubtful cases the teacher's report is of great value. For the reasons which I have already referred to it is not advisable to lay down a definite standard of visual acuteness, but almost none of the cases at present under review has less than 6/60, and all can read smaller print than J. 14.

This work may be said to be still in the experimental stage, but it has already two very encouraging features. The one is its ready approval by the parents of partially blind children, in contrast to their horror of any suggestion of a "blind school." The other is the enthusiasm of the teachers for its educational results.

DISCUSSION.

Mr. BISHOP HARMAN (London) said that he was greatly interested in the experiences of Glasgow in the working of these myopia classes for children with defective vision. In London they had now 36 classes, accommodating over 600 children. They were an undoubted success, both at home and abroad. These classes saved many children from attending blind schools on the one hand, and from attending an ordinary day school with much suffering and ineffective attempts at education on the other. He thought that Dr. Thomson put an undue strain on the teachers by admitting children with so low a standard of vision as 6/60, unless he anticipated early improvement of vision. Everything in these classes depended on the enthusiasm of the teaching staff, so that care should be taken to make conditions reasonable for them. In rural districts myopia classes were impossible since there were not sufficient children to fill a class. Nevertheless it was quite possible to arrange for the few individual children who had defective vision to carry on the ordinary class work in the small country schools, doing such writing as was necessary upon the blackboard, and reading from large charts instead of from books. This had been done successfully in some of the larger public schools, for it was found that class arrangements could be made sufficiently elastic to meet the needs of children whose defect was not great. He had only had one refusal to make such arrangements from a public school headmaster.

Dr. JOHN ROWAN (Glasgow) congratulated the Glasgow School Board on having an enthusiast at the head of their eye department. They appreciated the work and enthusiasm of the teachers, without which the work would not progress, but the encouragement they got from the ophthalmic surgeon was a great stimulus. The work was being done in a quiet and unobtrusive way, and he was pleased to hear a paper giving information about what was being done, especially to prevent children having the stigma of having been in a blind school.

THE RELATION OF THE OPTIC NERVE TO THE SPHENOIDAL AND POSTERIOR ETHMOIDAL SINUSES.

BY

GAVIN YOUNG, M.C., M.B., Ch.B., F.R.F.P.S.,
Glasgow.

This investigation was undertaken in order to demonstrate the varying relations of the optic nerve to the sphenoidal and posterior ethmoidal cells, in view of cases of optic neuritis which had been referred to me by members of the staff of the Glasgow Eye Infirmary for nasal examination.

I have examined by dissection the sphenoidal sinuses in thirty subjects in the post-mortem room of the Western Infirmary, thanks to the kindness of Professor Muir. The specimens were obtained, after removal of the skull-cap and brain, by dissection out a block of tissue from the anterior boundary of the foramen magnum to the crista galli of the ethmoid. The cases were not specially chosen, the material being provided by whatever bodies happened to be subjected to post-mortem examination. The cause of death and the age of the patient are not important for the purpose of this paper, although it is worthy of note that the only two patients under adult age—boys of 12 and 16 respectively—showed sinuses far from full development, those in the former subject being indeed mere pits in the body of the sphenoid. I might also record here the fact that 56 per cent. of the subjects showed pus in one or both of their sphenoidal sinuses. Whether this is to be taken that 56 per cent. of the population of the West of Scotland suffer from sphenoidal disease is a controversial point unnecessary to be raised at this time.

The normal relation of the posterior ethmoidal cell to the sphenoidal sinus is that the posterior wall of the ethmoid cell lies on the antero-lateral aspect of the sphenoidal sinus. The relation, however, varies in accordance with the amount of bone absorption that has taken place to form the cells. In the sclerotic type the posterior ethmoid cell lies quite laterally to the sphenoidal sinus. As the walls of both cells become absorbed and the cells enlarge, the sphenoidal sinus becomes larger at the expense of the lateral wall, while the ethmoid creeps inwards towards the middle line. Varieties of this rule are found, however, in a considerable number of cases, but these abnormalities are not important to this paper.

It is necessary to remind you of these facts, on account of the relation of the canal containing the optic nerve to the sinuses. This structure is in close relation to the posterolateral angle of the post-nasal sinuses, near the roof, at the posterior end of the orbit. It will be noted, then, that in the sclerotic type the nerve is related, not to the sphenoidal sinus at all, but to the posterior ethmoid cell, which lies laterally to the sphenoidal cell. This relation is changed by degrees through the various types, according to the amount of absorption which has taken place, until in the thin-walled sinuses the canal of the nerve is in relation to the sphenoidal sinus posteriorly to the ethmoidal cell.

It is a commonplace that the optic nerve is in close relation to the sphenoidal sinus. How close this relation is may not be appreciated by all. As a practical demonstration of the relation I have passed a horsehair suture round the sinuses, following the course of the canal back to the position of the clinoid. In 27 cases (90 per cent. of the specimens) the bone between the nerve and the sinus is so thin, in at least part of its course, that the suture is easily apparent through it. The wall is practically transparent. In four specimens (13 per cent.) there is actually a hiatus in the bone covering the nerve, while in one of these specimens it is no exaggeration to say that there is more hiatus than bone in the posterolateral and lateral walls of the sinus, so much absorption had taken place. With regard to the relative size of the sphenoidal sinuses, the intersinus septum was markedly deflected in many cases, making one sinus much larger than the other. This difference in size was sometimes so great that the larger sinus was found to be in relation to the heterolateral optic nerve or cavernous sinus, or both. The actual figures were that in 13 cases (46 per cent.) the sphenoidal sinus of one side was in relation to the heterolateral cavernous sinus, and in 9 cases (30 per cent.) the sphenoidal sinus was in relation to the heterolateral optic nerve. The sclerotic type of sinus was in a very small minority, 10 per cent. of cases being in this category, the walls of the remaining 27 being very thin. Ostia in the bone were very commonly found in the lateral wall of the sphenoidal and ethmoidal masses, the boundary between the nose and the orbit. These led into the sinuses, giving passage to numerous blood vessels. They varied greatly in size and position, although one fairly sized one was constantly found in the neighbourhood of the sphenoidal partition. Numerous blood vessels were noted occupying these ostia as the lining membrane was stripped from the nasal wall of the orbit.

These facts may be applied to support the clinical evidence that optic neuritis may arise from diseased post-nasal sinuses. It is quite apparent how this spread of infection takes place. A virulent infection might easily spread through bone of the thinness of the majority of these specimens. If this be dispensed it will be remembered that there are actually

hiatuses in the bony walls in a percentage of these specimens, and in addition to this the numerous blood vessels connecting the orbit with the sinuses must constitute a considerable danger.

OPHTHALMIC PROGRESS IN EGYPT.

BY

A. F. MACCALLAN, C.B.E., F.R.C.S.,

Director of the Egyptian Government Ophthalmic Hospitals.

THE last occasion on which I had the honour of addressing the Ophthalmic Section of the British Medical Association on ophthalmic progress in Egypt was at the Aberdeen meeting. By that year, 1914, I had been engaged for ten years in the post-graduate teaching of ophthalmology and in ophthalmic organization, so that when war broke out the routine work of the hospitals was maintained in spite of reduction of British personnel. Among the more important war work carried out by the ophthalmic staff may be mentioned the organization of two clearing hospitals for Turkish wounded during the attack on the Suez Canal in January, 1915, a hospital for 150 Senegalese troops at Zagazig, and a 650-bed general hospital under canvas at Alexandria in May, 1915 (which was removed to Giza in 1916). This latter hospital was referred to officially by the Director of Medical Service, Egypt Command, as "the model of what a war hospital under canvas should be."

One of the results of the war has been to take away from my staff all British Their work was invaluable during the but their places have now been taken by Medical officers who have studied under me for many years, and who carry out their duties with keenness and intelligence.

The Egyptian system has some claim to distinction in the fact that twenty special ophthalmic hospitals are grouped together under one direction. This not only enables a large amount of clinical work to be done, but also facilitates the systematic trial of various methods of operation and of treatment. The system was inaugurated in 1903, when the late Sir Ernest Cassel created a trust fund of £41,000 for the purpose of teaching ophthalmology to qualified Egyptian medical men. In that year I was one of the senior clinical assistants at the Royal London Ophthalmic Hospital, having previously been house-surgeon there for three years, and I had the good fortune to be invited to organize and direct the movement. We started with one travelling hospital in tents and one Egyptian medical officer, at a place a hundred miles from any sort of civilization. A few years later on my recommendation the Egyptian Government took over the organization, and undertook to maintain permanent hospitals in each of the fourteen provinces, if we were able to raise a sufficient sum to build and equip each hospital from local sources. We have succeeded in raising a sum of about £100,000 since then, and have built or are building a permanent hospital for each province. There is one exception and that is in the province of Assuan, where one of the original travelling hospitals has been allocated to the long and narrow stretch of country which intervenes between Assuan town in the south and Luxor in the north. Besides the permanent hospitals in the capital of each province several of the provincial or county councils are maintaining hospitals under my direction.

A small central laboratory for clinical investigations in temporary premises in the vicinity of Cairo is about to be replaced by an adequate building adjacent to the new hospital at Giza. This, being within a quarter of an hour's drive of the centre of Cairo, will be very convenient both for teaching and research. The money for this has been given by the Imperial War Graves Commission. Besides the actual hospital work I have instituted a carefully organized ophthalmic inspection and treatment in the Government primary schools, which has been in force since 1903 by means of the ophthalmic staff.

I submit, gentlemen, that I have said enough to show that in Egypt we have succeeded in organizing a useful system of special hospitals and a very live school of ophthalmology.

DISCUSSION.

Dr. M. A. EL KATTAN (Cairo) said: As an Egyptian I have to thank Dr. MacCallan for the good work he is doing for the Egyptian people. In regard to research work on trachoma, I have to say a few words. We know now that the organisms causing acute conjunctivitis disappear mostly on the fourth or fifth day from the beginning of the attack. We can deduce

from this that any research work for the investigation of the trachoma virus in an established late case of trachoma is likely to turn out fruitless. To get hold of an early case it is well to investigate animals inoculated with trachoma. It is fortunate, from the point of view of the research worker, that whereas organisms causing acute conjunctivitis fail to cause an infection in animals, trachoma does occur in the monkey and the rabbit. I think, therefore, that the research workers of the Institut Pasteur of Tunis, who are following up this line, are on the right track.

The PRESIDENT said that he thought that Mr. MacCallan's statement of the progress of ophthalmic work in Egypt was most satisfactory, and reflected great credit on the responsible authorities.

THE CEREBRO-SPINAL FLUID IN DISEASE OF THE FUNDUS.

BY

W. J. WELLWOOD FERGUSON, M.B., CH.B.,

Clinical Assistant, Glasgow Eye Infirmary.

IN the series of cases about to be detailed the cerebro-spinal fluid was examined by the following methods: (1) The Wassermann reaction of the blood and cerebro-spinal fluid was determined in all cases; these were carried out in Professor C. H. Brownie's laboratory in Glasgow University by his assistant, Dr. E. M. Duulop. (2) Test for protein content by the Ross-Jones method. (3) Lange's colloidal gold reaction. Without going into details of technique, this test depends on the fact that the normal cerebro-spinal fluid when diluted with 0.04 per cent. solution of sodium chloride has no effect on the solution of colloidal gold while in certain diseases of the central nervous system characteristic changes are often produced. There are three groups of reactions—paretic, luetic, and meningitic. It has been found that in neuro-syphilis a luetic or paretic reaction is obtained, the Wassermann reaction being positive. In disseminated sclerosis the Lange reaction gives a paretic or luetic curve and the Wassermann reaction is negative. In functional nervous disease, as far as the present state of knowledge goes, it is invariably negative. The technique adopted was that of Cruickshank.¹ (4) In a certain number of cases a cell count was carried out, using a Fuchs-Rosenthal chamber.

The work which has recently been done on the colloidal gold reaction in the cerebro-spinal fluid suggested that there might be a useful field for this investigation in the cases seen at an eye hospital. In particular the work of Adams² on this reaction in disseminated sclerosis suggested that a number of cases of this disease are first seen at an ophthalmic clinic and may be unrecognized in their early stages. Accordingly, in conjunction with Drs. Marshall and White, a number of suitable cases were investigated.

In all the cases examined the condition of the nervous system was thoroughly gone into, the following points being specially noted: pupillary reactions to light and accommodation; nystagmus; abdominal and epigastric reflexes; knee-jerks; plantar reflexes; patellar and ankle clonus. The results fall into three distinct groups:

Group I.

Cases with a positive Wassermann reaction in the cerebro-spinal fluid, together with a paretic or luetic reaction to colloidal gold: 6 cases. Of these, 4 were cases of bilateral optic atrophy associated with definite signs which made the diagnosis of tabes obvious. One was a case of neuro-retinitis of the left eye associated with slight ankle clonus on the left side, increased knee-jerks and absent reflexes. The sixth was a case of p

nerve, with the exception of the pupillary fibres. This case is of interest in that there was a history of specific disease twenty years ago, treated by mercury and iodides. His blood was examined on two occasions during the war, and the Wassermann reaction found to be negative; it was still negative when seen. His cerebro-spinal fluid, however, was strongly positive to the Wassermann and colloidal gold reactions. Under treatment by salvarsan his condition has cleared up, but the Wassermann reaction of the cerebro-spinal fluid remains positive.

Group 2.

In this group the Wassermann reaction of the cerebro-spinal fluid is negative, while the Lange reaction gives a paretic or

lucio curve. Of these cases several are of interest, and may be detailed:

Case 1.—M. W., aged 25. Optic atrophy right and left. Visual acuity: right, counts fingers at three feet; left, 6/18. The nervous system appeared quite normal. Colloidal gold reaction lucio; Wassermann reaction of blood and cerebro-spinal fluid negative; Ross-Jones test negative. Cell count 3. This case gives the identical picture in the cerebro-spinal fluid as that seen in disseminated sclerosis, but all signs of this disease, except optic atrophy, are absent.

Case 2.—S. B., aged 30. Optic atrophy right and left, associated with the loss of the light reflex and absence of the knee-jerks. Visual acuity: right, 6/18; left, 6/36. There was a history of specific disease two years previously. The Wassermann reaction in both blood and cerebro-spinal fluid was, however, negative, while the colloidal gold test gave a lucio reaction.

Case 3.—A. N., aged 22. Complained of diplopia, with staggering gait, of nine months' duration. There were slight lateral nystagmic movements in the right eye, with paresis of the left internal rectus. Nervous system otherwise normal. Fundi normal. Wassermann reaction, blood and cerebro-spinal fluid, negative. The colloidal gold reaction gave a lucio curve.

Case 4.—G. O'N., aged 30. Had complained of diplopia for a year, the left superior oblique being at fault. Nervous system otherwise normal. Fundi normal. Wassermann reaction, blood and cerebro-spinal fluid, negative. Colloidal gold gave a lucio curve.

Case 5.—J. Y., aged 31. When seen had diplopia of a week's duration. Seven or eight years ago had a similar attack which passed off in three months. This was followed six months later by another attack which passed off in a few weeks. At that time she had no other complaint. A year ago, she states, she had optic neuritis and paralysis of the left side of the face. Nine months ago she had neuritis of the left arm. The fundi showed optic atrophy right and left, and there was nystagmus. The nervous system was otherwise normal. The Wassermann reaction in both blood and cerebro-spinal fluid was negative, while the colloidal gold test gave a lucio curve. The Ross-Jones test was negative.

The remaining cases of this group showed nystagmus with exaggerated knee-jerks and unsteadiness of gait. They all had similar reactions in the blood and cerebro-spinal fluid.

Group 3.

In this group the Wassermann reaction of the blood and cerebro-spinal fluid was negative, the colloidal gold test being also negative. This group included one case of primary optic atrophy with no signs of general nervous disease, one case of retinitis pigmentosa with advanced optic atrophy, and several cases of choroiditis and iridocyclitis.

From the results of this work it would seem that the condition of the cerebro-spinal fluid would be worthy of investigation in a large group of cases, in particular those of young adults suffering from diplopia, optic atrophy, or retrobulbar neuritis. The colloidal gold reaction is, I think, considered of undoubted value as indicating the first definite sign of organic disease of the central nervous system,¹ and as some cases of the types mentioned are known to develop later into frank disseminated sclerosis or neuro-syphilis its value in early diagnosis, especially with a view to prognosis and treatment, is considerable. Additionally it may enable one to say whether a transient diplopia is or is not purely functional, and may help to differentiate cases of retrobulbar neuritis and optic atrophy, indicating those in which the condition is part of a more general nervous disorder, and more especially those which may be followed after a considerable period by disseminated sclerosis.

MONOCULAR AND BINOCULAR VISION.

BY

T. STEWART BARRIE, M.B., F.R.F.P.S.G.,

Assistant Surgeon, Ophthalmic Institution, Glasgow.

THE subject of monocular and binocular vision is one which has engaged the attention of scientists and philosophers from the earliest times, and many of its problems are still unsolved. The empirical theory of Berkeley and the nativistic theory with its conception of the specific energy of the nerve cell have had their day, and the discussions thereupon have contributed much to our knowledge of the nature of vision. With the passage of the years a new orientation has been given by psychologists to our conceptions of the nature of vision, and their views are gaining ground. "Vision is a

sensation and one of the elements of sensory experience." The one-eyed man looks out upon a landscape and sees fields, trees, hills, and valleys with streams of running water; he can localize the position of the trees, the depth of the valley, and the glint of the running water, while he can differentiate the various greens of trees and herbs and the colour and hues of natural objects. At least six attributes of visual sensation can be separated from this observation: the colours and hues of green illustrate the attributes of quality and intensity, the gleams of running water illustrate time and duration, while the fields and the trees exemplify extensivity and position. These six attributes of visual sensation are not in the objects themselves, for the observer can shut his eyes and mentally picture the view that lies before him; in fact, he projects it outwards, and the physical reality is of less importance than the psychological impression. The man who is suddenly rendered blind suffers great mental distress until he realizes that sight is only one of the gateways of experience—that touch, passive and active, joint sensations, hearing, and even smelling, all contribute their quota to our knowledge of our surroundings. The splendid work of the late Sir Arthur Pearson was based on this conception. "We who cannot see in the ordinarily accepted meaning of the word still see in our own fashion, with those portions of our brains which respond to impulses given by other senses." "To visualize a room in which you are sitting or a scene through which you are passing is to increase your enjoyment, and often to make more easy your movements."

A great deal of confusion has arisen in the minds of medical men and others by a sort of tacit understanding that vision is comparable to a photograph. I agree that the image formed of an object on the retina of the eye is practically identical with the image formed on the focusing screen of a camera, but the formation of an image is merely the first step towards the recognition of an object and the realization of what it actually is. From the image on the retina we deduce the three dimensions—width, height, and depth. The first two can be represented graphically in a vertical plane, but the third requires the horizontal plane for its demonstration. The perspective of the image gives an indication of depth, but in the living eye, as it is never at rest, many images are formed per second and therefore vision is largely cinematographic. When one looks with one eye closed at the photograph of a landscape, the three dimensions are easily recognized and the scene stands out in moderate relief, an effect which is intensified by the use of a lens; on looking at a film of the same landscape taken by a cinematographic machine carried directly forwards, depth becomes exceedingly well marked. The cinematographic camera represents one eye. One can hazard the opinion that in the human subject a similar result follows the continuous movements of the eyes and the forward movement of the body. Of course this is merely a form of parallax, with a difference that the sensation, rather than the knowledge, of space is emphasized, Gniloz alternately stimulated each eye by the alternating halves of stereoscopic pictures and produced vision in solidity, though the interval extended to one second and successive fusion took place. It is difficult to realize that there can be appreciation of depth without the extraneous aids of perspective, "atmosphere," light and shade, etc., but in a perfectly dark room two faintly red luminous points can be localized at different distances monocularly and binocularly if they are deliberately moved by another experimenter.

Memory plays a very important part in vision, and we endeavour to bring our present visual experiences into relation with those which have gone before. In most cases this is of immense advantage, but occasionally, as will be shown later, it allows us to see things which have no existence. The fact that vision is psychological and that we mentally project outwards what we see explains certain abnormalities of vision—for example, a person whom you see crossing a room does not become appreciably smaller as he goes from you, but retains his apparent size, though according to the laws of perspective he should rapidly diminish in size. In the same way accurate localization of an object is obtained monocularly (by those who have at an early period in life lost the sight of one eye), partly as an innate property of visual sensation and partly through the cinematographic effect already referred to.

Binocular vision, or vision with two eyes, has certain peculiarities. Under ordinary circumstances there is no diplopia, but once the attention has been drawn to the fact that it can be elicited easily diplopia is found to be the rule

and not the exception; in fact, the only object seen singly is the object directly under observation, all others being double. This is the well-known physiological diplopia, and it can be shown to be present wherever the fields of vision of the eyes overlap. A suggestion has been made and commonly accepted that the non-occurrence of diplopia under ordinary circumstances is due to "suppression of one of the images," but the case with which diplopia can be elicited would point to another explanation.

Using the dot test (a card with two groups of two dots upon it in a horizontal line, the groups being 56 mm. apart and the members of each group being 3 and 3.5 mm. apart respectively), and examining it by means of a stereoscope, we observe the following: (1) that the two groups are brought near to each other with partial overlapping; (2) when binocular vision is present there is fusion of the four dots to form two, one considerably behind the other. This simple experiment does not show the development of a new faculty, for the arrangement of dots is really a projection on a vertical plane of two dot-like objects at different distances from the place of observation and as seen by each eye separately. When the dots have been brought by the stereoscope into the correct position to allow of projection forward, each eye separately and together, the immediate impression is of two dots only. This is not a physical fusion of the dots, but a psychological fusion; in brief, a new interpretation has been given to the picture received by each eye. In fact, it can be regarded as simultaneous parallax as distinguished from consecutive parallax. If one of the sets of dots be coloured

red, fusion results as before, but is associated with a flicker, the psychological dots appearing alternately red and black, as if there were a strife between the visual impressions received from each eye for predominance.

The accompanying diagram shows what is meant by projection in a vertical plane. Let A and a be two pin-heads projecting slightly from the plane of the paper and let o and o be the nodal points of the corresponding eyes; the lines A, a, n, n, and A, a, c, c, represent rays of light passing from A and a to the nodal points n and o respectively. Let EF be a vertical plane (a card); then where the four rays cut this plane

(or card) we have four points G, H, L, and M, which are the projection on a plane surface of the two pin-heads A and a.

In the experiment of the four dots we have a card with two sets of dots, the positions of which correspond to G, H, and L, M, and the two sets are separated by a space equal to the interpupillary distance. In the simplest form of stereoscope we suspend accommodation and bring convergence into play, and thus obtain the so-called stereoscopic effect or fusion of the dots with the production of the sensation of distance or nearness.

Based on this principle of projection on a vertical plane innumerable stereoscopic pictures can be made, of which the following are examples.

1. The four lines:

2. The crossed lines:

3. The oblique line and circle:

4. The double circle:

These figures are all simple and give good stereoscopic results. They show flickering when variously coloured pigments are used. If complicated figures not true to the conditions indicated are used there is no fusion (or at most it is partial and gives unexpected results), overlapping can and

does take place, but there is no permanent equilibrium and the figures appear to swing to and fro.

The alternation of impressions from each eye suggests that binocular vision is essentially alternating in character, and pushing the argument still farther we come to the conclusion that physiological diplopia is due to the effort to make simultaneous an action actually consecutive and therefore the exception rather than the rule. Other evidence of this alternative character is seen when we look at a bright scene through spectacles glazed with lenses made of red glass for one eye and blue glass for the other. There is no permanent fusion of the colours, but objects are seen alternately red and blue, often described as due to "strife of the fields." Sherrington's binocular flicker experiments lead to the same conclusion. Alternation is most marked in macular vision and gives rise to the condition known as psychical suppression of part of the retina of one eye.

In one of the series of cards published by Messrs. Dixey and Son, London, for use in the stereoscope, the subject is a dog jumping through a hoop. As a test it is merely one for orthophoria or its production, but one can obtain a modified stereoscopic effect with it. The point of interest is that when the dog is passing through the hoop you either see the whole of the dog with part or the whole of the hoop missing, or, vice versa, the whole of the hoop with part or whole of the dog missing.

The experiment of the transparent finger is another example of the same nature. The finger is held at a short distance in front of the face and if you look at any object with the finger in a certain position you will see the object apparently through the finger. Though the position of objects appears the same in space, relative to the position of your own body they have moved, as you can easily determine if you rearranged matters so that the object seen is a sharp point or you try to touch it. The vision for the time is monocular and localization is as if one eye were closed. Recovery of correct orientation occurs simultaneously with the removal of the finger. From these two series of observations one deduces that from each eye there is developed a definite sensual image. These normally appear as one, but the true character of the sensation is appreciated when these cannot be combined into a single image, for there is alternation of the two images or actual suppression of one over the area where confusion would normally result. This is one of the advantages of binocular vision; one eye may be more or less obstructed in its vision by obstacles of various kinds—trees, pillars, etc.—yet unless our attention is directed to these they pass unnoticed.

In binocular vision the mental impressions or projections derived from the two eyes are similar, and the two alternate with such rapidity that they appear as one. When, on the other hand, the impressions received are on the whole incapable of being understood and projected, it sometimes happens that a portion can be considered as a consistent figure. This can be seen by taking a number of stereoscopic slides and remounting them after separating the two halves, turning them upside down, and lastly reversing them. Some of the pictures treated in this way will appear as inverted views when seen by the stereoscope, with the sense of solidity and distance absent, but others will show an extraordinary appearance, for a portion will stand out in relief while the remainder of the two pictures not necessary for this effect will form a screen at some distance in front.

In conclusion, vision is a sensation; in monocular vision the appreciation of depth is inherent in the sensation of vision and is accentuated by the consecutive stimuli resulting from the formation of retinal images; binocular vision is essentially monocular vision, but simultaneous stimuli from the formation of two retinal images is the rule—though apparently a single sensation, it is in reality alternating monocular vision. The practical importance of this conception of vision is that in ordinary circumstances the man amblyopic in one eye from infancy is at no disadvantage compared with the person with two normal eyes.

DISCUSSION.

Mr. BISHOP HARMAN (London) said that the subject and the paper were of the greatest interest both academically and practically. He was prepared to maintain the superiority of binocular over monocular vision, and he thought that any doubt on the point could only arise where binocular vision was imperfect or absent. Parallax was insufficient to give that sense of position, distance, and solidity which was so wonderfully realized in perfect binocular vision, and he did

not think that anyone could convey what this possession meant to a luckless possessor of mere monocular vision. The phenomenon of "the struggle of the retina" was not evidence of alternate monocular vision, it was really cerebral. The brain was accustomed to register more or less coincident images, and if diverse images were presented through each eye the brain did not know which to register. If to one eye were presented a St. Andrew's Cross and to the other a St. George's Cross, constant fusion could not be obtained, only alternation of images; if one cross were slowly rotated, at a point where both nearly coincided fusion was obtained with a wonderful sense of solidity. Industrially, binocular vision was of the utmost importance, and it should not go out from this Section that monocular vision was as good or nearly as good. From his experience in observing the efforts of students in removing foreign bodies from the cornea, he would say that no monocular person could become a first-rate ophthalmic surgeon, though he might be a good ophthalmic physician.

Dr. PERCIVAL HAY (Sheffield) mentioned, as illustrating the superiority of binocular vision over the unocular form, that on one occasion a friend and himself were looking over some old mounted stereoscopic landscape photographs, and could not recognize one of them, but on placing it in the stereoscope they recognized it at once.

Mr. JOHN ROWAN (Glasgow) said that he quite agreed with Mr. Bishop Harman that binocular vision was of the greatest importance, and that the individual who had only monocular vision was very seriously handicapped. This applied very specially to ophthalmic surgeons. For example, they all knew that a man who had lost one eye could not at first drive a car, although he might gradually acquire the power, no doubt running risks while doing so, but a person who had never had binocular vision could drive quite well. He had a patient with 6/6 and J.1 in each eye, but unfortunately a squint which his parents would not have operated on; in later life the patient wanted the squint removed, and he operated with a most satisfactory result as far as appearance was concerned, but of course with no binocular vision. As this patient took an interest in a number of scientific subjects, and was very keen about photography, he quite realized what binocular vision meant. He tried to get it in different ways, but of course was never able to develop it. He quite realized the handicap he was labouring under.

Dr. STEWART BARNIE, in reply, said that there had been perhaps some misunderstanding of the nature and scope of his contribution. Binocular vision meant nothing more than vision with two eyes. Stereoscopic vision was a totally different thing, and was possessed by people with one eye only as well as by those who had two. Each half of a stereoscopic picture was a projection on a plane surface of something beyond in exactly the same way as each half of the "four dot" card. No wonder, therefore, that the person with one seeing eye failed to receive the same impression as the normal individual from these pictures. They were, in brief, tests for a variety of stereoscopic vision—namely, binocular—and nothing more. On innumerable occasions he had tested one-eyed men as to their appreciation of depth, both at great distances and at a distance of one metre, the latter by means of three pins stuck into a table at different distances from the observer and in approximately the same plane as his eye. Taking them all over, their judgements of position were as accurate as his own (with binocular vision). The fact that a one-eyed man could drive a motor car (or horse, vehicle) through a crowded street with safety was known to all, and was a practical example of accurate judgement of distances. Needless to say, there were limitations to his argument; aviators, for example, should have binocular stereoscopic vision, both for their own safety and for that of others.

THE "OPEN" TREATMENT IN EYE OPERATIONS.

BY
W. B. INGLIS POLLOCK, F.R.F.P.S.G.,
Surgeon, Glasgow Eye Infirmary.

DURING the last seven or eight years I have been using the "open" method of treatment, after cataract, glaucoma, and other eye operations. The chief reason which led me to undertake this method is that it is impossible to sterilize the eyelids and the conjunctiva completely in a number of

hospital and other patients. Cultures of the conjunctival sac are taken in all intraocular operations by most ophthalmic surgeons, having been first advised, so far as I am aware, by Mr. Fergus of Glasgow. While these cultures are often clear, there are a number with *Staphylococcus albus* and *Bacillus aerosis* present, which are usually regarded as non-pathogenic for the intraocular tissues. These cultures, however, do not show how many germs are lurking around the edges of the eyelashes and the skin immediately adjoining them. A number of our operation cases are found, on the first dressing, to have the eyelids adherent with a mucopurulent discharge of greater or less amount in different patients. This condition is not always present, but it is fairly frequent, and occurs when there is no sign of dacryocystitis.

These septic lids, which appear clean to culture, are always to me a danger in operating upon the eyeball, or immediately in the neighbourhood of the edge of the eyelids. By this I do not mean the ordinary dirty eyelids which one sees so often in hospital patients, but rather those which are clean at the beginning and appear septic after the bandage has been applied. The mere bandaging of the eyes seems to be the cause for the collection of matter around the edge of the eyelids. In the pre-culture stage a bandage was often applied one night before the operation, and if there was matter around the eyelids the operation was delayed. But this may be done, and is done regularly, and yet it is found that after the operation, after the first or the second dressing, there is sometimes matter along the edge of the lids. The longer the bandage is worn the worse the condition is liable to become, with all the conditions favourable for microbial life—namely, moisture, heat, etc.

I have used zinc sulphate 1 and 2 per cent, argyrol 5, 10, and 25 per cent., and collosol argentum at different times, and yet, on one or two occasions in the last twenty years I have had an eye operated on for cataract lost by suppuration. Since abandoning a bandage, however, I can only recall a single case lost by suppuration.

The eye guards were first used for private patients in nursing homes before beginning to use them for hospital patients, and now I use them for nearly all cases, both hospital and private. The chief advantage of the guard is that it allows the discharge to get away by the natural lavage of the eye with the tears, and if there is any conjunctival irritation, tears will wash away the deleterious object, whereas under a bandage it could not be removed until the bandage is taken off by the surgeon.

One must always warn the patients, however, to open the eye now and again under the eye guard. I have seen patients keep the eye tightly closed, and the result has been the same as though a bandage had been applied, and you find them in the morning with the eyelids closed and the two lids stuck together with discharge.

A further advantage which has been claimed for the guards is that they allow the eye to be bathed out three times a day, or oftener if necessary. In cases of septic eyelids this is very useful, and it does not mean disturbing the patient's head so much as it would in taking off a bandage. It is well known that the closed lids with the discharge lurking around them form a good terrain for the development of pathological organisms, and it is therefore necessary that all discharge should be removed as quickly and completely as it is formed.

Another advantage is that the bandage is often uncomfortable and causes smarting and pain, and it has also been said that the bandage causes a rise in temperature in the eyeball and in its neighbourhood, from 35.5° to 37.5° C., and that it favours the growth of micro-organisms. This is more important because the eye should be under the same conditions of temperature as in everyday life.

It has also been claimed for the guard that it does away with the mental depression which accompanies the double bandage of cataract patients. I have only once seen a patient become mentally deranged with a guard on, and on that occasion she took it off to hit her eye with, while she declined against the nurses and all around her.

Before I began using the guard I had given up the double bandage in cataract patients, and only covered the one eye, sometimes, however, letting a fold of the bandage cover the unoperated eye, but without cotton-wool under it, and it helped the patient to keep the eye closed. On the other hand, when the guard does not fit and the patient has a very sensitive skin, it may be difficult to persuade him to wear the guard without having cotton-wool placed below it, where it touches the forehead and the cheek.

The eye guard which I use is Bronner's, and it is much better than the original guard of Fuchs, which is very heavy and lies flat on the cheek, whereas the Bronner's is very light and has a large bulge opposite each eyeball. The guards which have been sent to me since the war have had the ends of wire sticking through the linen binding the edge, and I have had to have them all covered with white felt and fitted with new tapes before using them. For children I use the original Pagoustelector's guards; they are small, and although they fit some adults they are very good for children. They are sent out by the firm of Weiss, bound with white felt.

Two disadvantages of a guard are where one is suspicious of retinal haemorrhage or explosive choroidal haemorrhage within the eyeball, in which case one must apply a bandage firmly, but not too firmly. In all cataract operations this is one of the dangers which may occur with any patient; but it occurs so seldom, and I have never seen it occur in a case where a patient was wearing a guard, that I cannot say if the liability is increased by wearing a guard.

On the other hand, with restless patients and younger cataract patients, between the ages of 40 and 60, it is wise to put a bandage on for the first night until they are aware of the importance of lying still. With my private patients I generally tie their hands to prevent their touching the guard. The tied hands enable the patients to reach the chin but not the eyes. They are only tied at night, and I always explain to the patients that the object is not to prevent them from touching the eye but to waken them in time before they have touched the eye. Some surgeons apply a pad of cotton-wool under the guard, but that seems to me to be simply going back to the disadvantages of a bandage without the advantages of it when you wish a moderately firm pressure.

The eye guards I use for all my glaucoma cases, both trephining and sclerecto-iridectomy, unless there is any danger of haemorrhage, and if any glaucoma patient has had retinal haemorrhage before the operation it always makes one go extremely cautiously with the guards. Recently one glaucoma patient had a subretinal bleeding with prolapse of the vitreous.

I have also been using the guard for excision of the lacrimal sac and other operations around the eyelid. If all the bleeding has stopped at the end of the operation then the guard may be applied immediately before sending the patient back to bed; otherwise it may be deferred until after the first or second dressing, until the danger of haemorrhage is past.

While speaking on the subject of operations I would like to urge that each ophthalmic surgeon should wear a face mask reaching from the nose to the chin, so that when bending over the eye of the patient he does not breathe on the operating area. So many general surgeons are using them now that it shows that the ophthalmic surgeon must not lag behind in knowledge of the most modern aseptic methods. In most of my operations, especially in private cases, I wear rubber gloves for operating in. It is impossible to make one's hands absolutely sterile, and therefore when any mistake is made it is better to make sure that the sepsis does not come from the hand of the surgeon.

A REVIEW OF THE WORK OF THE VENEREAL DISEASES CENTRE OF THE GLASGOW EYE INFIRMARY.

BY

E. J. PRIMROSE, M.A., B.Sc., M.D.,

Assistant Surgeon, Glasgow Eye Infirmary.

On January 17th, 1921, the Glasgow Eye Infirmary, in conjunction with the Public Health Department of the City and with the approval of the Scottish Board of Health, opened a Centre for the treatment of venereal diseases affecting the eye. A staff of two was appointed, one medical officer and one assistant medical officer, with lay assistance. It was not intended to deal with venereal affections of other organs than the eye, nor with ophthalmia neonatorum, for which already other provision was made.

The cases seen have been practically all syphilitic, and almost without exception have been in the secondary and later stages of the disease. Most of them have attended as outdoor cases at the venereal diseases centre in Charlotte Street; a proportion, not amounting to 10 per cent., have been for a part of their time at least treated in the wards as in patients at Berkeley Street. The patients come, referred

to us by the ophthalmic surgeons of the ordinary hospital clinics, and bring a note from their surgeon with any remarks he has to make, the result of his clinical examination, and in many cases the Wassermann report on the blood. In this way the centre is saved the ophthalmoscopic or other tedious examinations and tests, and overlapping of work is avoided. This is also avoided in the further progress of the cases, by their being referred to their surgeon from time to time, with a note of what has been done and in order that definite examination may be made of their progress, and for suggestions.

There is a temptation to which the surgeon at the ordinary clinic is liable when the Wassermann reaction obtained by him is negative to regard this as a final test in this line of research. The work done at the venereal diseases clinic shows that this is not a safe conclusion to make. Cases have been found whose blood had a negative Wassermann and whose cerebro-spinal fluid gave positive results either to the Wassermann or to the Lange and Ross-Jones tests. In some of these cases the Wassermann test of the cerebro-spinal fluid was negative, though the other tests of the fluid were positive.

In other cases in which the blood at first gave negative results it was found to give positive results after a few doses of salvarsan substitutes had been administered. It would seem advisable, therefore, where a presumption of syphilis is at all tenable, that when the blood gives a negative Wassermann there should be an examination of the cerebro-spinal fluid and further trial of the blood after a few doses of salvarsan have been used as provocative agents.

When a new patient arrives at the centre his history is inquired into and recorded along with the surgeon's notes, and if not already done the blood is sampled. This Wassermann test is made for us by the City Bacteriological Department.

In very small children or in cases of difficulty, and where the diagnosis of syphilis is hardly in doubt, this blood sampling is sometimes dispensed with at this stage, as it has been found that in a few cases the pain and fright associated with the taking of the blood have deterred the patient from coming back. It is much less upsetting to have the injection made than the blood drawn off, and in any case as the painful eye affection is usually immediately relieved there is at once an inducement to return and brave the discomfort of subsequent injections.

The salvarsan substitutes used have been novarsenobillon, sulfarsenol, and neo-salvarsan; kharsivan was tried on a few occasions at first, but was discarded because the other dissolved up so much more rapidly. For rapidity of solution there is little to choose between these three, the sulfarsenol being slightly slower. The water used to dissolve them is the Glasgow tap water, sterilized by boiling in a large Winchester quart bottle, and allowed to settle and cool sufficiently. The uppermost portions of this are used. The sterilization of needles and syringes is done with methylate spirits and absolute alcohol, after a thorough washing with hot tap water between all injections. The patients' right and left arms are injected alternately. The skin is prepared by the use of methylated spirits, with the previous use of soap or turpentine as seems desirable. After the injection a touch with collodion is made, and a pad and bandage is applied when there is bleeding.

The doses are administered usually at weekly intervals, sometimes less seldom, but no iron-fast routine is followed as modifying factors are looked out for and given due weight. A course of injections varies, according to the progress of the case, from eight to ten, eighteen, twenty, or more injections, usually with a considerable interval after ten injections have been given—that is to say, from six to eight or twelve weeks' interval. Concurrently with these injections mercury, potassium iodide, and iron, or other tonics, such as thyroid extract or cod-liver oil, may be ordered, and one or more continued in the intervals above mentioned.

Serious after-results seldom occur. The most annoying to the patient is pain and swelling at the site of the injection. This may be severe and may last long, but usually has not been very bad and passed quickly off. Suppuration practically never occurs, though once at first a little necrosis did take place. More alarming has been faintness or sickness, occurring in a few hours or on the next or the second day after. This again, has seldom deterred the patient from persevering with the treatment. In a few cases there has been diarrhoea, in one case black stools were reported; one case had slight jaundice.

On the whole there have been few complications reported to us. It may be, however, that cases of serious illness have actually occurred, and neither the patient nor anyone else has returned to report to us.

Nearly every kind of eye affection has occurred showing a syphilitic basis, or having such as a complicating factor; and injuries to the eye seem to cause a seat of election for the subsequent development of the poison which until then had been only latent.

In the great majority of cases the exhibition of the salvarsan substitute has rapidly been followed by amelioration, often after the first dose, and the improvement has gone on without interruption. In a few cases, however, there have been many doses given ere any response in the way of improvement has taken place, and in yet a few others no improvement, and even the reverse. The rapidly improving cases include the most of the congenital keratitis, the choroiditis, iritis, and the third nerve paralysis, and many of the optic atrophies.

In many cases in the course of their treatment a point seems to be reached beyond which the improvement seems to decline to move any farther forward. After an interval of rest, the improvement sometimes goes on of itself—perhaps aided by the other measures, and a further course of an arsenical compound later on sometimes seems to enhance this; sometimes a change to another compound seems to act better.

It has been observed in cases of interstitial keratitis, in which observation is easy and open to all, that where one eye has at first been alone affected, and the treatment begun, and the eye has begun to improve, the other eye suddenly shows redness and tenderness, and threatens to become involved. With perseverance with the treatment this is seen to pass off fairly rapidly. Apparently this phase may occur where the affection is more deeply seated and withdrawn from our immediate observation, as we have records of cases where an eye not previously complained of has become dim, while the other has been improving, and with the continuance of treatment, sometimes with a slightly longer interval, and perhaps modifying the dose, it has come all right again.

In some cases, again taking the easily observed cases of interstitial keratitis, the eye has not improved, or after improving has relapsed, and refuses to respond to further anti-syphilitic treatment. The Wassermann reaction may even have become negative. In some of these cases it has been found that tuberculin in minute doses administered regularly has acted like a charm, doses of 1/20,000 mg. being used. No doubt where at first one finds all the typical signs of congenital syphilis, accompanying a keratitis and improving under anti-syphilitic treatment, one is tempted to overlook a tuberculous element in the case. This may be glandular, or affecting the bones. It is possible that, like syphilis following an injury to the eye, tubercle searches out the eye damaged by syphilis, and thus causes what appears to be a relapse or recrudescence of the original affection.

In certain cases of corneal opacities, where the eye has been apparently quiet and in a stationary condition, with the Wassermann reaction positive, the exhibition of one of the few arsenical preparations, along with or following the use of the other drugs and local eye measures, has brought about much clearing up of the cornea. It is interesting to note that transitory reddening of the eye occurred in these cases, followed by the improvement.

In conclusion I wish to express my indebtedness to my colleague Dr. Conway for his valuable assistance in the work, and to Drs. Marshall and Ferguson for work done at our own laboratory.

DISCUSSION.

Dr. A. J. BALLANTYNE (Glasgow) said that to him the most interesting aspect of this work was that bearing on cases of interstitial keratitis. The point had been much debated as to whether the institution of treatment, with the newer arsenical preparations, did or did not retard or prevent the occurrence of the disease in the second eye. Dr. Primrose's experience seemed to show that it did, and although a large mass of cases was necessary to justify conclusion on this question his own impression from the cases treated for him by Dr. Primrose was that there was a definite improvement in this respect. Another point which interested him was the reference to the benefit of tuberculin in certain cases in which the limits of benefit from salvarsan had been reached. He was much impressed in his student days by his old

teacher Dr. Roid with the existence of cases presenting the combined taints of syphilis and tuberculosis and he believed that many cases of this nature were still seen.

Mr. DAVID WILSON (Huddersfield) said that in Huddersfield the experience of treatment of interstitial keratitis in the venereal diseases clinic was that excellent results were obtained by salvarsan substitutes in children up to the age of puberty, but that in young adults the results were not so satisfactory.

CONJUNCTIVITIS ARTEFACTA.

BY

HERBERT CAIGER, M.B., F.R.C.S., D.O. Oxon.,

Sheffield.

SINCE 1914 a number of articles on conjunctivitis, deliberately provoked, have appeared in ophthalmic journals, especially in France. There are still, however, cases occurring, which have succeeded, time after time, in passing the ordeal of expert examination. It seems desirable again to call attention to the subject, because pensions are now being fixed by a final permanent award in as many cases as possible.

The conditions of ophthalmic work on pensions boards are not always favourable. Time is limited, and the number of cases to be dealt with may prevent exhaustive investigation of a difficult case. Microscopical examination of secretion for foreign particles and micro-organisms is likely to involve postponement of a decision, which is undesirable for various reasons. Owing to these circumstances, some cases escape detection or are given the benefit of the doubt.

The following is a case in point. It occurred within the last few months.

A pensioner who had been receiving a pension of 60 per cent. for the last three years for chronic conjunctivitis in both eyes came up for the usual periodical examination. His history was that he had been slightly wounded at the front in 1916, sent to hospital in England, developed conjunctivitis while in hospital, which persisted in spite of treatment until he was discharged from the army in 1919, with a 100 per cent. pension for chronic conjunctivitis; this was reduced to 60 per cent. after a few months and kept at 60 per cent. for three years. Since his discharge he had been examined on at least four occasions by different ophthalmic surgeons. When examined in 1922 his record aroused suspicion. The eyes showed acute redness with profuse recent irritation rather than a chronic atrophic discoloration, and he was kept an hour where he could be observed. It was found that the redness and watering of the eyes diminished considerably. He was then taken into the dark room, and purposely left alone there for a minute. An "acute exacerbation" resulted. The redness of the eyes was found to have increased again, and tears were running down his cheeks, just as when first seen more than an hour before. A previous search for any foreign material had been unsuccessful; but now under focal illumination, after a little manipulation of the lids, some very fine foreign particles were detected loose on the cornea, showing up against the black dilated pupil. Another examination a few minutes later failed to detect them, as they had by that time probably been washed out of the eye by the very copious lacrimal secretion. Their colour and size suggested very finely ground pepper.

In another somewhat similar case, seen in 1920, on evverting the upper lid a lump of grey foreign matter escaped, as big as the small shirt button. It crumbled on pressure and resembled Fuller's earth. This pensioner's history was much like that of the last case. He had been in hospital with an intractable conjunctivitis during the last six months of the war, and had been in receipt of a pension for more than a year since, although examined by different ophthalmic surgeons. I had myself seen him and recommended a 30 per cent. pension a year previously. In a third case, already reported, deliberately produced corneal abrasions complicated the diagnosis.

The moral of these cases is obvious. Every case of chronic conjunctivitis in receipt of a pension should be thoroughly examined. At the periodical boards diagnosis may sometimes be facilitated by the procedures described above—namely, by keeping the patient waiting under observation for an hour or more, and noting whether the signs of irritation diminish; by leaving him in a room by himself for a minute, and noting whether an "exacerbation" occurs; and examining carefully for fine loose particles on the cornea, best seen by focal illumination in the dark room against the dark background of the dilated pupil.

If the least doubt remains, before a pension is recommended for a case of chronic conjunctivitis, the patient should be admitted to hospital. The conjunctival secretions should be examined microscopically for foreign particles (for example,

ipocacumha, tobacco, pepper) and also for micro-organisms (for example, diplobacillus, Koch-Weeks bacillus). If the diagnosis still remains doubtful, a colloidal bandage should be applied for three days and its effect noted. An ordinary pad and bandage is useless for diagnostic purposes.

Obviously no final award of pension for a case of chronic conjunctivitis should be made unless conjunctivitis artefacta can be definitely excluded.

DISCUSSION.

Dr. THOMAS H. BICKERTON (Liverpool) said: Devices to escape work, school, or labour, to gain or retain pensions, or to secure compensation, are common; but they are not confined to that class. There is a class which utilizes them apparently for the purpose of exacting the attention of the family circle, or of exciting the sympathy of friends, or for no known reason. Of the latter class he had seen a young lady of good family, surrounded with affection and comfort, who had lain in bed for months, to the distress of her parents and the perplexity of the doctor, and who was attended by a nurse. One eye was chronically inflamed, with lachrymation and lid swelling, sometimes better, sometimes worse. The patient took great interest in her case, and discussed intelligently the various treatments which had been adopted. The eye was inflamed, but the inflammation was confined to the lower half. The doctor had begun to suspect that she was artificially creating the condition, which turned out to be the case, the foreign body used being lentils.

Dr. PETER MACDONALD (York) instanced the case of a boy, 17 years of age, who had been in the York County Hospital for a very long time, where, among other things, he had been operated on for congenital cataract. He came up some months later with his conjunctival sacs filled with foreign bodies, evidently ashes; some of the foreign bodies were of the size of a small pea, and under the upper lids were pieces the size of a lentil.

Dr. A. R. MOODIE (Dundee) said that they must be very sure of their ground before declaring a pensioner a malingerer. He cited a case of conjunctivitis artefacta, probably due to tobacco, which was unmasked by causing the man to wear a Buller's shield.

CLINICAL MEETING.

A CLINICAL meeting of the Ophthalmological Section was held at the Glasgow Eye Infirmary on July 28th, with Dr. A. J. Ballantyne, Vice-President, in the chair.

A series of demonstrations had been arranged by the officers of the Section, including a demonstration of the Sheringham artificial daylight; stereoscopic photographs by the Lumière process to show natural colouring, by Mr. John Rowan; a series of drawings showing abnormal conditions of the retinal vessels, by Dr. A. J. Ballantyne; a test for light sense, by Mr. A. S. Percival; and a demonstration of a motor trephine, by Dr. George Mackay. A number of books, pamphlets, photographs, and instruments connected with the Glasgow School of Ophthalmology were also shown, and pathological specimens, both microscopical and preserved.

Clinical Cases.

The following clinical cases were shown: Mr. John Rowan, cases of optic atrophy; and of congenital defect of cornea and lens. Dr. H. Wright Thomson, a case of glaucoma in a child. Dr. Garrow, cases of microphthalmos; and of proptosis. Dr. A. J. Ballantyne, a case of unusual ulceration of the cornea; and of chronic oedema of the eyelids. Dr. H. L. G. Leask, a case of birth injury of the cornea. Dr. Hislop Manson, a case of recent injury to the eyeball with paralysis of the superior rectus, but with little external evidence of the injury; and a case of spinal meiosis with optic atrophy. Mr. Inglis Pollock, a case of double traumatic dislocation of the lenses; a case of glaucoma with Lagrange's operation; and a case showing excess of the membrane of Bruch. Dr. Barbour Stewart, cases of enlargement of the socket by studs; of pigmented tumour of the conjunctiva with microscopical sections; and of exenteration of the eyeball. Dr. E. J. Primrose, cases illustrating the treatment of syphilis at the venereal diseases clinic at the Glasgow Eye Infirmary.

The meeting concluded with a vote of thanks to the officers of the Section for their excellent arrangements.

MEDICAL, SURGICAL, OBSTETRICAL.

ORAL ADMINISTRATION OF ANTITOXIN.

It has seemed to us that the recent correspondence in this JOURNAL on the oral administration of antitoxin and vaccines may possibly lead some of your readers to believe that this method of administering the specific antitoxin in cases of diphtheria is permissible. With the alleged non-specific action of antitoxic serums, when given orally or otherwise we are not now concerned, but we think it cannot be stated too clearly that to give the antitoxin orally in a case of diphtheria is to throw away a valuable remedy upon the correct administration of which life may depend.

It has been shown long ago by careful experiments, both in animals and in human beings, that antitoxin is not absorbed to any practical extent from the alimentary canal. Theoretically, perhaps, an exception must be made in the case of sucking animals; but this point has not been made quite clear; and it has been suggested that only the autogenous antitoxin in the milk of the mother is absorbed from the alimentary tract of the infant. The question is succinctly treated by G. Dean in Nuttall and Graham Smith's *Bacteriology of Diphtheria* (1908, p. 567), to which we would refer the reader for further details.

Though not questioning the correctness of the orthodox opinion on the matter, we nevertheless felt curious enough about it to do some experiments for ourselves. In view of the interest taken in the subject at the present moment, we venture to submit the results, though they contain no element of novelty.

The experiments consisted in causing guinea-pigs to swallow diphtheria antitoxin of high potency, and, after an interval of three or six hours, injecting a small dose of the toxin subcutaneously. As a control two guinea-pigs were given a very much smaller quantity of antitoxin by intra-peritoneal injection, and, after similar intervals, toxin was injected as in the other animals.

The antitoxin given by the mouth was well taken. Intra-peritoneal injection was chosen for administering the antitoxin to the control animals in order to avoid any possibility of the toxin and antitoxin getting mixed together; but there is no reason to think that it is more effective when given this way than when injected subcutaneously. Very young animals were chosen deliberately; the three last were only three days old when they were employed, and were kept all the time with their mother.

Weight of Guinea-pig in grams.	Antidiphtherial Serum.		Interval in hours.	Filtered Broth Culture of <i>H. diphtheriae</i> .	Result.
	By Mouth.	By Intra-peritoneal Injection.			
230	1,200 units (1 c.c.m.)		3	1 Lo dose*	Dead in 30 hrs.
230	2,400 units (2 c.c.m.)		3	0.1 Lo dose	Dead in 66 hrs.
200 (control)		50 units (0.04 c.c.m.)	3	1 Lo dose	Remained well.
95	1,500 units (1.15 c.c.m.)		6	1 Lo dose	Dead within 48 hrs.
65	3,000 units (2.3 c.c.m.)		6	0.1 Lo dose	Dead within 48 hrs.
65 (control)		10 units (0.08 c.c.m.)	6	1 Lo dose	Remained well.

* The Lo dose of toxin is that quantity of filtered diphtheria broth culture which is exactly neutralized by one unit of antitoxin.

It will be seen from the table that in one of the control animals (No. 6) ten units of antitoxin injected protected against one Lo dose of toxin, while in another animal (No. 5) 3,000 units, given by the mouth, failed to protect against a quantity of toxin only one-tenth as large as that injected with safety into the control. Thus antitoxin failed when administered by the mouth, even though 3,000 times as much was given as would have sufficed had it been injected.

CLINICAL AND SCIENTIFIC PROCEEDINGS.

BIRMINGHAM BRANCH.

THE first meeting of the clinical and pathological section of the Birmingham Branch, for the session 1922-23, was held at the Medical Institute, Birmingham, on October 27th, when Professor J. W. RUSSELL was elected chairman in succession to Mr. W. Billington, and Dr. L. BALL and Mr. G. P. MILLS were appointed secretaries.

Mr. BERNARD GOODWIN showed a male patient, 17 years of age, who since December, 1919, had complained of pain in the right shoulder radiating into the fingers. No physical or radiographic signs of bone disease were discovered, and the shoulder was fixed by splints. In September, 1921, further radiograms were taken, and these showed appearances suggesting osteomyelitis fibrosa. The patient again came under observation in April, 1922, and had then swelling of the head of the humerus, while definite signs of endosteal tumour were present in radiograms. Five inches of the upper end of the humerus were removed through an external incision, and replaced by a piece of the patient's fibula, which was driven two inches into the medulla of the divided humerus. The graft united firmly, but about six weeks ago the patient met with an accident which caused a fracture of the graft at its centre; the break united well with a large amount of callus. At present, movement at the shoulder was only fair, but promised to improve; the patient had full use of the forearm and hand. The resected portion of the humerus was expanded by a central myeloma which had perforated the bone at one point.

Dr. K. D. WILKINSON showed the case of a woman with scleroderma affecting the hands and face. The pathology of the condition was discussed, importance being attached to the neurotrophic theory because of the frequent association of atrophic changes in deeper tissues.

Dr. BALL described the case of a man who developed signs of acromegaly after an injury to the skull, with probable fracture of the base. Radiograms showed characteristic changes in the skull and jaw, and bitemporal hemianopsia and glycosuria were present. Hyperpituitarism was almost unknown as a sequel of injury to the head, though a number of cases of diabetes insipidus, of adiposity, and of hemianopsia were recorded in this connexion.

Dr. R. G. ABRAHAM showed specimens from cases of eclampsia and of uræmia in the course of pregnancy, contrasting the morbid changes present in the two groups.

The second meeting of the session was held on November 24th, Dr. W. H. WYNN occupying the chair in the absence of Professor Russell.

Mr. A. W. NUTHALL and Mr. BERTRAM LLOYD showed two cases of ectopia vesicae after transplantation of the ureters into the bowel. The method consisted in dividing the ureters close to the bladder mucous membrane, and transplanting the right ureter into the caecum and the left into the sigmoid, an interval of a few weeks being allowed to elapse between the operation on the right side and that on the left. Both the patients were children.

The first patient was now in good general condition, passing urine from the bowel two or three times a day and only exceptionally at night. In the second case the patient at present passed urine from the bowel about every four hours and was apparently in good condition.

Mr. GANGESE showed a woman, 42 years old, who had had a swelling of the thyroid gland for sixteen years. For the last five months she had presented a pulsating tumour of the manubrium sterni. The thyroid swelling was hard and fixed, though the patient denied that any recent change had occurred in it. In cases of pulsating tumours of bone secondary to thyroid tumours histological examination did not always show a tumour of typically malignant character. In discussing the case, Dr. PINNEY referred to the frequency with which he had found thyroid tissue or tissue of exactly similar structure in the marrow of normal bones, and suggested that the sternal tumour in this case might be a hyperplasia of such tissue in the marrow of the sternum, arising as a compensatory result of calcification of the thyroid gland, and not a deposit secondary to a malignant tumour of the thyroid.

Dr. EMANUEL showed a heart in which the left aortic arch had undergone extreme dilatation, for the most part in a horizontal direction, so that during life the dilated aortic arch presented in the right axilla, where it was tapped under the belief that it was a pleural effusion. The specimen was from a married woman who died at the age of 48. For the last ten years of her life she suffered from shortness of breath on exertion, cyanosis and oedema of the feet, all the symptoms being of gradual onset and of gradually increasing severity. There was a well-marked cardiac impulse in the eighth left space in the mid-axillary line four inches external to the left nipple line and eight inches from the mid-sternal line. The right border of the heart extended beyond the right mamma as far as the right anterior axillary line. The cardiac dullness did not extend upwards higher than the level of the fourth costal cartilages. At the apex beat there was a systolic thrill, and this thrill was palpable also outside the right mamma. At the apex beat a rough systolic murmur and a low diastolic murmur were audible. Radiography showed the heart to be dilated from the right to the left lateral border of the heart. The left aortic arch after fixation in formalin was found to hold forty ounces and the right twenty ounces of water; the mitral valve was

stenosed, the tricuspid and pulmonary valves were unaffected, and dense pericardial adhesions were present over part of the left auricle.

Dr. K. M. TILLYARD showed the heart and lungs of a woman, aged 42, who was admitted to the maternity hospital on November 6th with hæmorrhage due to placenta prævia. An embolism occurred a week after delivery, with rise of temperature, cough, hæmoptysis, and pleural friction. Recovery from this took place, but a second embolism occurred in the fourth week, which led to death in ten minutes. The embolism was shown *in situ* in the pulmonary artery. No large thrombi had been found in the pelvic veins at autopsy, but the small veins of the broad ligament were thrombosed.

Reports of Societies.

HOUSE INFECTION IN CHOLERA AND
CANCER.

At a meeting of the Edinburgh Medico-Chirurgical Society held on December 6th, with the President, Sir ROBERT PHILLIP, in the chair, Lieut.-Colonel A. G. McKENDRICK read a communication on house infection in cholera and cancer. He said that the sciences of medicine and physiology, in that they dealt with affections of a community of cells, were in his opinion essentially statistical in nature. The law of chance must be operative in all medical phenomena, and anomalies of behaviour could never be ascribed to external agencies until the possibility had been excluded that they were not merely the rare cases which occurred in the normal operations of the laws of chance. The so-called exact sciences dealt as a rule with the average individual in whose behaviour the underlying law found true expression; but by the very nature of medical problems one was often forced to consider the behaviour not of the average but of the extremely exceptional individual. The speaker proceeded to describe a statistical method which he had evolved and which was very general in application, an example of its value being shown in the case of house infection in cholera and in cancer. He described how this method had been helpful in the investigation of outbreaks of cholera in India; in particular it was shown how minimal contaminations of water might in certain cases be detected by the methods of statistical mathematics. This was achieved by the comparison of figures showing the house and individual incidences with an "avorage" figure. A concrete example of the investigation by this method of an outbreak of cholera in India was given, which was chosen to illustrate how medical science was so frequently concerned with facts which were unrepresentative. The statistical outlook recognized these difficulties and to some extent overcame them. The method had been applied with success to many medical problems, such as phagocytosis, agglutination, the measurement of conferred immunity, and the epidemicity of disease.

The communication was discussed by Professor RUSSELL, who pointed out that statistics were often misleading and the law of averages open to grave misinterpretation.

Artificial Pneumothorax.

Dr. J. S. STEWART then read a communication on artificial pneumothorax in the treatment of pulmonary tuberculosis. While strictly unilateral disease was the ideal case for this treatment, the usefulness of the method would be limited if so confined. Disease of the opposite lung, provided it were limited to the upper lobe without either intense consolidation or excavation, was not a contraindication, nor was tuberculous laryngitis. Recurrent dry pleurisy and pleurisy with effusion were indications, as was also hæmoptysis if one could be sure of the source of bleeding. The method was unsuitable for early cases which would recover under general treatment; marked cardiac disease was a strong contraindication. The apparatus and technique were fully described; a preliminary injection of morphine and atropine, and local anaesthetization of the skin and pleura was stated to lessen the risk of pleural shock. The patient was supported on pillows on his sound side, and, under a negative pressure of 10 mm. Hg, 200 to 300 c.cm. of oxygen were slowly introduced. With oxygen there was, he believed, less risk of air embolism, and a definite sedative effect on the inflamed pleura was produced. Frequently repeated small injections had the advantage that an opportunity of accommodation was given to the opposite lung. The intervals of subsequent injections were gradually increased, until at the end of the third month injections were made every three or four weeks. Frequent

x-ray examinations were essential both before and after refills. Pleural adhesions complicated the operation, and were shown by a rapid rise of pressure on the manometer from negative to positive after a small injection. In all cases of bilateral disease the opposite lung had to be watched carefully, and where pleuritic effusion developed aspiration should be carried out at once. Illustrative cases were described and numerous lantern slides shown.

The paper was discussed at length by Sir ROBERT PHILIP, Professor LEVELL GULLAND, Professor J. C. MEAKINS, Dr. DAVIES, Mr. GUR, Dr. STEVENS, and others.

ASTHMA IN CHILDREN.

A MEETING of the Manchester Medical Society was held in the University of Manchester on December 6th, with Sir WILLIAM MILLIGAN in the chair.

Dr. C. P. LAPAGE read a paper entitled "Asthma in children—the part played by local lesions of the chest." He said that asthma was often divided into true nerve-stem asthma and bronchial asthma, the latter being due to enlarged bronchial glands and other troubles in the chest; but in both cases there was an element of spasm which was probably of reflex origin. A study of the factors determining asthma showed that they could be put under three headings: (1) The case of the individual who might be of exudative type or might have become sensitized. (2) Cases due to external irritants, which might be (a) foreign proteins—from animals, pollens, eggs, milk, or bacteria, (b) metabolic excess, (c) climatic. (3) Cases due to internal irritants—local lesions—in (a) nose and throat, (b) lungs and bronchi, (c) intrathoracic glands, (d) from adhesions and fibrosis. The paper was intended to show that the internal irritants often played an important part in the determination of attacks of asthma and perhaps in the sensitization of the individual. An analysis of cases of asthma in children showed that in a large proportion there was a family history of the exudative diathesis, and in many there was also a personal history of manifestations other than asthma in the case under observation. The common manifestations of the exudative diathesis in childhood were: (1) curd dyspepsia, (2) urticaria, (3) eczema, (4) asthma, (5) hay fever (periodic nasal catarrh), (6) angio-neurotic oedema. Coming to the question of local lesions, in 75 cases of asthma in children which were quoted it was shown by a correlation of the clinical examination and the x-ray examination that 73 per cent. of them had definite chest lesions pointing to tuberculosis. The estimation of tuberculosis was made first on the clinical examination, supplemented by the evidence from the x-ray screen. It was noticed also that in many cases attacks of asthma tended to increase in frequency with the onset of the illness and to subside when the chest lesion, and to some extent the antituberculous lines. Slides were shown demonstrating the changes found, which were as follows: bronchial glands 31, mediastinal 6, cervical 5, fibrosis (roots) 18, adhesions 5, chronic bronchitis 11. Many of the cases showing the changes had a personal history of the exudative diathesis. The conclusion drawn therefore was that the subjects of asthma in children were of the exudative diathesis and that the exhibition of asthma often depended on the presence of the local lesions of the chest, which in most cases were of a tuberculous nature, and that the asthma attacks might culminate and subside concurrently with the culmination and subsidence of these lesions.

Pernicious Anaemia.

Dr. E. M. BROCKBANK read a paper on some aspects of pernicious anaemia. He said that he agreed with the opinion that blood plates came from red corpuscles; their behaviour to solvents and peptic digestion, which was like that of nuclein, supported the view that they were the remains of the nuclei of the erythroblasts. Blood plates were therefore an indication of the activity of the marrow. There were many more blood plates in secondary anaemia than in normal blood and there was increased activity of the marrow in that condition. He mentioned evidence showing that the average age of the normal red cell was about ten days and that in secondary anaemia when there were four times as many blood plates as normally, it was about one-fourth of the age of the normal red cell. In pernicious anaemia very few blood plates were seen. This suggested that in pernicious anaemia the red corpuscles were

older than normal and that they resisted the usual destruction of the red cells, and that there was evidence of erythroblastic inactivity.

Surgery of Meckel's Diverticulum.

Mr. J. P. BUCKLEY read a paper on Meckel's diverticulum and its urgent complications as illustrated by two rare cases. He drew attention to the fact that Meckel's diverticulum was probably more common than was suggested by Sir Norman Moore's note in the *Transactions of the Pathological Society*, in 1834, where he stated that only thirteen were found in the post-mortem records of St. Bartholomew's Hospital over a period of sixteen years. He raised the question of which was the more likely method by which the vitello-intestinal duct disappeared normally, whether—as stated by Keith—it became occluded and shrivelled up, or—as stated by Marshall—it separated from the intestine. He went on to describe two cases upon which he had operated—namely, a case of Littre's hernia in a woman aged 49, and a case of acute intestinal obstruction in a boy aged 14, due to volvulus of a Meckel's diverticulum. He summed up the rarity of Littre's hernia by saying that if that rare individual who possessed a Meckel's diverticulum and a congenital sac did develop a hernia it must be very long odds against the particular inch of gut which carried the diverticulum being the intestinal site of the hernia. He raised again the question, previously raised by Macready, of whether the name of Ruysch rather than that of Littre should not have been attached to the hernia of the diverticulum. Mr. Buckley insisted that a true Littre's hernia was one containing only the diverticulum, with no small intestine in addition. He pointed out that Littre's hernia rarely occurred other than on the right side, and that it was seldom recorded other than in the complicated state. He was sure that the complication of the hernia should be described as inflammation rather than strangulation. The signs, symptoms, and pathology were rather those of inflammation than of obstruction. Differential diagnosis would have to be made between inflammation of an appendix in a hernial sac, inflammation of a Littre's hernia, and acute suppurative funiculitis. He pointed out that an inflamed Littre's hernia was a much less dangerous condition than a Richter's hernia. Regarding the case of volvulus of a Meckel's diverticulum, he pointed out that it was rare, because for that condition to occur the diverticulum should have a fair bulk and a narrow attachment to the bowel; such diverticula were uncommon. He called attention to the fact that during the last nine months the diverticulum in his case had been causing occasional attacks of "stomach ache." On this point he said that the progress of the pathological changes leading up to many forms of acute intestinal obstruction was insidious. How often were abdomens opened for acute intestinal obstruction and a condition found which had been going on for a considerable time, gradually narrowing the lumen of the small intestine? The lumen had to get very narrow before absolute obstruction to the fluid contents of the small intestine was produced. If they went into the past history of such cases it could usually be found that the patients had had occasional attacks of "colicky" pain. More importance ought, he considered, to be attached to such premonitory attacks.

FOETAL SYPHILIS.

A CLINICAL meeting of the Cardiff Medical Society was held on December 12th, when, in the absence of the President, Professor EWEN MACLEAN, the chair was taken by Dr. F. BUCKHAM.

Dr. G. I. STRACHAN gave a demonstration of foetal syphilis, pointing out that in the course of his investigations on foetal death he had found much that was new to him in that aspect of the subject. As a cause of foetal death syphilis had previously been ranked too high, and it was safe to say that not more than about 15 per cent. of stillbirths could be attributed to this cause. The typical maternal history of several previous stillbirths was not always present and, of course, in a primipara was not available. Some of the mothers presented specific lesions, but the majority either showed no lesions or these were present in a slight degree only and were easily missed. While in the majority the Wassermann reaction was positive, that was not always so; he had examined cases where the reaction of the maternal blood was negative but in which spirochaetes had been demonstrated in the foetal tissues. In the examination of the foetus the main naked-eye

chango found was enlargement of the spleen; liver enlargement was usually also present, but was not so constant or so reliable a sign as splenic enlargement. The lungs were mostly of a firmer consistence than normal, but typical pneumonia alba was found in only two cases. Some irregularity of the osteo-chondral junction, in the long bones was usual, but well-marked osteo-chondritis, as shown by a broad irregular area of defective calcification extending from the epiphyseal line, was found in only one case.

A number of microphotographic lantern slides illustrated the microscopic lesions found in the various organs. These were in the nature of cirrhosis, and the difference between the open texture of a normal foetal organ and the firm thick texture of a syphilitic organ was well brought out. Sections of the lung, liver, spleen, pancreas, and placenta were shown, also a plate showing the differences between normal, syphilitic, and macerated bones. Regarding the placenta the main changes found consisted in relative and absolute enlargement with pallor and a firmer consistence than normal; haemorrhage and infarction formation had not been observed.

CASES AND SPECIMENS.

A case of miliary disseminated tuberculous iritis was shown by Dr. J. W. TUNOR THOMAS.

The patient was a girl aged 5, whose left eye had become inflamed four months previously. At that time there was some ciliary injection and very little pain. The iris was covered with yellow tubercles, mainly at the periphery, some at the pupillary margin. A few posterior synechiae were present, and deposits of keratitis punctata on the posterior surface of the cornea. There was no evidence of tubercle in the lungs. The treatment had consisted in injections of tuberculin, syrup. ferri iodidi internally, and atropine ointment locally. The condition was now very much better, the injection having disappeared and only one patch of deposit remaining on the posterior surface of the cornea. The tubercles were smaller, and some had disappeared. The other eye appeared to be quite healthy, and the general health of the patient had improved considerably.

Dr. ABEL EVANS showed a case of myotonia congenita (Oppenheim's disease).

The patient, a boy 3 years of age, could not sit up, stand, or walk. He lay in any position in which he was placed and, although there was no absolute paralysis, there was great muscular weakness: all voluntary movements were devoid of vigour. His muscles were small and soft, but showed no wasting; it was almost impossible to distinguish them by palpation from subcutaneous tissue. The facial and sphincter muscles were unaffected. Passive movements at all the joints were unusually free in every direction. Electrical excitability was diminished to faradism and galvanism; he could bear strong faradic stimulation without distress. The deep reflexes were absent, but the cutaneous and organic reflexes were normal. His general health had always been good. Little was known of his family history except that his mother died of eclampsia at his birth.

Dr. Evans further related a case of myotonia congenita (Thomsen's disease) occurring in a man 40 years of age, who had pronounced spasm of the laryngeal muscles and also of the muscles of the arms and hands on performing voluntary movements. The man was well nourished, free from any abnormality of the nervous system, and muscular, but there was no hypertrophy of the affected muscles as was sometimes met with in that type of case. The symptoms were first noticed when he was about 8 years old. His father had been similarly affected. The patient had ten children, all girls, who were normal. The disease appeared to occur less frequently in females than in males.

Mr. D. J. HARRIES showed a lobulated fibro-lipo-myxoma, weighing 9 lb., removed from the calf of a woman 40 years of age. The tumour had been present for several years, steadily increasing in size, but giving rise to no symptoms beyond those referable to its weight and dimensions. Although underlying the gastrocnemius and soleus, and producing considerable atrophy of these muscles, there was no interference with the movements of the foot. The tumour mass was undergoing early degenerative changes; there were small areas of blood extravasation and some calcareous deposit in the lipomatous portion. Professor A. W. SHEEN showed an encapsulated tumour, weighing 1 lb., removed from the inner side of and behind the knee-joint of a man, where it had existed for eight years, producing some slight inconvenience only. It proved to be a pure myxoma with large numbers of small blood vessels forming a network in the substance of the growth. Professor EMERY-ROBERTS commented on the comparative rarity of a pure myxoma, most tumours of that character resembling the specimen shown by Mr. Harries. The latter had, in all probability, started as a lipoma, with subsequent fibroblastic proliferation of the accompanying stroma and a conversion of a certain proportion of fibroblasts into myxoblasts, with a corresponding production of mucin.

Mr. ALWYN SMITH exhibited a child, 4 months old, suffering from Hirschsprung's disease. He had seen the infant when it was 12 days old; it then presented a large hypertrophied colon, with stretched rectus abdominis and diaphragmatic ligaments, a high barrelled chest, incarcerated rib cartilages and right torticollis, due to posture *in utero*; the liver and spleen were easily felt, and the thickened colon felt like leather between the fingers. He gave a poor prognosis, forecasting permanent constipation; the child, however, had had daily movement of the bowels. Dr. OWEN RHYNS showed radiographs of fourteen cases of various types of hour-glass stomachs. Two of these showed a double constriction, persistent at operation. A case of pseudo-hour-glass was found to be due to extrinsic causes—namely, to six calculi in the gall bladder, so opaque that they could be counted on the x-ray film.

Professor EMERY-ROBERTS and Dr. H. A. HAIG showed a number of pathological slides and specimens.

(1) A blood film and a section of a chloroma of the lower jaw occurring in a boy. The blood showed very large numbers of myeloblasts, and the tumour similar cells infiltrating the alveolus. (2) A section of an endothelioma of the orbit. There was a characteristic whorled arrangement of the tumour cells, bearing a superficial resemblance to the cell nests of an epithelioma; the central areas, however, were composed of degenerated cells, and, at times, contained a calcareous deposit. (3) A section of a metastatic deposit on the surface of the liver from a case of diffuse combined carcinoma and sarcoma of the peritoneal cavity, of untraceable primary origin. The secondary mass showed a high degree of fibroblastic proliferation; the carcinomatous elements, in the form of acini, had undergone considerable degeneration, and were the seat of much calcareous deposit. The mass had formed a hemispherical bed for itself in the liver by pressure atrophy and destruction of the subjacent liver cells, from which it was separated by a fibrous band continuous with the capsule. The great omentum was converted into a solid mass weighing 12 lb. Here the fibroblastic proliferation had proceeded to such a degree that a condition of fibro-sarcoma had evolved, the carcinomatous elements being discernible with the greatest difficulty. (4) A brain from the case of a woman, aged 52 years, who for some time past had shown symptoms of mental irritability. A sudden attack of vomiting was followed by right-sided hemiplegia, aphasia, and semi-consciousness; she lingered over a month without any alteration of the symptoms. Examination of the brain disclosed a large gliosarcoma in the left temporoparietal lobe, into which extensive haemorrhage had occurred, and this in its turn had produced pressure on the fibres of the internal capsule.

PATHOLOGICAL DEMONSTRATIONS.

A MEETING of the Pathological Section of the Royal Academy of Medicine in Ireland was held in the Royal College of Surgeons on December 8th, with the President, Dr. W. D. O'KELLY, in the chair. In the absence of Sir WILLIAM WHEELER, Dr. MILNE HENRY read a paper on rhabdomyosarcoma of the kidney, after which Professor O'SULLIVAN demonstrated the specimen, and a discussion followed.

Dr. MOONHEAD showed three specimens of hearts. The first was an example of the rare congenital abnormality consisting of an abnormal opening between the aorta and the pulmonary artery, immediately above the sigmoid valves; in addition, there was an aneurysmal dilatation of the beginning of the aorta, a well-marked stricture of the aorta above the opening, while the wall of the aorta and pulmonary artery were not separated, but consisted of a single partition. During life the symptoms were those of aortic regurgitation. The second specimen was an example of extreme fibrosis, the wall of the left ventricle being as thin as tissue paper; the third specimen was an example of combined mitral and tricuspid stenosis.

Dr. ABRAHAMSON remarked on the coexistence of stenosis and patency in the congenital case. It was hard to know, he said, how the stenosis was formed, and it would be interesting to work up the mechanism of the whole case. Professor O'SULLIVAN said that when sections of the aorta and pulmonary artery were cut the appearance was as if it was a single artery, divided by a partition instead of being two independent vessels. Dr. O'FARRELL said that in regard to the second specimen, he would like to know what the condition of the coronary artery was; in cases of this sort which he had experienced death had been due to thrombosis locally. He wondered whether, when the coronary artery was cut, thrombosis was found. Dr. E. C. SMITH, who demonstrated the specimen, said, in reply, that in this case no local thrombosis was found.

Dr. SINGER read a paper on Banti's disease, and showed specimens from a case which had been under his care. He

said that no operation was performed, because when the case was in hospital the amount of anaemia was very slight. The red cells were found to be normal. There was no thrombosis of the splenic vein, although it was big, and, so far as he could make out, there was no thrombosis in any of the veins. A discussion followed.

TREATMENT OF FRACTURES.

A GENERAL discussion on the present-day treatment of fractures was held at the meetings of the Royal Medico-Chirurgical Society of Glasgow on December 1st and 13th. The discussion was opened by Mr. J. W. DOWDEN (Edinburgh), who spoke particularly of fractures of the upper extremity as capable of treatment by the general practitioner. The use of a sling and active movements were the important factors in the treatment suggested by him, but for the first two or three nights not only must a sedative be given but possibly a splint to prevent the undue displacement of parts while asleep. The chief onus of the treatment lay on the patient himself and he should be frequently seen and encouraged to carry out progressive active movements, which should go farther and farther each time so long as severe pain was not induced. Mr. ARCHIBALD YOUNG (Glasgow) referred to the unsatisfactory position to-day of the treatment of fractures so far as the general practitioner was concerned, and in the out-patient departments of the larger general hospitals. His general contention was that open operation with direct fixation was the correct treatment in a large number of fractures. Mr. Young showed a large number of x-ray photographs supporting his thesis. Dr. J. N. MARSHALL (Rothsay) presented the case from the point of view of the general practitioner, with special reference to the value of the x-rays in diagnosis. Mr. HENRY RUTHERFORD (Glasgow) was not enthusiastically in favour of Mr. Dowden's methods; he referred to the influence of the Workmen's Compensation Act in stimulating interest in the treatment of fractures.

At the second meeting several speakers referred to points connected with variations in the methods of treatment, and Dr. W. B. MORN considered the matter particularly with regard to accident insurance.

TREATMENT OF TUBERCULOUS CONDITIONS BY INFLATION WITH OXYGEN.

At a meeting of the Nottingham Medico-Chirurgical Society, held at the society's rooms, 64, St. James Street, Mr. ROBERT PURVES (Lincoln) read a paper on the treatment of tuberculous affections by inflation with oxygen. He detailed notes of fourteen cases, including tuberculous plastic peritonitis, and psoas and other abscesses, which had been traced and examined recently. After reference to the articles on the subject by Lieut.-Colonel Rost, I.N.S., he reviewed the method, technique, and apparatus required. He recommended the use of a large trocar and cannula for evacuation of the abscess after a preliminary "nick" in the skin, or, in deep-seated abscesses, an incision. Introduction of the gas might be effected through the evacuating cannula, or by an aspirating needle introduced beside the incision, prior to its closure. Special caution should be observed in tuberculous peritonitis with adhesions. Closure of the puncture was best effected by one or two Michol's clips. Cases with mixed infection or any reddening of the skin were unsuitable. Results showed that 50 per cent. of all cases, without selection, had remained well. The virtue of the oxygen, which was passed through a wash bottle containing H_2O_2 prior to introduction, was considered by Rost to be due to its acquisition of a nascent character. Mr. Purves suggested an alternative explanation as more probable—that in the presence of excess of oxygen an inhibitory substance was developed which was deleterious to the bacterium. He pointed out that it had been demonstrated by Macleod and Gordon that the pneumococcus and some other cocci, when grown in excess of oxygen, developed H_2O_2 , which led to their early death; also that Pasteur utilized oxygen to attenuate anthrax and other cultures. This had a possible bearing upon the open air methods of treating pulmonary and other forms of tuberculosis. He suggested that the simplicity of the inflation method, which might frequently be carried out under local anaesthesia, and the ease of the after-treatment, commended it as a useful alternative method which might well be given an extended trial.

Reviews.

THE APOTHECARIES' PHYSIC GARDEN.

In a charmingly written and attractively illustrated book all too short, but full of anecdote and historical lore, Dr. DAWTREY DREWITT has presented *The Romance of the Apothecaries' Garden at Chelsea*,¹ which, in spite of the fact that it registers 3,000 students' attendances a year, is no nearly so well known as it deserves. The London Society of Apothecaries broke off in 1617 from the great Grocers' Company, which, like Pharaoh of old, was loath to let them go, but was constrained by King James I to hold its peace. Soon afterwards the Apothecaries' Society gained possession of Cobham House on the bank of the Thames, "where the little Fleet joined it at Blackfriars"; but although the time wore troublous and its Hall was destroyed in the Great Fire in 1666, the Society was able in 1673 to take a lease of three and a half acres in the then pleasant riverside village of Chelsea as a garden for the cultivation of rare plants. The official title "Physic Garden" is a little misleading, for the word originally meant "concerning physical"—that is, natural—science, and the Botanic Gardens at Oxford and Kew formerly shared this label, which, however, naturally stuck to that of the Apothecaries' Society. Maintenance expenses weighed so heavily on the Society that the garden would probably have been sold had not Sir Hans Sloane in 1722 practically made the Society a gift of the site. As the present existence of the Physic Garden is largely the result of his generosity it is most appropriate that an account of Sloane's life should find a place in this record, and Dr. Drewitt happily remarks how well the present Sloane Street represents the life of Sir Hans for do not "those who walk all the way down it know that it is very long, obviously prosperous, and very straight." He observes too that, like Thomas Wheeler, for forty-two years demonstrator of botany at the Garden, Sloane died at the age of 93, which may therefore be regarded as a fatal year in the life of botanists.

In the description of the surroundings of the Physic Garden many interesting points are brought out. Thus in discussing Paradise Row (now Royal Hospital Road) the use of the word "paradise" as the equivalent of park makes it probable that Paradise Row led to the great Paradise made in the sixteenth century by Sir Thomas More, now the Elm Park Estate; reference is made also to the translation of his own name by John Parkinson, Apothecary to Charles I, into *Paradisus-in-sole* (Park-in-sun). Again, there is a fascinating sketch of Sir Joseph Banks, who as a boy lived in a large house close to the Physic Garden, and in later life did much for it. In 1893 the Apothecaries' Society handed over its charge to the Charity Commissioners, and a committee now superintends its management; it is, indeed, fortunate that Dr. Drewitt was made one of this committee, for thus was he stimulated to write a book that everyone will read with pleasure.

GUILLAIN'S NEUROLOGICAL STUDIES.

BRITISH readers are familiar with the writings of Dr. GUILLAIN on various aspects of the neurology of war, and it will be a pleasure to many to have the works of an author who has achieved a very distinguished position among contemporary French neurologists collected in a single volume.² It is divided into nine sections, each of which again consists of a number of chapters dealing with different aspects of the same larger problem.

The first subject, that of the fixation of poisons in the nervous system, is of particular interest to the neuropathologist. The opinions expressed on the pathology of diphtherial neuritis are very interesting when we recall the recent work of Walshe in this country, who has independently reached very similar conclusions. Other aspects of the subject are illustrated, and Dr. Guillaumin's views should be studied by all neurologists. The second section, on the pathology of the brain, contains detailed accounts of some cases of particular interest and a study of the important changes found in the cerebro-spinal fluid in certain examples of cerebral tumour. An especially interesting and careful account of a case of a

¹ *The Romance of the Apothecaries' Garden at Chelsea*. By F. Dawtreay Drewitt, M.A., M.D., F.R.C.P. London and Sydney: Chapman and Dodd, Ltd., 1922. (Cr. 8vo, pp. xii+306; 11 plates. 7s. 6d.)

² *Etude Neurologiques*. By Georges Guillaumin, Professor in the Faculty of Medicine in Paris. Paris: Masson et Cie, 1922. (Med. 8vo, pp. viii+469; 18 figures. Fr. 25 net.)

lesion of the mid-brain from a revolver bullet is given also, and forms a valuable exercise in the applied anatomy of the nervous system.

The chapters dealing with diseases of the spinal cord contain careful descriptions of cases of trypanosomiasis, disseminated sclerosis, syringomyelia, Landry's paralysis, and other conditions, in all of which the lucid style of the writer and the way in which he marshals his facts combine to render their perusal both pleasant and profitable. In the section on syphilis of the nervous system the author is concerned chiefly with tabes, which is considered from both its clinical and pathological aspects. It is interesting to note that the views Dr. Guillain enunciated in 1903, which were in agreement with those expressed by Nageotte in the previous year, on the essential and earliest lesions of tabes dorsalis have recently received striking confirmation from Richter.

A section on the pathology of the cranial and spinal nerves follows; it is evident that the author is a believer in the theories of ascending neuritis, and he describes at considerable length a case which he attributes to infection from the appendix. In an interesting discussion on the significance of the Argyll Robertson pupil we are glad to see that he does not confine this symptom to cases of syphilis only.

In the chapters on the cerebro-spinal fluid, lumbar puncture, and various states of meningitis there are many points of great clinical interest, and here, as elsewhere, we must congratulate the author on the excellence of his clinical descriptions. Different aspects of the important subject of epidemic encephalitis are fully discussed in several chapters; one of the most novel and striking contains an account of a case in which contagion was observed, an event so rare as to deserve record.

Although this is not a book for the junior student, the senior student and the neurologist will find much profit in its pages; unlike many, it represents the personal views of the writer, whose experience and skill are both made evident.

CLINICAL LABORATORY METHODS.

DR. CUMMER'S *Manual of Clinical Laboratory Methods* describes the chemical and bacteriological methods which are employed in the laboratory for diagnosing disease. The blood, urine, gastro-intestinal contents, faeces, sputum, and body fluids and exudates are each considered in separate chapters. In most chapters a definite plan is followed: first, an outline for the routine examination is given, then a description of the simpler qualitative methods which are frequently employed, then an account of quantitative methods and those of intricate technique, and finally a discussion of what is found in various morbid conditions. It sometimes happens that in books of this sort the student is left bewildered by the multitude of different methods described for the performance of any laboratory test; this is not likely to happen with the present volume, for the author discriminates between reliable and indifferent, and does not hesitate to indicate the method which his experience has led him to prefer. Another good point is that elaborate quantitative tests, from the performance of which no useful knowledge can be derived, are omitted; such tests have their place in books of quantitative chemical analysis, but would be an encumbrance to such a manual as this. Nearly half the book is concerned with the examination of the blood, which is dealt with in a very comprehensive manner; the author has embodied an account of much of the recent work on the chemistry of the blood. The estimation of blood sugar, diastatic activity, blood urea, and the acid intoxication tests are all well described.

In face of so much that is accurate and helpful it is somewhat startling to read the statement which appears on page 321: "The typhoid bacillus forms acid with lactose and causes no change with glucose, while the organisms of the colon group form acid and gas with both glucose and lactose." Reading a little farther we find that in describing *Taenia echinococcus* (p. 335) the author writes that the "diagnosis is usually made only by finding the cysts on the operating table or at post-mortem." In connexion with the diagnosis of *Entamoeba histolytica* it is said (p. 326) that "a diagnosis is not possible without demonstration of amoeboid movement." These are possibly only errors of expression, overlooked in

compiling such a large book, but there are many branches of laboratory work, more particularly those concerned with bacteriological diagnosis, in which the author has passed over important points. The book will be useful for the chemical tests it describes; when dealing with bacteria and protozoa it should be read with caution.

RADIOLOGY.

THE third edition of *Electrologie et Radiologie* by Dr. GUILLAINOT, is a large, well-illustrated volume which aims at being a complete treatise on medical electricity, including radiology. The first edition appeared in 1905, was translated into English, and obtained recognition in France from the Academy of Medicine. The present edition has been brought thoroughly up to date and is very comprehensive. In its present form it consists of three main parts. The first (318 pages) is given up entirely to the study of physics and of electrical technique. The second (93 pages) deals with the physiological effects, electrobiology, and radiobiology. The third (313 pages) is entirely medical. Those who are interested in the subject, and who read French, will find it an admirable textbook although it is arranged and written on somewhat conventional and stereotyped lines. The index is comprehensive and should add to its value as a book of reference.

DR. REGINALD MORTON has edited an English edition of *Dosage Tables for Deep Therapy* as compiled and published by Professor Friedrich Voltz. The book should be of considerable value to those who are working upon the newer deep-therapy treatment and who do not understand the German language. Whilst the major portion of the book consists of the dosage tables themselves, there are preceding chapters which explain in detail the principles on which the tables are based, and the formulae by which the various calculations are made. In his preface Professor Voltz states that the tables, which are the result of a large number of exact measurements and calculations, should enable anyone to ascertain correct dosage in practical x-ray work without making arduous and time-wasting repetitions of measurements and calculations. The introductory chapters are arranged in three divisions. The first discusses the three conditions which determine the radiation dose—(1) dispersion, (2) absorption, and (3) scattering of radiations—and the essential rules are laid down and illustrated by diagrams. The second chapter takes into consideration six factors of paramount importance in x-ray therapy. These are the physical dose, the biological dose, the dosage quotient, the percentage of the depth dose, the effective dose, and the appropriate dose for specified conditions. The third is devoted to a consideration of three methods of measurement—the ionization meter, Kienböck's strips, and the selenium cell; and of these the first is considered to be the most reliable. Following the tables a concluding chapter deals with the management of the x-ray apparatus and the x-ray tubes, and in this the editor has included certain material which is the result of his own experience. In his preface Dr. Morton points out shortly the difficulties which have to be met in carrying out this new departure in x-ray therapy in a satisfactory manner, and we are in entire agreement with him when he states that the best results will be obtained only by those who devote themselves to this class of work to the exclusion of everything else. We recommend this book, which is quite a small one, to every radiologist whether he practises deep therapy or not; if he does practise deep therapy then it should be indispensable and it will save many mathematical calculations and much time. The printing is admirable, and for a somewhat difficult subject the explanations are easy to follow; the diagrams are good, and the general arrangement of the text satisfactory.

La Roentgentherapie des Tumeurs Malignes en Oto-Rhino-Laryngologie is the title of a treatise by Drs. PORTMANN and LACHAPÈRE of Bordeaux. It begins with an historical review

¹ *L'Electricité Médicale: Electrologie et Radiologie*. By Dr. H. Guillauminot. Third edition. Paris: Masson et Cie. 1922. (Roy. 8vo, pp. xvi + 632; 270 figures. Fr. 40.)

² *Dosage Tables for Deep Therapy*. By Professor F. Voltz. English translation edited by Reginald Morton, M.D. London: William Heinemann, Ltd. 1922. (Cr. 8vo, pp. x+98; 16 figures. 10s. 6d. net.)

³ *La Roentgentherapie des Tumeurs Malignes en Oto-Rhino-Laryngologie*. By Drs. G. Portmann and A. L. Lachapère. Paris: A. Maloine et Fils. 1922. (Demy 8vo, pp. 165; 7 figures. Fr. 5.)

⁴ *A Manual of Clinical Laboratory Methods*. By C. L. Cummer, Ph.B., M.D. London: H. Kimpton. 1922. (Med. 8vo, pp. viii + 484; 136 figures, 7 plates. 28s. net.)

of the many communications on the subject which have been published since 1896, when, within twelve months of the discovery of x rays, Despeignes reported a case of cancer of the tongue which had improved under x-ray treatment. A short account of the technique adopted is followed by a consideration of the 84 cases treated by the authors, and a large part of the book is taken up with reproductions of the case sheets in which all the details of each case are given in full and with meticulous care. These cases include such conditions as malignant disease affecting the tonsils (sarcoma, lymphosarcoma, etc.); epitheliomas of the soft palate, of the tongue, and the larynx; epitheliomas and sarcomas affecting the superior maxilla; fibrosarcoma of the ethmoids; and lymphosarcoma of the nasopharynx. This portion is illustrated by a few photographs of cases before and after treatment. In a comparatively short chapter the authors discuss the different kinds of growth affecting each region and indicate the treatment—x rays or surgical interference—which in their opinion should be recommended. In a concluding chapter the present position of deep therapy, and what results can be expected from it, is shortly reviewed. To those interested in the subject, especially laryngologists and radiotherapists, this book, dealing mainly with the personal experiences of the authors, should prove of distinct value.

PHYSICS AND CHEMISTRY.

THE progress of the physical and chemical sciences causes them to cover an ever-widening area, and thus tends to produce separate territories of work and interest; the isolation of these from each other acts disadvantageously when, as not infrequently happens, developments in one branch of study have important bearings on problems which are the peculiar study of another branch. There is generally little literature bridging the gulfs that separate divergent lines of work; textbooks fail to keep pace with discovery, and to understand even decisive original papers necessitates a preliminary perusal of previous researches on the subject.

We welcome therefore the appearance of a volume entitled *Some Physico-Chemical Themes*,⁷ by A. W. STEWART, which aims directly at breaking down the barriers. Its twenty chapters deal with as many subjects of characters so diverse that they appear at first sight arbitrarily chosen; they are, however, connected by the author's manner of treatment into a scheme by which they illuminate each other. Explanations introductory to each subject suffice to qualify the reader to understand the matters under discussion. A description of the oceanic salt deposits is founded on an account of the properties of double salts, in the formation of which the effects of residual affinity are illustrated. An account of the characters of the pseudo-acids leads to an excellent discussion of the theory of indicators. One chapter deals with non-aqueous ionizing media. A study of the properties of colloids leads on to an account of methods of computing the number of molecules in a given volume (Avogadro's constant), and so to the determination of the real dimensions of molecules; connected with these ideas are the subjects of absorption and catalysis. Dr. Stewart's volume concludes with a critical survey of the periodic properties of the elements in which the imperfections of Mendeléef's arrangement are brought under review.

In any criticism of such a book as this it is necessary to recognize the difficulty of deciding what explanations are superfluous for the average reader, a difficulty which is not lessened by the author's own high attainments. In the main, however, the error, if any there be, has been in explaining more than was necessary. The chapter on the theory of indicators deserves special mention for its excellence. Very good judgement is shown in the weighing and handling of evidence; from a study of the author's methods the reader may acquire skill in these important respects. The book is easy to read; it deals with many of the subjects most interesting to the majority of students and will be welcome to all whose interests are broader than can be gratified with the time at their disposal for reading original papers. There is room for more books that will do for other sections of science what Dr. Stewart has done for the sections treated in this volume.

⁷ *Some Physico-Chemical Themes*. By A. W. Stewart, D.Sc. London and New York: Longmans, Green and Co. 1922. (Demy 8vo, pp. xii + 419; 3 plates, 38 figures, 21s. net.)

NOTES ON BOOKS.

IN *First Aid in Childbirth and during Infancy*⁸ Dr. GERTRUDE CAMPBELL has published a series of lectures addressed to European and native ladies in India, where the almost complete absence of trained midwives and the shortage of properly qualified doctors may make knowledge of such matters of extreme value to women in every walk of life. By spreading such knowledge as widely as possible it is hoped that a demand may be created for a higher general standard of midwifery practice throughout the country. Dr. Campbell has tackled a difficult subject with conspicuous success, and much that she has written about the care of the expectant mother and the newborn infant might be read with advantage in Europe, where, in spite of attempts to educate the rising generation of mothers by means of ante-natal clinics and so on, ignorance, even among the better educated classes, is still profound.

In a book with the title, *Hay Fever and Asthma*,⁹ Dr. WILLIAM SCHEPPEGRELL relates the history of the growth of knowledge of hay fever and of its relation to pollens and grasses. For over a hundred years hay fever has been everywhere recognized as a definite disorder. The early investigations, which removed the disease from the category of mysterious conditions to one for which more or less specific causes could be assigned, were made in England, and recent researches have brought out its relation to asthmatic conditions; in fact, the two conditions are now often regarded as in their main essentials of the same nature. The author of this book is President of the American Hay Fever Prevention Association and chief of the Hay Fever Clinic at New Orleans, and is therefore probably in as good a position as anyone to speak with authority on the various grasses and pollens responsible, a subject on which knowledge is somewhat vague. He deals in succession with the nature of pollen and its relation to flowers in general, with the chemical composition of pollen, and with the chief characteristics of hay fever plants in the different states of America, though the common hay fever plants in other parts of the world are also mentioned. There is a chapter also on plants not responsible for hay fever. For those who are desirous of becoming more familiar with the actual botanical characters of the many grasses held to be responsible for hay fever this book may with confidence be recommended.

A revised edition of Mr. CLIFFORD WHITTINGHAM BEERS's well-known book, *A Mind that Found Itself*,¹⁰ has been published. The book, first published in 1908, contains a record of the writer's experiences during the three years he was confined in various asylums in America. Apart from its literary merit and human interest, this record has a special importance to the psychiatrist because of the insight it gives into the workings of a disordered mind, and Mr. Beers has given a particularly vivid description of his distorted mental processes during his illness. The book has been a most effective instrument in bringing about an altogether changed social attitude towards the insane. Upon his recovery in 1903, Mr. Beers determined to devote his energies and influence to the remedy of those abuses and defects in the treatment of the insane which he had observed—and himself experienced—while confined in asylums. The history of his work is described in the second part of the present edition of his book. He has been largely responsible for the organization of the National Committee for Mental Hygiene in America, and the outline here given of the growth of this new health movement is of the greatest interest. The National Committee has already done much to arouse public interest in the problem of mental disorder, and its influence is becoming increasingly felt.

The "Nem" system of feeding, devised by Dr. CLEMENS PIQUET, professor of pediatrics in the University of Vienna, has been much used in that city. An account of the system was given in our columns in the review, published on October 30th, 1920 (p. 656), of a large book by Professor Pirquet. Last winter he gave the Silliman lectures at Yale University; they dealt with pediatrics, and some of them with this particular plan of feeding. He has now written a small book entitled *An Outline of the Pirquet System of Nutrition*,¹¹ it contains a practical account of the system, and will be found useful by any practitioner who may wish to adopt it.

British Medical Journal.

SATURDAY, DECEMBER 30TH, 1922.

THE SECTION OF OPHTHALMOLOGY.

IN this, the last issue of the year, we complete the full report of the clinical and scientific proceedings of the ninetieth annual meeting of the British Medical Association, held in Glasgow during the last week of July. The scientific sections this year numbered nineteen, and held, in all, forty-one sessions, exclusive of the many clinical and laboratory demonstrations which took place in the afternoons. To record all these transactions—first in brief outline and later at full length—has been no small undertaking, and it will, we hope, be a source of satisfaction to our readers that this task has been brought to a conclusion by the close of the year.

The final instalment of the full report, printed at p. 1249, covers the second part of the proceedings in the Section of Ophthalmology, the first part having been reported in our issue of December 16th, at p. 1153. The occasion may perhaps be turned to advantage by reviewing very shortly the work and organization of this Section. The practice of ophthalmology touches both medicine and surgery, and in its scientific aspects it makes close contact at several points with pure science. Ophthalmology is therefore a subject of particular interest both for the specialist and for the general reader. The programme of business in this Section at Glasgow was clear-cut, according to the simple pattern favoured by many other sections in recent years. The first two mornings were each given to the general discussion of a particular topic, followed by the reading of short papers on unrelated matters of current interest. The third morning was set apart for a clinical meeting at the Glasgow Eye Infirmary, where a large series of demonstrations had been arranged by officers of the Section, and clinical cases were shown by the staff of the hospital.

The first of the set discussions, on the etiology of optic atrophy, was opened by a paper on the clinical side by a physician, Dr. C. O. Hawthorne; the more surgical aspects of causation were discussed by Mr. Hogarth Pringle, who gave his experience of atrophy following diffused violence to the skull; and Dr. Traquair dealt in particular with the finer points of diagnosis by the aid of perimetry. In the course of the debate on these papers Dr. James Alex. Wilson remarked on the value of this presentation of the subject by workers whose studies had proceeded along separate but convergent lines; he made the further point that close consideration of optic atrophy—an end-result—led necessarily backwards to early stages and so to underlying causes, and thence directly to the problem of prevention of eye disease, a subject opened up in that Section by Mr. Bishop Harman in 1921. The discussion as a whole may be confidently accepted as an adequate presentation of what is known of optic nerve atrophy as a clinical and pathological fact, and here it is impressive to note how wide and various are the relations of optic atrophy and how obscure in not a few instances are the ties which unite cause with effect. Even in such a conspicuous condition as violence applied to the skull the traditional view that a resulting optic atrophy must be the consequence of nerve injury due to fracture at the optic foramen is now challenged, and haemorrhage into the nerve sheath appears as a rival explanation. This latter suggestion has the chance of surgical verification, and it may be hoped that opportunities of putting it to the proof will not be lost. If in an issue relatively direct and simple there is room for doubt, it can hardly be a matter for wonder that optic atrophies

appearing in the course of various diseased states of the nervous and cardio-vascular systems offer many difficult and puzzling problems. In the first of the opening papers these atrophies were presented by Dr. Hawthorne as facts gathered from clinical experience, and some more or less hypothetical interpretations were proposed. Not on every point did subsequent speakers seize the chance either for controversy or for confirmation, and this is the more remarkable as the circulation in advance of the leading addresses gave intending speakers the opportunity to come fully armed for the fray. We should like, for example, to have heard opinions on the suggestion that some cases of sudden unilateral loss of vision, with subsequent nerve atrophy, may be due to embolism secondary to intracardiac thrombosis occurring apart from valvular disease; and on the argument that certain instances of post-neuritic optic atrophy associated with recovery from severe cerebral symptoms mean intracranial tumour. A third point worthy of debate is the possibility of primary bilateral atrophy as a consequence of intracranial tumours other than enlargements of the pituitary body.

On future occasions it might, perhaps, be possible to arrange beforehand to secure speakers who would undertake to address themselves to particular points raised in the opening papers, and such a plan need not necessarily interfere in any way with the full freedom of debate. In the paper dealing with the refinements of perimetry the appeal is mainly to the technical expert, but seeing the bearing of the observations on the early diagnosis of certain forms of nervous disease, the subject cannot safely be neglected by the physician. The general discussion produced many interesting records of personal experience and much valuable comment. There was universal acknowledgement of the medical as well as of the surgical aspect of clinical ophthalmology, and one of the speakers favoured the recognition of the "ophthalmic physician." Whether this would be accepted may be doubted, for anyone with the status of physician would hardly welcome a term implying limitation, even as Mr. Gladstone denied that he was a *Gladstonian* Liberal. Altogether the first day's discussion in the Section of Ophthalmology was worthy of the efforts of the officers to make it a success.

The second day's discussion, on the clinical significance and treatment of heterophoria, was opened by the President, Mr. A. S. Percival, who purposely made his introductory remarks brief in order that the guest of the section, Professor Webster Fox of Philadelphia, might be able to develop his thesis at greater length. Heterophoria, or the tendency of one eye to deviate in one direction or another owing to imperfect balance of the ocular muscles, is a subject of great interest to ophthalmologists. This motor anomaly of the external muscles of the eye will always be associated with the name of the late George Stevens of New York, who introduced the term "heterophoria" and classified the various forms of latent squint. To the general practitioner this condition is chiefly important as a cause of asthenopia and of diplopia; to the physiologist and the comparative anatomist it presents an interesting example of a defect of muscle balance; its attraction for the practising ophthalmologist can be perceived in the brisk debate which followed the opening papers at Glasgow.

THE AFTER-CARE OF TUBERCULOUS PATIENTS.

WHAT is to be done with the tuberculous patient who has passed through a sanatorium, who has made considerable progress towards recovery, and who yet, if he returns to his old conditions of life and work, will incur a serious risk of breaking down again? To this question there is no definite answer. The disease with which one

is dealing is so protean in its manifestations, so insidious in its reappearance, and so inconsistent in its response to treatment, that it is too much to hope for any ideal solution of such a problem.

With regard to the present somewhat tentative measures which are being employed in the after-care of tuberculous patients we have received from Dr. W. H. Dickinson, Tuberculosis Officer of the Dispensary, and Dr. Cecil G. R. Goodwin, Medical Superintendent, Barrasford Sanatorium, an admirably summarized report to the Human Tuberculosis Subcommittee of Newcastle-on-Tyne. During the month of September the authors paid a visit to the Cambridgeshire Tuberculosis Colony, Papworth, to the Industrial Settlements, Preston Hall, Kent, to Nayland Sanatorium, Essex, to Burrow Hill Colony, Frimley, and to West Heath Training Colony, Birmingham, in order to gain first-hand information of the schemes which have been inaugurated in these places. At Papworth—visited by many members of the British Medical Association during the Annual Meeting at Cambridge two years ago—there is accommodation for 210 men, besides 50 cottages available for married patients and their families. Instruction is provided in various suitable trades, such as carpentry, boot-making, tailoring, printing, hand-made jewellery, etc., and the men are so trained that after a time they are capable of earning sufficient to render themselves self-supporting. The settlement is permanent, a home is provided for the settlers for life, and it is the business of the colony to find a market for their products. This scheme is ambitious and comprehensive; it has met with considerable success, but, on account of the heavy initial outlay, to apply it generally would obviously be very expensive.

The other institutions, with the partial exception of Preston Hall, provide only for the training of the patients, and not for their permanent settlement. With the assistance of the Government a year or eighteen months is spent in teaching them a trade, in the hope that after the completion of their course they will be able to maintain themselves independently. The great objection to this method is that it is very difficult for men with handicapped lives to compete in the open market with others whose working ability is unimpaired. The usual sequence in these cases seems to be either that they fail to find employment at all or they are unable to earn sufficient for a livelihood without working so hard as to imperil their health. If they are so exceptionally placed as to set up a business on their own account, they find considerable difficulty in obtaining a market for their goods. Failing all along the line, they either return to their own work or apply for a training in another branch.

In their report the authors condemn the second scheme, largely because of its incompleteness. With the first they are obviously impressed, but they foresee, in the case of Newcastle, too many economic difficulties to recommend its general application. In the House of Commons recently the Minister of Pensions mentioned, apparently with approval, the fact that the late Government had decided that in the present financial circumstances it would not be justifiable to incur large expenditure in respect of such settlements. Whatever measures may be taken to solve the problem as it applies to the general population it will always be necessary to consider the permanent rather than the immediate effects which may be hoped for. However laudable it may be to build ideal cottages for persons who have developed tuberculosis, it is still more important to clear the slum areas and erect sanitary dwellings for those who are in danger of contracting it. It is in the prophylaxis of the disease that money and energy will best be spent, and it is in the prophylaxis of the disease that the ultimate benefit to humanity will be most evident.

PASTEUR.

The one hundredth anniversary of the birth of Pasteur was celebrated in Paris at a meeting at the Pasteur Institute on Wednesday, at which eulogies on Pasteur were spoken. On the previous day a meeting of the Académie de Médecine had been held, when M. Béhral presided over a large assembly, and speeches in praise of Pasteur were delivered by Professor Widal and others. A national celebration is to take place at Strasbourg in the spring, probably on May 1st, when a monument to Pasteur, consisting of an obelisk bearing a portrait medallion, will be unveiled within the university, where Pasteur was a lecturer on chemistry for six years (1849-1854). The cost of the monument has been defrayed by international subscription, to which a committee under the presidency of Sir Charles Sherrington, President of the Royal Society, has been able to forward a substantial contribution. An exhibit illustrating the results of Pasteur's discoveries and their influence on the development of the fermentation industries and of medicine will be open in Strasbourg from May to October, and it is hoped to retain many of the exhibits to form the nucleus of a permanent museum of hygiene. The best monuments to Pasteur are the Institut in Paris, and its analogues in other countries, among them our own Institute, bearing appropriately the name of Lister, in whom Pasteur recognized a kindred spirit and the greatest of his disciples. The Institut Pasteur was erected by the Académie des Sciences with money subscribed by all classes in all countries of the world. It was opened in 1883, but the life work of Pasteur, *vaincu du temps* as he said himself, was almost done. For a few years he followed the work of those who, in the words of his pupil and successor Roux, "were doing the best that was in them that the Institute should not be unworthy of him whose name it bore." Pasteur's character, his perseverance under difficulties, and the greatness of his achievements have made a strong appeal to the sentiment of the French people. He was born early in the morning of December 27th, and it was arranged that the bells of Dôle should ring for two minutes before 5 a.m., and that those of all the churches in Franche-Comté from the Jura mountains to the plain of the Saône should ring in response.

ARSENIC IN COCOA.

The occurrence of arsenic in cocoa must rank among the most unexpected events. A summons was heard at Richmond on December 18th against the Home and Colonial Stores for selling cocoa containing one-fortieth of a grain of arsenious oxide per pound. Messrs. Rowntree and Co., Ltd., of York, were also summoned for aiding and abetting in the alleged offence. Both defendants formally pleaded guilty. Evidence was given which showed that the seller had blended seven different cocoas, one of which, supplied by Messrs. Rowntree, was found to contain arsenic to the amount of one-tenth of a grain per pound. The arsenic was traced to a quantity of potassium carbonate, used by the manufacturers to render the cocoa soluble. Nothing was stated as to the source of the potassium carbonate or the origin of the arsenic it contained. Formerly arsenic as an impurity of potassium carbonate was so unlikely as to receive no consideration. Such proportions as a hundredth of a grain per pound might have been found, but that proportion is a commonplace in manufactured chemicals. The *British Pharmacopoeia* permits two parts of arsenic per million, or one-seventieth of a grain per pound, in potassium carbonate. Shortly before the war there came on the market for the first time a sort of potassium carbonate which contained arsenic in a proportion of about one grain per pound. No one seemed to know where this stuff came from, but there is little doubt that it was of German manufacture, and had been produced by some unusual process. On the outbreak of war a scarcity of potash salts arose, and this particular supply disappeared. Now apparently it has come back on the market more vitiated than ever. What must have been the proportion of arsenic in a sample of potassium carbonate which, being added

to cocoa in quite small amount, produced a mixture containing one-tenth of a grain of arsenic per pound? The statement made to the court on behalf of Messrs. Rowntree showed that the firm had taken precautions to ensure the purity of the materials they used in the manufacture of cocoa. In July they were informed that some of the loose cocoa they supplied contained traces of arsenic. The chemists employed by Messrs. Rowntree immediately instituted a searching analytical examination, and it was ascertained that the potassium carbonate used for the purpose already mentioned contained a substantial quantity of arsenic. Inquiries were addressed to the manufacturers of this lot of potash, but no explanation had been obtained. Messrs. Rowntree sacrificed the whole of the cocoa—some 300 tons, varying in value from £100 to £250. The period during which the impure cocoa was sent out was about two months, and since August 1st the firm was confident that all the cocoa issued from its works was made from ingredients absolutely free from arsenic. A witness for the Home and Colonial Stores stated that that company, as soon as it heard of the discovery, had withdrawn 65 tons from its shops and 20 tons from its warehouses. How it came about that arsenic was present in the common potassium carbonate supplied to Messrs. Rowntree has therefore not been satisfactorily established, but it is certainly to be hoped that it will be ascertained, in the interest of food manufacturers as well as for the safety of the public. It is impossible to examine everything for arsenic regardless of whether it is a likely or unlikely impurity, but it seems evident that more extensive analytical scrutiny will be needed in future.

SMALL-POX IN THE PAST.

BEN JONSON began his Epigram to the Small-pox with the apostrophe:

"Envious and foul disease, could there not be
One beauty in an age and free from thee?"

and the literature of the next two centuries contains many expressions of the repulsion with which small-pox was regarded. Many of these were collected by Dr. J. G. McVail in an article he wrote in 1893. The evidence is conclusive and all goes the one way. Coming down to the nineteenth century, we may recall how Mr. Holman Hunt related in the *Times* a conversation he had had with Dr. Stephen Lushington, the famous lawyer whose portrait he had painted. Lushington was born in 1782 and lived until 1873. His name is now, perhaps, best remembered for his share in the separation of Lord and Lady Byron in 1817. He was not only a very distinguished lawyer, who became Judge of the High Court of Admiralty, but one who in his time had mixed much in society, both political and aristocratic. Holman Hunt asked him for his opinion as to the good looks of the women at the beginning of the nineteenth century as compared with those of the women of the period in which the conversation took place. Lushington began his reply by saying that it was difficult to make any comparison, because in his early days it was very rare to see a young woman who had not a pock-marked face, so common was small-pox. Another instance of the way in which vaccination was regarded early in that century is afforded by what Joseph Farington—extracts from whose diary of the period between 1793 and 1821 are being published in the *Morning Post*—had to say upon the subject of the opposition to vaccination in 1806. Farington, who has already been mentioned in our columns with reference to his acquaintanceship with John Hunter and Edward Jenner (March 25th, 1922, p. 430), was a landscape painter of considerable repute, a member of the Royal Academy, who lived from 1747 to 1821. In his diary under date June 27th, 1806, he wrote: "The opposition to Vaccine Inoculation was spoken of & its destructive effects & the necessity of doing something to prevent it. Wilberforce [William Wilberforce, of anti-slavery fame] had said in the House, when the difficulty of discouraging the natural small-pox was under discussion, 'Should the plague appear in the Country wd. you not consider it necessary to stop its progress,

& why not this fatal disorder.' Barnard much approved this. Dr. Jenner's disinterestedness was [already] mentioned. Before He published an acct. of his discovery, Sir Walter Farquhar sd. to Him that if He chose to preserve it a secret He might make £100,000 by it. It wd. be easy for Him to prove its value to Medical men of Character, who wd. recommend & warrant its efficacy, which wd. enable Him to get £10,000 a year by it; but Dr. Jenner determined to give it at once to the world.—Wilberforce sd. The obstinacy of the people in refusing to avail themselves of it seemed to rise out of their Characteristic disposition; they would be at liberty, & sulkily say, They wd. do what they pleased with their own. 'I will,' continued He pleasantly, 'have a right of choice,—if I have a mind to beat my wife who shall hinder me.'—But, He added, though people cannot be forced to use Vaccine inoculation, some inoculation might be enforced of necessity.—He said the vaccine inoculation has spread more considerably in other Countries than in England; Even in remote Countries, and even in China, a country in which innovation is jealously opposed, it has been admitted.—In India it is used." Glancing over some of the periodicals antivaccinists issue to-day, a note like the following (*The Vaccination Inquirer*, August 1st, 1922, p. 98) strikes the eye: "The chairman [at Taunton] 'was afraid some people needed an epidemic to teach them the need of vaccination,' and we ourselves fear another epidemic may be needed to fully reveal to them its [that is, vaccination's] murderous folly!" Surely a person who thinks in that strain must have a mind which responds merely by opposing what everybody else affirms. It may partly be the fault, as Wilberforce suggested, of the traditional British "bull-dog" obstinacy in claiming to "do what they pleased with their own."

SCIENTIFIC RESEARCHES ON FOOD PRESERVATION.

THE Department of Scientific and Industrial Research has issued the report of the Food Investigation Board for 1921. It is a record of scientific investigation both valuable and interesting; the problems the Board seeks to solve are primarily industrial, and in some of them only is there matter of direct hygienic interest. The report opens with a general account of the very complete low temperature station for research in biochemistry and biophysics at Cambridge, which has just been erected, and of which several illustrations are given. An original feature of this is that on the roof of the building there is a greenhouse having a plain glass roof, but insulated walls and floor, together with refrigerating pipes, so that while exposed to the sun plants can be kept at any selected temperature and their rate of growth under varying conditions noted. The work of the Board is carried out under the direction of a number of committees, including the Fish Preservation Committee, the Meat Committee, the Engineering Committee, the Fruit and Vegetables Committee, the Oils and Fats Committee, and the Canned Foods Committee. For the Fish Preservation Committee Dr. Clarke, working on "pink," a condition observed in dried salted fish, found one type to be due to a coccus (*Rhodococcus*) which grows not only on the fish, but also on the salt incrustations of storing sheds. In the endeavour to preserve herrings fresh it was found that some stored at 20° F. became soft in a few weeks; this was apparently due not to bacterial growth but to certain autolytic ferments in the liver of the fish, active even at that low temperature. One-third of the report is devoted to the work of the Fruit and Vegetables Committee, which has concentrated its attention mainly on apples, their preservation in cold and gas storage, the chemistry of their ripening, and their diseases when stored. Large scale "gas" storage tests have been continued; gas storage means a reduction of the oxygen in the atmosphere to between 5 and 8 per cent., as compared with 21 per cent. in normal air, while the CO₂ is increased to between 12 and 15 per cent., as compared with minute traces normally. Since in gas storage the

¹ Report of the Food Investigation Board for the Year 1921. London: His Majesty's Stationery Office. 1922. Price 1s. net.

atmosphere is dependent on the respiration of the particular variety of apple, the rate of that respiration and factors affecting it have to be determined, and are being studied. For the Oils and Fats Committee Dr. Ida Smedley Maclean has made some interesting researches on the formation of fat by yeast. She has found that the amount of fat obtainable from yeast depends largely on the method of extraction, and that a large part of the fat seems to be held in combination in the cell and built up into some complex which is broken down by a method of acid hydrolysis she has devised; yeast incubated for forty hours in glucose is found to gain most if not all of its fat from the carbohydrate, for the weight of protein lost from the yeast is considerably less than the weight of fat formed. The Canned Foods Committee reports at some length upon an investigation of the changes occurring in the canning of herrings; the bacteriological results were inconclusive, and further experiments are to be carried out. The constituents of the herring by itself were found to exercise some solvent action on tin, and the amount of tin dissolved under conditions similar to canning was found to be proportional to the free acid present. A special report by this Committee on the bacteriology of tinned meat and fish was published recently under the auspices of the Food Investigation Board, and has already been reviewed in our columns (October 14th, 1922, p. 700).

MEDICINE'S DEBT TO THE FINE ARTS.

That medicine and surgery owe much to the ancillary sciences of biology, chemistry, and physics is an obvious truism, but the help and inspiration that the profession of healing has received from pictorial and sculptural arts have not been so freely acknowledged. In examining ancient descriptions of patients and morbid conditions, the reader often looks anxiously, and too often in vain, for an illustration to clear away the mist of doubt left by the account in the text; for it is easy to recognize in old pictures examples of disease, such as achondroplasia, only within comparatively recent times awarded a place in our nosological lists. But the value of art to medicine is by no means confined to illustration, great as that help may be, especially in anatomy, and in a thought-exciting paper on "The debt of medicine to the fine arts," read before the History of Medicine Section of the Royal Society of Medicine on December 20th, Dr. J. A. Nixon of Bristol rightly laid stress on the intellectual stimulus that the fine arts have conferred on the followers of Aesculapius. He remarked that all the real progress in medicine has been won by those who, like artists, being by nature richly endowed with keen gifts of perception, have retained those gifts unimpaired, together with the Hippocratic secret of vivid mental imagery. Artists and medical men have different ways of looking at things; scientific and medical training often dulls the power of mental imagery that gives accuracy to our perceptions and justness to our generalizations, and, as Dr. Nixon points out, the acuity of observation shown in the masterpieces of Praxiteles and Phidias finds expression in the clinical descriptions of Hippocrates, who saw with the eye of an artist. Harvey's genius lay in his powers of artistic perception, not employed for creative art or merely for illustration, though he was a keen student and critic of the fine arts, but applied to accurate observation; further, his power of imagination enabled him to construct hypotheses which he tested by way of experiment. Christopher Wren, the greatest draughtsman of his age, had much to do with the invention of intravenous transfusion, and Leopold Auenbrugger, "a great friend of music and the arts in general," and the composer of an opera (*The Chimney-Sweeps*), laid the foundation of our whole method of physical examination of the chest by his *inventum novum* of percussion. Sir Charles Bell, who wrote of his discovery of the functions of the anterior and posterior nerve roots—"I know this will put me beside Harvey"—Louis Pasteur, J. M. Charcot, Sir James Paget, and others, such as Sir Prescott Hewett, though not so outstanding, had much artistic talent. Dr. Nixon's paper, though

pleasantly expressed and without a trace of the odour of the midnight oil, must have been based on much research, as is shown by the excellent examples he brought forward to support his thesis that the best work in medicine has been done by those who have the qualities of an artist.

RESEARCH IN ANIMAL DISEASES.

THE discussion on the importance of comparative pathology which took place at the Annual Meeting of the British Medical Association at Glasgow emphasized the fact that the problems of disease and of health, whether in man, animals, or plants, are nearly related, and the medical profession has therefore a close interest in the steps which are being taken to promote research in animal diseases. This is one of the many varied activities which the Development Commission sets out to encourage, and in its twelfth report considerable prominence is given to this subject. An advisory committee, consisting chiefly of representatives of the medical and veterinary sciences, which was appointed to report on the facilities available for the scientific study of the diseases of animals, came to the conclusion that the present state of affairs constitutes what the committee characterizes as "a national disgrace." Such a verdict was not unexpected; the apathy shown by the public at large towards the progress of scientific investigation has prevented the undertaking of any of the broadly conceived schemes of research known to be vitally important to public health. The committee considers that, in view of the great wastage caused by the diseases of animals, it would be unwise to neglect measures likely to increase the food supply and at the same time to lessen the cost to the taxpayer of the compensation payable in checking outbreaks of disease. The committee points out also that whereas in human medicine there has been an organized attempt to secure the benefits of new knowledge and new methods, in veterinary medicine the effort has been slight. Benefactions for the study of disease in animals have been, as the committee states, "surprisingly few." Moreover, students of diseases of animals have received relatively small support from State funds in comparison with those engaged in other branches of study. The appeal for support must be based on the benefits likely to accrue to human medicine from ancillary studies in animal pathology; on the saving which the consumer would effect if the waste caused by diseases in British flocks and herds could be reduced; and on the gain to trade within the Empire which would follow if more attention were given to the investigation of the many diseases which hinder the prosperity of the Dominions and Colonies.

THE CAUSE OF A COMMON COLD.

In the course of a public lecture given recently by a well-known member of the medical profession, he is reported to have said that colds were not caused by draughts. The speaker had plenty of precedents for making this statement; indeed, it has become almost an accepted doctrine of preventive medicine. Yet its truth is, we venture to say, very doubtful. It has certainly never been established with any scientific precision by a full series of observations. Without doubt it is contrary to the experience of many who are satisfied that in their own persons a chill may be followed by a "common cold" or coryza. The chill may be produced by sitting in a draught, especially if exercise has previously produced a slight perspiration, or even by spending some time in a cold room. The belief that a chill may be the affective cause of a common cold is quite in accord with the trend of modern views of the etiology and pathology of infections. The modern explanation would be that persons who are disposed to develop coryza after a chill are carrying about in the throat or nose one or more of the organisms capable of producing catarrh; it may be the pneumococcus or the *Micrococcus catarrhalis* or some other. The reaction following the chill seems to produce conditions favourable to the growth of the organism and the development of its pathogenic properties. Pasteur made an

observation which is very much to the point: the domestic fowl is refractory to anthrax under ordinary conditions, but he found that if he inoculated a cock with a virulent anthrax culture and then kept the bird's legs in cold water for some time, so that its body temperature, which in health is 42°C., fell to 39°C., it suffered from a generalized attack of anthrax. We do not, of course, call into question the belief, which is held alike by the public and the medical profession, that a cold can be caught from another sufferer; but we desire to make the point that a common cold or coryza may be due to an autogenous infection. We recognize equally that the chilly sensation which marks the actual onset of acute coryza may be mistaken for its cause.

MILK AND DAIRIES ORDER.

In a circular (335) dated August 28th, 1922, the Minister of Health drew the attention of county councils and sanitary authorities to the provisions of the Milk and Dairies (Amendment) Act, 1922, which came into force on September 1st, 1922, with the exception of Section 3, which relates to milk sold under special designations, such as "certified," "Grade A (tuberculin tested)," "Grade A," and "pasteurized," and which comes into force on January 1st, 1923. Hitherto the conditions relating to this specially designated milk were laid down in Orders made originally by the Food Controller, but in Circular 335 the Minister of Health said that he proposed modifying those conditions in a new Order. This Order (as so announced recently) was made on December 9th, 1922, and is called the Milk (Special Designations) Order, 1922. Under its provisions a county council or a county borough council is given power to grant licences to producers to sell milk as Grade A, but if a county council is unwilling or does not propose to exercise this power it may be conferred by the Minister on a district council, which is independently authorized to grant licences to those who are not producers to sell milk as "certified," "Grade A (tuberculin tested)," "Grade A," and "pasteurized." Licences may be suspended or revoked, but aggrieved persons may appeal to the Minister of Health against decisions to suspend or revoke. Schedules to the Order set out the conditions subject to which licences may be granted. Those relating to pasteurized milk differ materially from the conditions at present in force. The first two are: The milk shall be pasteurized—that is to say, retained at a temperature of not less than 145° and not more than 150°F. for at least half an hour, and be immediately cooled to a temperature of not more than 55°F. The milk shall not be so heated more than once and shall not be otherwise treated by heat. In Circular 335, to which we have already referred, the Minister of Health stated that before he issued the new Order he would consult representatives of local authorities and of the milk trade. This consultation does not appear to have been very effective, for on December 18th he found it necessary to make an amending Order, and in a circular (362) gives as a reason that he now finds it will be impossible for the necessary apparatus to be installed by January 1st, 1923, to ensure compliance with the terms of the original Order as regards pasteurized milk. The amending Order therefore defines such milk until July 1st, 1923, as that which "is treated not more than once by a suitable heating process and immediately cooled to a temperature of not more than 55°F." The Minister of Health has been singularly unlucky in the orders and circulars he has issued relating to milk. The well-known army phrase "Order, counter-order, disorder" is quite as applicable to civilian as it is to military instructions.

THE PREVENTION AND CURE OF SCURVY.

MISS E. MARION DELF, D.Sc., has recently carried out an investigation into the antiscorbutic value of South African food substances for the South African Institute of Medical Research.¹ The work was undertaken to discover the best

method of preventing scurvy amongst the native labourers in the Rand mine compounds. The commoner South African fruits and vegetables were tested in guinea-pigs, and, in a few cases, in monkeys also. Oranges were found to have a higher antiscorbutic value than peaches or pineapples, and the navel orange was superior to the naartjie. The pawpaw was found to be nearly as potent as the orange; this result is of importance because fresh pawpaws are obtainable in South Africa for eleven months of the year. Sweet potatoes and green mealies were found to be the strongest antiscorbutics amongst the common South African vegetables; pumpkins, sugar-cane, and dry Kaffir corn were of very little value; Kaffir beer was found to have the same antiscorbutic value as fresh milk. South Africa is well known to be one of the chief citrus-growing countries of the world, and it is surprising to learn that scurvy amongst the mine labourers is sometimes a serious economic problem. The reason for this is that during a drought fresh vegetables are very difficult to obtain. Dr. Delf's results show how necessary it is to have accurate knowledge when planning antiscorbutic measures, for pumpkin, sugar-cane, and Kaffir beer are cheap, easily obtained, and liked by the natives, hence they would be the natural first choice if fresh vegetable foods were not available as antiscorbutics; the results recorded show that they are nearly useless for the purpose. Miss Delf recommends sweet potatoes as antiscorbutics, and failing these a supply of fruit. Experiments were made to compare the total quantity of antiscorbutic required to prevent scurvy and the quantity required to cure the disease, and it was found that at least five times as much was required to cure as to prevent. A few experiments were made to test certain dried products to ascertain whether there was any potent antiscorbutic available in a dried form. Sun dried orange cake was found to be almost inactive, although an orange marmalade prepared without boiling the orange juice had a moderate antiscorbutic action.

THE INTERNATIONAL CONGRESS OF OPHTHALMOLOGY, 1925.

At the International Congress of Ophthalmology held in Washington in April, 1922, Mr. Treacher Collins presented an invitation on behalf of all the ophthalmological societies of Great Britain and Ireland to hold the next congress in London in the year 1925. The invitation was accepted on the motion of Professor Gullstrand, of Upsala, Sweden, seconded by Dr. Lucien Howo, of Buffalo, New York. A general committee consisting of representatives of the inviting societies has since met and has formed an executive committee, empowered to make arrangements for the 1925 Congress. It is to be held in London during the four days Tuesday, July 21st, to Friday, July 24th, 1925. The three official languages are to be English, French, and German. The subscription for membership has been fixed at £2. Invitations will be sent to the principal ophthalmological societies or other representative bodies in every nation, asking them each to nominate a delegate to the Congress who would be responsible for promoting its interests in the country which he represents, so as to endeavour to make it a great reunion of all those interested in ophthalmology throughout the world. The Executive Committee is composed of the following members: Mr. E. Treacher Collins (chairman); Mr. J. Herbert Fisher (vice-chairman); Mr. Ernest Clarke, (treasurer); Mr. Leslie Paton, 29, Harley Street, London, W.; and Mr. R. R. James, 46, Wimpole Street, London, W. (secretaries); Mr. A. B. Cridland, Mr. J. B. Lawford, Mr. Humphrey Neame, Sir John H. Parsons, F.R.S., Mr. A. H. H. Sinclair.

At a meeting of the Society for the Study of Inebriety to be held in the rooms of the Medical Society of London (11, Chandos Street, Cavendish Square, W.) on Tuesday, January 9th, at 4 p.m., Dr. Harry Campbell will open a discussion on "The pathology and treatment of morphia addiction."

Novæ et Vetera.

WITCHCRAFT.

MEDICAL men who deal with the ignorant and backward—a class by no means confined to the lowest social stratum or to the least accessible districts—not infrequently find themselves in contact with beliefs and practices that come under the heading of "magic." Such magical ideas and customs were long disregarded, save by a very small group of antiquaries, as beneath contempt and unworthy of notice. During the last generation, however, largely under the stimulus of the writings of Sir J. G. Frazer, these phenomena have attracted the attention of scientific investigators in several fields, and it has become apparent that such customs represent a survival of an earlier and pre-scientific attitude towards Nature. The general character of the beliefs, if beliefs they can be called, that underlay these practices and this attitude can now be reconstructed, in outline at least. This attitude, which we may call "magical," was not peculiar to one race or people but was the common inheritance of mankind. Moreover, the survival of such beliefs is in itself an important psychological phenomenon and as such of high interest to medical men.

Magic and Superstition.

It has become increasingly evident as a result of recent psychological investigation that man is even less a creature of reason than we had thought: that in many or most matters of life our opinions are formed first and the logical justification for them is the result of a later process. This fits in well with the general conclusion of anthropology that, in an early stage in man's development, feelings and impressions give rise to actions which seem contradictory to the rationalizing mind since they are not linked together by any clear body of belief. Such practices, especially when they are considered to be of a "religious" character, have therefore often been gravely misunderstood by investigators. These have often had the models of the higher religions before their eyes, and have regarded ritual as something based on a definite faith. It is, however, only in a later stage of his development that the underlying vague and inconsistent attitude toward the world around him becomes elevated by man into anything that can be called a consistent religion or body of belief. A yet later stage shows man giving reasons for the faith that is in him, when religions begin at last to seek to justify themselves and to explain their origin and nature. They now develop beyond a ritual into a rigid legal system and a fixed sacred tradition. All the great religions have done this, and all have sought to provide their followers with a complete explanation of the world in which they live. Then comes another stage in man's mental development. He finds that his world is not only subject to laws but that these laws are further and further discoverable. By accumulating experience and by investigating these natural laws he finds at last that even his own opinions and thoughts are subject also to laws, and he seeks to know something further of them too. Without this knowledge he cannot understand himself, for to do that he must first seek to learn how he came to be what he is. This last stage has proceeded but a very little way and cannot at present be traced back beyond the Ionian Greeks of the sixth century B.C.

Every modern society exhibits each of these stages of man's mental development. Even the most scientific and highly rationalized individuals show in the various departments of their thoughts all the several stages through which our species has passed. Moreover, in the process of development our minds like our bodies recapitulate in some sense the history of our kind. That recapitulation needs very careful and knowledgeable interpretation, but the general principle of its existence is, we think, fairly established. The child is, after all, not only the father but also the remote ancestor of the man. It is strange, too, how very persistent are some even of the very lowest of all folk beliefs. Under the stress of war with all the uncertainty of life and disturbance of society that it brought, have we not seen a marvellous recrudescence of the very lowest and simplest form of magic known to us—the imbecile "mascot"? The accidental association of success or good fortune with some trivial object—a common phenomenon among the least elevated races, and frequently encountered among the most degraded members of civilized society—spread itself through all classes under the disintegrative influence of war. It is one of innumerable instances that reveal how much of the savage

there is still in our mental make-up. With such facts before us a systematic study of the beliefs of the lower culture must perforce be of interest to our profession.

The Witch-Cult in Western Europe.

Miss Margaret Murray, who is best known as an eminent Egyptologist and an associate of Professor Flinders Petrie in much of his work, has recently produced an important and revolutionary book on the subject of witchcraft,¹ a particular department of magic. About the learning and labour involved in preparing this collection there can, we think, be no two opinions. As the result of many years of work Miss Murray has brought together in very convenient form a vast mass of evidence concerning the practice of witchcraft in our own and other Western countries. All medical folklorists and anthropologists, as well as all students of the "backward" human mind, will be grateful to her for this well arranged and documented record. For all these classes Miss Murray has rendered a literary service of no mean value. Concerning her interpretation of the facts that she has so skilfully collected opinions will naturally differ.

There can be no doubt that, given a belief in the effectiveness of witchcraft, human nature is so constructed that a certain proportion of mankind will seek to avail itself of the advantage over enemies and the help to friends which is held out to it. No anathema by a church or forbiddance by a law could wholly prevent this. Witchcraft was and is a reality in the sense that, like the wearing of the mascot, it always has been and still is practised by some minds on a certain level. Scientifically trained men have adequate tests of the effectual working of the measures they employ and the educated but unscientific community is partly, at least, under their influence. There are, however, strata of society that are not under this influence, and among them magical beliefs are common, and the practice of witchcraft is even nowadays by no means unknown. Farther back in history, in the seventeenth century and earlier, the belief in the power of magic was practically universal throughout the whole community, and the control by the scientifically minded hardly existed. What wonder, then, that witchcraft was much commoner than it is now?

Miss Murray has traced in great detail the actual practices of these earlier witches. She finds much in common in their practices throughout Western countries; she finds some traces of a common ritual, of a common form of government, and of a common form of initiation. In all this we can follow her and see the interest of her findings. She sees, too, in many of these practices the evidence of an earlier "religion" long antecedent to Christianity. Here, too, the great majority of anthropologists will share her views, save that probably most of them would like to substitute for the word "religion" some such phrase as "point of view," "mode of approach," or "attitude." There can be little doubt, we think, that in any community or group that believes in magical influence an extensive magical tradition will be handed down from generation to generation more or less unconsciously. Thus the foolish notion of the unluckiness of sitting thirteen at table or passing under a ladder permeates even intelligent society, though none can say how the belief reached him. Among unintelligent, uneducated, and unscientific people, and above all among those with idle hands and empty heads, much more elaborate ideas and even practices and rituals are passed on by some imperceptible and little understood process, the investigation of which is a part of the task of the new science of social psychology.

Witchcraft and Religion.

But Miss Murray goes beyond this, and it is here that we feel we must part company with her. She adduces these rituals and practices as evidence of the existence and consciousness and separate persistence of a peculiar "witch religion." This body of belief, in her view, is or was professed by a group of men and women in communion with one another, conscious of a common cause and a common faith, and united in opposition to the prevalent religion of Western Europe. Here, we think, she not only misinterprets the facts, but misinterprets also the nature of the early beliefs that these witch phenomena have preserved for us. The ancient attitude of man to supernatural powers, the attitude that preceded the world religion, was perforce a tolerant attitude. It was not, and did not profess to be, consistent with itself. The savage magic worker is fully prepared to admit the existence of

¹ *The Witch-Cult in Western Europe: A Study in Anthropology.* By Margaret Alice Murray. Oxford: Clarendon Press. 1921. (Med. 8vo, pp. 303. 16s. net.)

other magic workers who do their deeds of darkness or of light by quite different methods from his own. Why should he not? He professes no monopoly of truth; still less has he any clear idea of natural law. Intolerance can only begin after man thinks that he has a consistent view of the world, and when it further dawns on him that his is the *only* consistent view. Witchcraft of its very nature can take no such attitude.

Now, the great majority of trials for witchcraft in Western Europe were conducted by judges who were most deeply convinced that Christian doctrine gave the sole clue to the world's meaning. In their interpretation of the alleged facts of witchcraft the witch is almost invariably a blasphemous being who renounced God and consciously and formally rejected the Christian faith. That many of the poor wretches they condemned had indeed, in their ignorance and folly, attempted works of magic we most readily believe; that some of them in their despair, madness, or natural revolt did formally abjure religion we need not deny; that some in misery, fear, and bewilderment blasphemed and confessed all manner of foolish belief that had been handed down to them by others as ignorant and foolish as themselves, the evidence confirms. But the evidence proves too much. The very formality of the rejection of the hope of Christianity of which the poor wretches were accused shows that in the more elaborate of these cases we have to do with something more than the primitive magical attitude. It shows that the intolerance of the age, the prevalent faith, and inflamed minds worked upon by a popular obsession, were producing the very evil that they sought to destroy. In the outbreak of the witch mania we can see, therefore, no evidence for the good organization of the ancient and basic attitude to the world—the magic and Nature worship—of which we may still discern large traces in our population and of which times of social disintegration reveal yet ampler reservoirs. We see only a deterioration of the popular judgement which is as much a subject for the student of social psychology as is the witchcraft which it sought to overcome. While the general character of these witch phenomena was undoubtedly suggested by that old attitude to Nature that is summarized by the word "magic," most of the details which Miss Murray adduces are of far different origin. The use of the number 13, the statement of a rejection of the prevailing religion, the formal adherence to the "devil," the general character of the "worship" and of the "Sabbath," and of the "Mass," even the very names of the demons invoked, and the recitation of the Lord's Prayer backward, suggest nothing more than an inversion of Christianity. It is a very likely interpretation of the acts of suspected and heretical individuals on the part of an ignorant and fanatical population. The Albigenes, Cathari, and other heretics were accused of similar practices; and even if the actual occurrences of such practices were proved—and Miss Murray, we admit, goes some way in this direction—we should still consider that in the circumstances of the time such ceremonies might well be expected from souls in revolt. While many medical men will be greatly interested in Miss Murray's general thesis, and some will be stimulated perhaps to collect material from their own experience, there will therefore be very few, we believe, who will follow her to her main conclusion.

THE fifth Italian Congress of Medical Radiology will be held at Palermo in the last week of September, 1923, when the following subjects will be discussed: Pneumo-radiography, introduced by Professor Gortan of Trieste; Roentgenotherapy of cutaneous diseases, introduced by Professor Rossi of Parma; Radio-diagnosis of the urinary system, introduced by Professor Boidi-Trotti of Turin.

AT the one hundredth anniversary meeting of the Kings County Medical Society in Brooklyn, U.S.A., a resolution was unanimously adopted approving the establishment of a school of medicine to give free post-graduate instruction to medical practitioners in the county. It was announced that the use of all the city hospitals would be given for the course, and co-operation was contemplated in medical extension education between the Long Island Medical College and the welfare department of the city.

THE next congress of French-speaking alienists and neurologists will be held at Besançon in August, 1923, under the presidency of Dr. H. Collin. The following subjects will be discussed: psycho-analysis, introduced by Dr. Hesnard of Bordeaux; nervous diseases due to supernumerary ribs, introduced by Dr. André-Thomas of Paris; criminality in toxic psychoses, excluding alcoholism, introduced by Dr. Legrain of Paris.

Scotland.

PRESENTATION TO COLONEL MACKINTOSH, C.B., M.V.O.,
M.B., LL.D.

AT the Christmas meeting of the Glasgow Western Infirmary opportunity was taken to recognize the service of Colonel D. J. Mackintosh as medical superintendent of the institution for the past thirty years. The chairman of the board of managers, Colonel Roxburgh, referred to the position Colonel Mackintosh held as an acknowledged expert on hospital planning and administration, a reputation which extended far beyond the bounds of Glasgow and the West of Scotland, for not long ago he went to South Africa at the request of the Cape Hospital Board to lay out a large new hospital, which is to be utilized as a teaching school for the University at Cape Town. A man of enormous capacity for work, his hospital duties have never sufficed to exhaust his energy. For many years an officer in the Royal Army Medical Corps (Volunteer and Territorial Forces), during the South African war he equipped the Scottish National Red Cross Hospital, and for his help in this connexion he received the M.V.O. At the beginning of the great war he was A.D.M.S. of the Lowland Division (T.F.), and to him fell the duty of mobilizing the medical department of that division, and he had the responsibility of the health and sanitation of the division over a wide area. In addition, he was appointed to supervise the whole of the military, war, and territorial general hospitals in the Glasgow area. For his work in the great war he received the Military C.B. He has been a prominent member of the British Hospitals Association since its commencement, and was at one time chairman of its council. He is chairman of the Saint Andrew's Ambulance Association, and was for some years chairman of Branch and a member of Council of the British Medical Association. He has taken a keen interest in the nursing profession, and has been of considerable service in connexion with the formation of the College of Nursing and in all the negotiations which led up to the State registration of nurses. The presentation took the form of an antique salver in silver, for which Colonel Mackintosh made suitable acknowledgment.

GLASGOW WESTERN INFIRMARY.

The annual meeting of this institution was held on December 22nd, and Colonel Roxburgh, chairman of the board of managers, presided over a large and representative gathering. In reviewing the year's work the Chairman reported an increase of work in all departments. The financial position was more favourable than for some years past, and this was due to the large number and amount of legacies during the year, and also to a very substantial reduction in running costs. In all the managers were enabled to carry to capital account £19,294. Legacies and donations reached the high figure of £39,879. Ordinary sources of income showed a decrease of £5,893. Ordinary income reached £70,456 and expenditure £83,425 (a reduction on last year of £19,291). This deficit on ordinary working is the smallest since 1905. Intimation was made of a very handsome legacy of £50,000 for special purposes from the trustees of the late Mr. Alexander Elder, Liverpool. This money was to be devoted to an extension of the Nurses' Home, which was urgently required, and to the erection of a memorial chapel, both of which would bear the name of Mr. Elder.

GLASGOW VICTORIA INFIRMARY.

The report of the year's working was presented to the qualified contributors to this institution at their annual meeting on December 7th. The chairman (Sir John Stirling Maxwell, Bt.) announced that there was a deficit of £2,968 between ordinary income and expenditure, but that the yield from legacies over the year was unusually high, and the Governors were thus enabled to carry to capital account the very substantial sum of £25,557. Contributions from patients or patients' friends amounted to £770, as compared with £1,139 during the previous year.

LISTER MEMORIAL IN GLASGOW.

At a meeting, on December 20th, of the Executive Committee of the Lord Lister Memorial Fund, held in the City Chambers, Glasgow, the design submitted by Mr. G. H.

Paulin, A.R.S.A., for the statue in Kolvingrove Park, was unanimously accepted. Among those present at the meeting were the Lord Provost, Sir Donald MacAlister, Sir Hector Cameron, Professors R. Kennedy and J. H. Teacher, and Dr. R. M. Buchanan. Mr. Paulin's model shows Lord Lister seated and wearing academic robes. The Glasgow Corporation will be asked to provide for the statue a site adjoining that of Lord Kelvin. Professor Teacher informed the Committee of the arrangements made by him for the exhibition in the Pathological Institute of the Royal Infirmary of objects of interest and other personal relics relating to the life and times of Lister.

THE CENSUS OF SCOTLAND, 1921.

County of East Lothian.³

East Lothian, or Haddington, had a population of 47,487, being an intercensal increase of 9.8 per cent., probably due in part to June holiday-makers, especially in the golfing town of North Berwick, where the increase was 39.4 per cent. The urban population is 48 per cent. of the total, including Tranent, North Berwick, Haddington, and Dunbar. In 1801 the county population was 29,986 and it has grown irregularly to its present maximum, the growth being most observable in summer resorts and in the coalfield. The proportion of females to 100 males is 106.8, against 101.5 in 1911—summer visitors being again in question. The average male age is 28.9, and the female 30.5. Of children under 15, 6.7 per cent. had lost their father, 3.5 their mother, and 1.0 per cent. both parents. There were 4.9 persons per occupied house, and 123 occupants per 100 windowed rooms. This is higher than at the last three censuses, but lower than at the three previous to that. In one-roomed houses there lived 2.8 per cent. of the people, in two-roomed 34.7 per cent., in three-roomed 20.3, and in four-roomed 13.6. There were 264 Gaelic speakers, all bilingual. Of occupied persons aged 15 and upwards, 25.6 per cent. were in agriculture, 16.4 in mines and quarries, and 12.6 in personal service.

County of Fife.

This important county,² lying between the Firth of Tay and the Firth of Forth, had a census population of 292,925, being an intercensal increase of 9.4 per cent., to which summer visitors to St. Andrews and other coast towns could have contributed comparatively little. At the 1911 Census the decennial increase was found to be 22.3 per cent., and ten years earlier 16.8 per cent. In 1801 the population was 93,743, or less than a third of its present total, and every decade has shown an increase. Fifeshire is notable for the number of its burghs, of which there are no fewer than 28, ranging in population from 508 in the ancient village of Culrois to 39,899 in Dunfermline and 39,591 in Kirkcaldy. The University city of St. Andrews had 9,336 inhabitants, an increase of 18.4 per cent., but the largest increase was 36.6 per cent. in Dunfermline, which now includes the naval station of Rosyth. The total urban population in the county is 182,867, or 62.4 per cent. of the whole; the female population in the proportion of 104.7 to 100 males. The average age of males was 28.4 years, and of females 29.9. Of children under 15, 6.2 per cent. had lost their father, 2.9 their mother, and 0.5 both parents. Of males aged 15 and upwards, 39.7 per cent. were single, 55.1 per cent. married, and 5.2 widowed or divorced; for females the corresponding figures were 38.5, 51.3, and 10.1 per cent. Gaelic speakers numbered 893, all bilingual. In regard to housing, the average number of persons per 100 windowed rooms was 143, a figure differing little from that of the last four censuses, though less than in 1861, 1871, and 1881. The urban average of persons per 100 rooms was high in the coalmining and industrial areas, being 226 in Cowdenbeath and Lochgelly, 197 in Buckhaven, Methil and Inverkeithing, and 158 in Dysart. There were 3,858 one-roomed houses in the county, of which 2,460 were in the burghs. In Cowdenbeath 14.6 per cent. of the houses consisted of a single room. Of males aged 12 and upwards, 90.6 per cent. were in remunerative occupations, and 28 per cent. of females. Of the total occupied population, 22.9 per cent. were in mines and quarries, 8.2 in commerce (excluding clerks), 7.6 in personal service, 7.3 in agriculture, 6.6 in metals, 6.3 in transport and communication, and 6.0 in textiles. In coalmining 28,140 males are engaged. Female occupations include 8,185 in personal service and 5,936 in textiles.

Ireland.

CITY HOSPITAL FOR DISEASES OF THE SKIN AND CANCER, DUBLIN.

At a recent meeting of the City Hospital for Diseases of the Skin and Cancer, Dublin, Dr. C. M. O'Brien read a report, which stated that the number of attendances registered from September 30th, 1921, to September 30th, 1922, was 9,529 (2,799 at the Finsen Light Department, 6,730 at the dispensaries). Patients were admitted on the recommendation of the various general hospitals (military and civil) including some on the recommendation of Poor Law boards, county councils, and certain charitable institutions. The number of in-patients was 182, and of this number 47 had cancer in various stages of development. Of these 47 cases 17 were discharged cured, 13 cured sufficiently to allow of their resuming work, 11 had their cancer controlled and their pain considerably relieved, one died, and 5 are still under treatment. Of the remaining 136 patients suffering from acute skin diseases, such as lupus, psoriasis, eczema, ringworm, etc., 115 were discharged cured, 9 relieved, and 11 were incurable. The report continued:

"This year we accepted invitations to Paris and Berlin. At these scientific congresses we had the privilege of examining the success and failures of men of all nations with our success and failures. We now find that we have already said fourteen years ago. This was that cancer in certain stages of development and in certain situations of the human body is curable by radium, and without egotism we claim the credit of being amongst the very first in Europe to proclaim to the world these joyous tidings, and to exhibit to our professional brethren undoubted cases of cancer perfectly and permanently cured."

"When cancer is internal or has already attacked the bones and cartilages or glands there is at present no known cure, and the fight between man and this fell disease never for one moment leaves the ultimate issue in doubt. Here again we in this hospital claim to be amongst the very first in Europe who have had the courage of making known this most tragic fact."

"We disclaim any connexion with sensational announcements or nauseating literature as to the causation or cure of cancer. The widespread distribution of such literature, we believe, to be the bane of true scientific research. We are conscious of the painful fact that to-day there is nothing really known as to the cause of cancer that was not known to the physician of old."

Correspondence.

CANCER DEVELOPING AFTER CESSATION OF IRRITANT.

SIR,—Having read Dr. Archibald Leitch's important contribution on the above subject (p. 1101) with great interest, I desire to place on record the fact that the results obtained experimentally are in conformity with, and substantiated by, clinical experience, as far as the dermatoses of the paraffin workers of the Scottish shale oil industry are concerned.

I have had frequent opportunities of verifying the fact that epithelial hyperplasias continue, and that cancers may develop long after workmen have ceased work in the paraffin departments, such opportunities arising through (1) permanent incapacity for work the result of illness or injury, (2) prolonged periods of unemployment, and (3) the subsequent progress of workmen affected after their removal from contact with crude or semi-refined paraffin on account of extensive dermatitis or conditions suggestive of future malignancy. A few instances may be given to illustrate the point:

1. A stillman (oil-boiler man) was permanently incapacitated by injury some fifteen years ago. Prior to his disablement he had a chronic dermatitis of the face due to paraffin. This has persisted since his injury up till the present time, and on three occasions since ceasing work epitheliomata have been removed from his face, the first occurring several years after his incapacity began, the last about one year ago; several years have elapsed between each occurrence. This man is now about 75 years of age.

2. Paraffin worker, aged 69 years, twenty-four years of service in paraffin departments, has had chronic indurated dermatitis, with epithelial hyperplasias and wartiness of hands and arms for many years. Nothing suggestive of malignancy was apparent at the date of his ceasing work about two years ago. Since then he has developed an epithelioma of the forearm (one year ago), and an epithelioma of the scrotum within the last few months. Both growths were verified microscopically.

3. Paraffin worker, 74 years of age, removed from paraffin departments after excision of epithelioma of the face about ten

years ago, following a chronic dermatitis. The dermatitis and artiness of the face have remained since then, an epithelioma as removed from the face, about four years ago, and within the last year a similar condition developed on one foot.

In none of these instances were the subsequent growths metastatic conditions, each being primary, as far as clinical investigation indicated. The cases given are illustrative of a tendency for hyperplasias to persist, and show the possibility of cancers developing after removal from contact with paraffin in its crude or semi-refined state. In view of this feature it has been my custom for some years to keep under observation at regular intervals men who have been removed from contact with these materials on account of extensive dermatitis or conditions suggestive of possible future malignancy.

It would be most useful if similar cases were recorded by others who may have had experience of them.—I am, etc.,
Brosburn, Linlithgowshire. ALEXANDER SCOTT, M.D.

THE CANCER PROBLEM.

SIR,—In the issue of the *BRITISH MEDICAL JOURNAL* of December 9th there is much food for thought on the subject of cancer. I have already this year in the *JOURNAL* referred to the subject of cancer in connexion with the lymphoid diathesis—that is, a class of patients liable to disease of the lymphoid tissue, such as tonsillitis, appendicitis, and enteric fever. I pointed out as the result of years of clinical observation that in these patients, if they contract malignant disease, it takes the form of sarcoma. And I might go further and state that the incidence of sarcoma is the incidence of tuberculosis. There is, perhaps, one exception to this rule. People who have had chronic bronchitis for fifteen to twenty years, die as a rule of tuberculosis; and unless the sputum is examined the death certificate will be chronic bronchitis. I have proved the soundness of that view over and over again. Patients of the lymphoid type are practically immune to carcinoma. And in this connexion the immunity of the spleen should be kept in mind.

Dr. Murray, Dr. Leitch, Mr. Howtrec, and Dr. Scott deserve the thanks of the profession for their illuminating searches. I step in to make a few suggestions to these distinguished investigators, with reference to the possibility of the cure of malignant disease.

If the leucocytosis of the blood in the experimented animals could be raised three times the normal, I would hazard the opinion cancer injections would be nullified. In a normal man the leucocytosis is put down as 7,000 per c.mm. of blood. In favourable cases of pneumonia the leucocytosis may reach 10,000 or even 30,000 per c.mm. of blood. In erysipelas the leucocytosis is most marked. So, here we have two diseases, the germs of which (under proper precautions) could raise the leucocytosis in the animals experimented on and perhaps prove one means of cure and prevention.

Of course it might be necessary to attenuate the microbes of pneumonia and erysipelas; but that should not prove an insuperable difficulty. Until the parasite of cancer is discovered, I believe that on the lines I have laid down (that is, artificially raising the leucocytosis) lies our most promising hope of combating this fell disease.—I am, etc.,

Glasgow, Dec. 9th. JOHN T. MACLACHLAN.

SIR,—The rôle played by continued irritation in the production of malignant tumours has long been recognized, and periodically emphasized, as, for example, in the *JOURNAL* of December 9th, where cases of various forms, alleged to be caused by paraffin, arsenic, soot, and x rays, are adverted to. Another form might be added—namely, "kangri-burn," a squamous epithelioma of the skin of the abdomen and thighs of natives of Kashmir, alleged to be caused by charcoal heaters worn beneath the clothing in cold weather.

As, however, cancer is prevalent in all places, and in all classes of the community, it is obvious that none of these irritants can possibly be other than a contributory factor in its production. The true proximal cause of cancer must of necessity be of universal applicability.

However caused, cancer is a typically specific disease, and it is impossible for such a disease to arise without a definite specific cause. Like syphilis and tuberculosis, cancer is an auto-infective disease, and in most cases the point of origin is known, generally too late, owing to its insidious and unsuspected onset. There is every reason to believe that the healthy body is immune from the "x" cause of cancer, and

that it is only when vulnerability has been established that the disease can arise. This vulnerability I have elsewhere defined as the "condition precedent," and it is induced by degeneration of tissue from any cause, more especially from obsolescence of organs, senescence, senility, chronic disease, continual irritation from whatever source, traumatism, and congenital susceptibility. Once this "condition precedent" has been established the individual is at the mercy of the agent responsible for this characteristically specific disease, just as a predisposing condition favours and permits the attack of the pneumococcus. It is impossible to discuss this subject satisfactorily in a short communication, but in a book I have just published* I have sought to establish its etiology and exogenesis.

It is often asked, "Is cancer increasing?" Unquestionably it is, numerically. It continues, and will continue, to increase, *pari passu* with the increase of population. When the population of any place becomes doubled, then, at the end of this period of growth, there will be twice as many cases of death from cancer as there were at the beginning; but, when the population remains stationary, so also does the mortality from cancer, since the percentage ratio remains the same—practically a uniform 10 per cent. of all deaths. The annual return of the Registrar-General for England and Wales for 1920 states that the total number of deaths from all causes for that year was 466,130, of which 43,787 were attributed to cancer, and 42,500 to tuberculosis, each accounting for about 10 per cent. of all deaths. This is a very interesting and most significant fact.

It does not follow that, because more deaths are reported as due to cancer than to tuberculosis, the former disease is more prevalent than the latter, for many people who live to mature age and die from other causes have been at one time the subjects of tubercle, as proved by many cured tuberculous lesions found *post mortem*; whereas it is more than doubtful if any case of well established and undoubted cancer has ever been cured. Cancer may remain quiescent after operation for an indefinite period, only to light up into fatal activity later on, and had the victim died during the interval from intercurrent disease—for example, pneumonia, he would have been declared cured by operation of his original cancerous disease.

Of the total of 1,256 deaths during 19 years in my own practice in a town whose population remains practically constant, 136 were due to cancer; giving the percentage of 10.82, which is somewhat greater than that of the Registrar-General, namely, 9.39, but it goes to show that the percentage of cancer is not increasing.

Driffield, E. Yorks, Dec. 10th.

A. T. BRAND, M.D., C.M.

INTERNAL USE OF LIQUID PARAFFIN.

SIR,—For a considerable time I have been warning my patients against taking paraffin internally for constipation, as I felt that it might be leading to the development of cancer. I formed this opinion on two grounds: (1) the production of cancer by soot and hydrocarbons, and (2) the fact that the taking of a mineral substance was such a profound departure from the normal, a device of, one may say, super-civilization; and as our civilization expands, and we depart farther from natural living, we seem to suffer more from this dread scourge of our race.

The articles published in your issues of November 18th and December 9th confirm my forebodings. The occupational cancer seems to need ten years of the irritation of the paraffin ere it develops. We are now at more than that interval of time since this treatment of constipation was started; shall we soon see cases showing themselves?

I use as a substitute agar-agar. This can be purchased quite cheaply, in the form of sticks, and cut up with scissors and stored in a tin. A tablespoonful once or twice a day has an excellent effect.—I am, etc.,

MONTAGUE DIXON,
M.D., B.Sc.Lond.

Melton Mowbray, Dec. 13th.

PROFESSIONAL SECRECY.

SIR,—The question of medical secrecy has been agitating our ranks for some time. It has been proposed that information given to doctors in the exercise of their profession shall be privileged in courts of law, either absolutely or to a modified degree, varying with the opinions of the proposer:

* *Cancer: Its Cause, Treatment, and Prevention.*

but in each case it is claimed that the doctor shall be on a different footing from the ordinary witness.

Two classes of person at present have this special privilege—the lawyer, because without it the courts of law could not function; and the priest, because the Church was strong enough to take it. It has been proposed that a similar privilege shall be granted by Act of Parliament in the case of medical witnesses.

On the other hand, we are advised by lawyers that such an Act of Parliament would be difficult to obtain and would probably not give us what we want. We are further advised to take our stand when the occasion arises and put it to the judge that we do not claim privilege as doctors but that the particular communication in question was made to us in confidence and that we cannot, as honourable men, disclose it. We are at the same time assured that a judge has as acute a perception of honour as a doctor, and that we shall not be forced to violate our honour. We should have more confidence in this were it not for certain recent cases, such as *Needham v. Needham*, where the doctor has been forced into revealing to the court what he desired, on a point of honour, to keep secret. But I think that, if the medical witness had stood firm, he would have prevailed: and that, in my opinion, is the essence of the matter.

On weighing the whole question it seems probable that we should be better advised not to press for an Act of Parliament. But I do hold most strongly that information gained in the exercise of his profession should be as sacred to the doctor as to the priest.

After all, what is the basis of all medical work? Surely, trust and confidence in the doctor. No doctor should reveal the confidence of his patient without the consent of that patient except where enjoined by statute law. Such a breach of trust is dishonourable and inexcusable. The right to keep inviolate the confidences of our patients will have to be won by us in exactly the same way as it was by the Church—that is to say, it will have to be fought for. A priest has no privilege by law, but all courts of law recognize that by no threat or compulsion can a priest be forced to disclose what he considers himself bound in honour to conceal; and I submit that it is by a similar refusal that the medical profession will gain an equal immunity.

We can expect no help from the legal profession: their work is to carry out the administration of the law, and they are naturally opposed to anything which makes that more difficult. When I say they are opposed I mean as lawyers; as private persons, or rather as sick persons consulting in their doctors, they will, I think, agree with me.

It may be asked, what part has the British Medical Association in all this. The answer is that if and when such a refusal by a doctor to give evidence leads, as is not unlikely, to his committal for contempt of court, surely his position is greatly strengthened if he has at his back the official body of his profession. The British Medical Association can inform the general public by means of the Press and Parliament; and I am sure that if such a case be put squarely to the people there can be only one answer.—I am, etc.,

Brighton, Dec. 9th.

A. C. GEMMELL, M.B.

HELIO THERAPY.

SIR,—In your issue of October 14th Dr. A. Rollier of Leysin, Switzerland, in his address on "The share of the sun in the prevention and treatment of tuberculosis," states: "One must not take air and sun baths during meridian hours." And again: "It is also essential, as we have always said, that the heat of the midday hours should be avoided . . . and one should have recourse to the earliest morning sun."

Some years ago I pointed out that sanatorium treatment is a reversion to the wild—that the midday heat in England is baking and depressing—and that sanatorium patients in this respect should be treated as the inhabitants of the fields. One seldom sees the fox, hare, or rabbit abroad in the midday heat; they are then in the shade, and they feed in the bracing air and tonic sunshine of early morn and dewy eve. Heliotherapy should, I think, be administered on east and west balconies on similar lines—as it is the morning and evening sun which is tonic—and midday heat should be avoided.

A little time ago, during some sanatorium extensions, I tried to introduce the north and south position of the wards, but unfortunately without success, as I believe there is a Ministerial ruling against it. But emboldened by Dr. Rollier's experience, I would point out that the idea of hospitals and sanatoriums facing south is wrong. The administration

block should face south, but the wards should run north and south, and have east and west balconies. Then the morning and evening sunlight can be secured and administered, whilst the two balconies allow of air bathing in almost any weather. Shelters from the midday heat is also secured, as the sun beats down on the roof and gable end, and the patients can rest within the wards.

If a balcony faces south heliotherapy can only be carried on with difficulty; children do worse in summer than in the frosty days of early winter, when the air is bracing, and the sun's rays most temperate.

My friend Alderman Norman of Merpeth informs me that plant life under glass does better in a north and south glass-house than in one running east and west. And I venture to think that what is good for the animal and the plant is good also for man.

In the building of sanatoriums and hospitals this aspect of the question should, I think, be kept in view. I have had some considerable experience in the building of sanatoriums, and in my opinion they should be in the shape of the letter H, the lower half of the H being wards. And these wards in my opinion should run north and south to give the sun its proper share in the treatment of tuberculosis.—I am, etc.,

T. M. ALLISON, M.D.

Hon. Phy.

Newcastle-upon-Tyne, Dec. 9th.

PSYCHIATRIC CLINICS.

SIR,—While agreeing with Dr. Davison as to the enormous possibilities of an out-patient clinic of psychotherapy, I fear lest his appeal for an "open-handed philanthropist" to start the scheme may scare that rare bird unnecessarily. I cannot believe that such an institution would prove at all a costly business compared with the in-patient home set up by the munificence of the late Sir Ernest Cassel.

Psychotherapists will agree with me that it is essential for the sake of treatment that each patient should pay a fee commensurate with his means. This would often amount to very little, but the institute would receive among its patients people of the large class which, though unable to find the usual fee for a course of psychotherapy, would gladly contribute up to half a guinea a session towards the funds. Thus the income from fees might amount to a not inconsiderable sum; and, on the other hand, it would not be necessary to provide expensive instruments of diagnosis and treatment, or elaborate electrical apparatus of proven uselessness. The institute should have little to face in the way of running expenses beyond rates and taxes, light and heating, and the maintenance of a small clerical staff.

It seems to me that the philanthropist would not need to guarantee more than £1,500 a year for three years, to secure the financial safety of such a scheme even if it were started in a fairly large way. If it succeeded, the institute would become self-supporting before very long, and soon self-propagating throughout the country so soon as its usefulness were evident.—I am, etc.,

London, W., Dec. 19th.

G. LAUGHTON SCOTT.

PSYCHO-ANALYSIS.

SIR,—The discussion which has been proceeding in your columns is one of much wider significance than the title implies. In particular the question as to the exact relations of physiology and psychology has come under consideration. So far as I have understood Dr. Steen he merely wishes to point out that as he writes as a psychologist he must do so from the psychological point of view and use psychological terms, and that if he were to use physiological terms in describing his researches in "behaviour" there would arise inextricable confusion. In this I agree most heartily with him.

In the department which we call for convenience tropical medicine there are a large number of sections. We have protozoologists, bacteriologists, entomologists, helminthologists, chemists, physicists, not to speak of clinicians of every variety. Every one of these is approaching a common problem by different methods of research. Suppose we take as an instance the etiology of beri-beri which has brought into the field a whole army of workers. No doubt all the first four groups of biologists have been engaged in this quest, but in addition the food deficiency theory has engaged the attention of expert chemists and it is in connexion with this

 Smith, J. Skokoe, T. Strother, G. W. Wigg, N. Wren.

UNIVERSITY OF LEEDS.

At the congregation held on December 20th the Hey memorial medals were conferred upon the following: Humphrey Hart Gleave, George Armitage, and Digby Chamberlain.

Sir Berkeley Moynihan, who has established medals in memory of William Hey, the founder of the Leeds Infirmary, made the first presentation. He recalled the chief facts in the history of William Hey, and said that the students and staff of the present day had come into a great inheritance by intellectual and spiritual descent, and by the solemn adoption of the men who had made the school famous. "To embody this spiritual heritage in material form," concluded Sir Berkeley, "the Council of the University have permitted me to endow the William Hey Memorial Medal. It is a matter of pride to me that those who to-day are to receive the medal for the first time have proved themselves worthy of their association with the name of our immortal founder, William Hey."

The following degrees were conferred:

M.D.—G. H. Hust'er.
M.B., Ch.B.—J. Bernstein (second class honours), E. Bayon, I. H. Cohen, Edith Ghosh, A. Goodman, Christine M. R. Hare, Margarita Kitson, J. R. Oddie, Violet M. Redman King, Jessie Sheard, and M. Sornasky.

UNIVERSITY OF DUBLIN.

SCHOOL OF PHYSIC, TRINITY COLLEGE.

The following candidates have been approved at the examinations indicated:

Taylor, C. H. Thomas, A. H. Whyte.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.

THE following, having passed the requisite examinations between October 2nd and 9th, have been admitted Fellows:

A. J. Abren, W. R. Beavis, L. van R. Becker, D. P. Bhargava, E. C. Braithwaite, R. V. Honnessy, J. E. Hurworth, C. G. Irwin, W. E. Johnston, G. D. Lindsay, E. H. M. Luke, S. B. MacMillan, S. A. S. Malkin, B. G. von B. Mello, C. E. W. Mendes, B. Morrison, P. N. Pedersen, J. M. Robb, G. F. Stones, J. Thompson, M. C. H. C. Todd, C. S. Wood.

Mr. C. W. Cathcart, C.B.E., and Sir James Hodsdon have been appointed representatives on the board of the Edinburgh Royal Infirmary for the ensuing year.

CONJOINT BOARD IN IRELAND.

THE following candidates have been approved at the examination indicated:

FINAL PROFESSIONAL.—Enid Balle, V. V. Brown, C. Cohen, M. Coleman, J. J. Cosgrove, W. J. Crawford, D. Eppel, A. T. Gallagher, H. J. Gillen, A. Goldfoot, J. J. Mackey, M. J. Mallon, C. O. J. O'Connell, M. D. O'Connor, P. W. O'Connor, M. Price, I. Richmond, M. A. Walsh.

D.P.H.—He'len M. Murnane.

The Services.

COMMISSIONS IN THE ROYAL ARMY MEDICAL CORPS.

AN examination for not less than fifteen commissions in the Royal Army Medical Corps will be held on January 31st, 1923. The presence of candidates will be required in London from January 29th. Intending candidates can obtain a full statement of the duties and emoluments of the service on written application to the Secretary (A.M.D.1), War Office, Whitehall, S.W.1, and applications to compete should be made to the Secretary not later than January 21st.

DECORATIONS.

THE following are among the decorations conferred for valuable services rendered in the field with the Waziristan Force, 1920-21:

O.B.E. (Military).—Captain (temporary Major) William Moore Cameron, B.A.M.C.

M.B.E. (Military).—Temporary Captain Danlat Ram Bhalla, I.M.S., Senior Subassistaunt Surgeon (2nd Class) Sundar Singh, I.M.D.

Foreign Decorations.

The following decorations have been awarded by the Allied Powers for service rendered during the war of 1914-19:

President of the French Republic.—Médaille des Epidémies en Bronze: Temporary Captain Thomas E. Hincks, R.A.M.C.

The late King of Hellenes.—Order of Redeemer—Officer: Lieutenant Colonel Nathaniel J. O. Rutherford, D.S.O., R.A.M.C. Order of King George I—Officer: Captain Hugh G. Hobson, O.B.E., M.C., R.A.M.C.

Surgeon Captains William G. K. Barnes, M.D., and Edward J. Biden have been awarded Greenwich Hospital Pensions of £50 a year in the vacancies created by the deaths of Fleet Surgeon J. H. Whelan and Deputy Inspector-General F. Y. Toms.

Captain W. Hunt, O.B.E., M.C., R.A.M.C. (attached Egyptian Army), has been promoted to Brevet Major for distinguished service in connexion with the military operations in Southern and Western Darfur.

DEATHS IN THE SERVICES.

Fleet Surgeon William Bainbrigge Fletcher, R.N. (retired), died at Wimbleton on December 5th. He was educated at St. Thomas's, and after taking the M.R.C.S. in 1862, entered the navy, attaining the rank of fleet surgeon on August 1st, 1883.

Brigade Surgeon Lieut.-Colonel Andrew Deane, Bengal Medical Service (ret.), died at Westfield-on-Sea on November 29th, aged 75. He was the son of the late George Deane of Drumosla, co. Cavan, and was educated at the Ledwich School, Dublin. He took the L.A.H. in 1866, the L.R.C.S.I. in 1869, and the F.R.C.S.I. and the M.D. Durh. in 1882. Entering the I.M.S. as assistant surgeon on October 1st, 1899, he became brigade surgeon lieutenant-colonel on December 4th, 1895, and retired, with an extra compensation pension, on April 1st, 1900. Most of his service was spent in civil

employ in the North-West, near the United Provinces, but for the last few months of his service he acted as inspector-general of civil hospitals in the Punjab. After his retirement he was appointed superintendent of the Royal Victoria Hospital, Belfast, and held that post for nearly twenty years, till October, 1920. His younger brother, Surgeon William Deane, also served in the I.M.S., and also in the North-West Provinces, where he died, at Naini Tal, in May, 1895.

Major Frank Blair Robson, R.A.M.C., T.F., died at York on November 20th, aged 34. He was educated at Durham University, where he graduated as M.B. and B.S. in 1915, after which he took a commission in the R.A.M.C., T.F., becoming captain on January 7th, 1916, and major on January 4th, 1918.

Obituary.

T. H. KELLOCK, M.A., M.D., M.Ch., F.R.C.S.,

Surgeon, Middlesex Hospital; Consulting Surgeon, the Hospital for Sick Children.

THE death on December 19th, after a short illness, of Mr. T. H. Kellock, surgeon to the Middlesex Hospital, removes a well-known figure in the surgical world of London at the height of a successful career.

Thomas Herbert Kellock was born at Tetnes, Devon, in 1863. He was educated at Tetnes Grammar School, at Emmanuel College, Cambridge, where he was a mathematical exhibitioner, and at St. Thomas's Hospital, where he won the Cheselden Medal. He took the diplomas of M.R.C.S. Eng. and L.R.C.P. Lond. in 1891, and soon afterwards obtained the F.R.C.S. Eng. He graduated M.A., M.B., B.Ch. Cantab. in 1891, M.D. in 1894, and M.Ch. in 1904. After serving for three years as medical superintendent of the Hospital for Sick Children, Great Ormond Street, he became surgical tutor, surgical registrar, and later assistant surgeon at the Middlesex Hospital. He was promoted in due course full surgeon to the Middlesex Hospital and lecturer in surgery, and was one of the examiners in surgery at his own university. On his retirement from the active surgical staff of the Hospital for Sick Children he was appointed consulting surgeon. He was also on the consulting staff of the Yarrow Convalescent Home, Broadstairs, and the Treloar Hospital for Crippled Children at Alten, and was surgical consultant to the London and South-Western Railway. During the war Mr. Kellock held a commission as Captain R.A.M.C. (T.F.), serving on the *à la suite* staff of the 3rd London Territorial General Hospital. He was a former president of the Section for the Study of Diseases in Children of the Royal Society of Medicine, and had been one of the honorary secretaries of the Medical Society of London. He was the author of many contributions to surgical literature, one of his last publications being a paper, written in collaboration with Professor Sidney Russ, on an attempt to procure immunity in malignant disease. This was characteristic of his inquiring and alert habit of mind which led him to try, often with success, new methods in operative technique.

Mr. Kellock will be remembered with affection by a large circle of friends, and by many patients who have reason to be grateful to him for his devoted attention. He had a manner which attracted children very much and made them amenable to him. His work at Great Ormond Street was some of the most important of his life, and it was a matter of deep regret to him that it was necessary for him to resign the post of surgeon to that hospital. He was essentially a general surgeon, and his teaching was on very sound lines. He was assiduous in his attention to those classes of surgical cases which are very exacting in their demands on the surgeon's patience and industry—namely, the deformities of children and chronic disease of bone and joints. He was a most loyal colleague and always delighted in carrying out investigations in collaboration with others. His work in conjunction with the late Cecil Lyster probably first drew his attention to the importance of co-operation between the surgeon and radiologist in the treatment of malignant disease; and in later years he kept in the closest touch with the researches being carried out by Professor Russ in the Cancer Research Laboratories at the Middlesex Hospital. The fruits of that work are yet to be seen, but Kellock may be ranked with those who have devoted a large part of their lives to the study of the cancer problem.

Mr. Kellock was extremely fond of country life, and in conversation delighted to recall happy memories of times he had spent in his native county of Devon. It was only his keenness to do good surgical work which prevented him from leaving London and living in the country. His work at the 3rd London General Hospital was a great strain on his strength,

and during the most strenuous part of the war he suffered from serious symptoms which gave him grave warning that he was attempting too much. He still stuck to his work, however, though his friends noticed a great change in his appearance and realized what a serious sacrifice he was making in order to do his full share of war work. On committee Mr. Kellock was always a most useful member, and his knowledge of hospital affairs made him a valuable adviser in all cases of difficulty in organization or administration.

He married in 1915, and is survived by his widow and one son.

The funeral took place on December 22nd. The first part of the service, held at Holy Trinity Church, Marylebone, was attended by many past and present colleagues at the Middlesex Hospital, and by Mr. James Berry (President), representing the Medical Society of London. The interment took place at Highgate Cemetery.

THE death took place on December 10th of Mr. HERBERT LUCAS, of Huntingdon, at the age of 80. He was educated at Guy's Hospital, and took the diplomas of M.R.C.S. Eng. and L.S.A. in 1865. In 1868 he went into partnership with Mr. Foster at Huntingdon. For the previous six or seven years Mr. Foster had been assisted by his son Michael, who in 1867 was invited by Sharpey to become demonstrator of physiology in University College, and lived to be professor of physiology at that college and at Cambridge. The place thus left vacant by the future Sir Michael Foster was taken by Mr. Lucas, who, until his retirement in 1921, continued to practise at Huntingdon. In addition to the work of a large practice Mr. Lucas held practically all the local medical appointments, and was for forty years surgeon to the Hunts County Hospital. He was a member of the British Medical Association, and was president of the Cambridge and Huntingdon Branch in 1900-1. In his younger days Mr. Lucas was a keen cricketer and sportsman, and was at one time secretary to the Cambridgeshire Hounds. He leaves a widow, one daughter, and three sons.

DR. ERNEST WILLIAMS JONES, of Aldridge, Staffs, who died from pneumonia on December 14th, at the age of 45, received his medical education at Birmingham, took the diplomas of M.R.C.S., L.R.C.P. Lond., in 1901, and graduated M.B. Lond. in 1904, and M.D. in 1911. By his premature death the medical profession is robbed of an attractive personality and an unusual type of practitioner. Settling in Aldridge, a village partly agricultural and partly mining, twenty years ago, Dr. Jones speedily built up a flourishing practice, but he was not content merely to live the life of the average country general practitioner—he had aspirations. For a time he was satisfied to concentrate on the bacteriology and clinical chemistry of his patients, and in those days his consulting room was littered with every variety of clinical machine. Latterly he was inclined to forsake the more material side of his work and he had become an enthusiastic psycho-analyst. Day after day (writes a colleague) he went to Birmingham, where, as a Ministry of Pensions neurologist, he bore complexes to the surface and tore himself to tatters. He gave himself no rest, and was always obsessed by his patients and their troubles, even when on holiday. Always delicate, he died a victim to the profession he loved and served so faithfully. Dr. Jones was a man of many interests, and in his time had followed the lure of many different hobbies, but his chief love was for Oriental art. In his house were many specimens of the craftsmanship of the Far East which he cherished and delighted to exhibit to his friends. Dr. Jones leaves a widow and four young sons, to whom our sympathy goes out. He was a young man when he died and had little time to make adequate provision for those he has left behind.

WE regret to record the death from pneumonia, on December 8th, of Dr. ROBERT GARNER LYNAM of Oxford, at the age of 63. He was born at Stoke-on-Trent, and was educated at King William's College, Isle of Man, and King's College, London, where he gained in 1880 the Warneford scholarship. In 1882 he obtained the diploma of M.R.C.S. Eng. and the L.S.A., and in 1884 the M.B. degree of the University of London. He held the posts of house-physician and house-surgeon at King's College Hospital, and also at the North Staffordshire Infirmary, and in 1890 he joined Dr. W. T. Brooks in practice at Oxford. In 1896 he graduated M.A. Oxon. as a member of Hertford College. During the war he held a commission as

Captain R.A.M.C. (T.), and was attached to the 3rd Southern General Hospital, Oxford. He was also anaesthetist to the Ministry of Pousious orthopaedic hospital at Headington. During the thirty-two years of his life in Oxford Dr. Lynam's varied talents and wide sympathies won him many friends. He was president of the Oxford University Chess Club, and had played against Cambridge and the American universities, and he was an active member of the University Lawn Tennis and Skating Clubs. He contributed many papers, particularly on literary and artistic subjects, to the Oxford Medical Society, and comparatively late in life he took up water-colour drawing, in which he attained considerable success.

Dr. WILLIAM DOIG, who was the oldest medical practitioner in Galashiels, died there on December 3rd. He received his medical education at the University of Edinburgh, graduating M.B., C.M. in 1881, and M.D. in 1892; he subsequently took the D.P.H. in 1918. After a few years as assistant with the late Dr. Thomas of Selkirk Dr. Doig started practice in Galashiels, where he soon became well known and highly respected. In 1899 he became surgeon lieutenant in the Galashiels detachment of the Border Rifle Volunteers, and on the organization of the Territorial Force he transferred to the 4th or Border Battalion (T.F.) of the King's Own Scottish Borderers, and attained the rank of major in 1912; he received the Territorial Decoration. During the war he served in several military hospitals in Edinburgh, Berwick-on-Tweed, and elsewhere in the east of Scotland.

Fleet Surgeon WILLIAM HENRY PUTNEY, R.N. (retired), died at Bournemouth on December 7th, aged 79. He was educated at the London Hospital, and took the M.R.C.S. and L.S.A. in 1868. He then entered the navy, attaining the rank of fleet surgeon in 1888, retiring soon afterwards; he graduated M.D. Durham in 1892. As a student he worked in the London Hospital during the cholera epidemic in the sixties, the last serious outbreak of cholera in London. He served as staff surgeon of H.M.S. *Condor*, then commanded by the late Lord Charles Beresford, in the Egyptian war of 1882, and was present at the bombardment of Alexandria, receiving the medal with a clasp, and the Khedive's bronze star. Admiral Sir Doveton Sturdee was under his care for malaria when serving as a midshipman in H.M.S. *Undaunted* at Bombay. After his retirement he practised for some time at Bournemouth, with Dr. Cory. He was a member of the British Medical Association, and took part in the first Annual Meeting of the Association there. He was unmarried. He was buried in the churchyard of St. John the Baptist's Church, Moordown, Bournemouth.

Medical News.

THE second part of the fifth course of lectures for the diploma in psychological medicine at the Maudsley Hospital will begin on Monday, January 8th, when Sir Frederick Mott will give the first of six lectures on the pathology of mental diseases, including brain syphilis, its symptomatology and treatment. On the following day Dr. Mapother, the medical superintendent, will begin a course of eight lectures on morbid psychology, illustrated by demonstrations. On January 10th Dr. Shrubbsall will begin his course on the practical aspects of mental deficiency, and Dr. W. S. Sullivan, medical superintendent of Broadmoor Asylum, his course on crime and insanity. On Monday, February 5th, Dr. Bernard Hart will begin a course on the psychoneuroses, and later on Dr. Hubert Bond his lectures on the legal relationships of insanity and treatment. Demonstrations will be given by Sir Frederick Mott and Dr. Golla, beginning on January 11th. The inclusive fee for all the lectures is 10 guineas; for a single course 2 guineas. The lectures and demonstrations will be given at various hours in the afternoon, mostly at 2.30 p.m. Applications should be made to the Director of the Pathological Laboratory, Maudsley Hospital, Denmark Hill, S.E.5, or to the Fellowship of Medicine, 1, Wimpole Street, London, W.1.

At a meeting of the Röntgen Society on Tuesday next (January 2nd, 1923) at 8.15 p.m., at the Institution of Electrical Engineers, Dr. A. E. Barclay will read a paper on the organization and equipment of a modern x-ray department, with special reference to the new department at the Manchester Royal Infirmary.

The address of the London and Counties Medical Protection Society has been changed to Victory House, Leicester Square, London, W.C.2.

GUY'S HOSPITAL is one of the institutions at which combined research on insulin is being undertaken under the auspices of the Medical Research Council. In order to help in this work the directors of Ashton and Parsons, Ltd., have arranged to pay £400 a year for six years and a half to the President and Governors of Guy's Hospital as a contribution to the cost of research on diabetes mellitus and other related diseases of metabolism to be carried on at Guy's Hospital Medical School. It is intended to use the money to establish a Parsons Fellowship.

THE first annual dinner of the Association of County Medical Officers of Health for England and Wales was held on December 15th at Pagani's Rooms, London, with Dr. G. Reid (Staffs) in the chair, when the guest of the evening was Sir George Newman. The president, in proposing the toast of "The Guest," briefly surveyed the evolution of the Association and its relation to the Government public health departments, the British Medical Association, and the County Councils Association. Dr. Bostock Hill, who supported the President, eulogized the work of Sir George Newman as a friend, adviser, and colleague. Sir George Newman, in reply, reviewed his work and relationship to the public health branch of the medical profession. He felt amply rewarded, he said, by the friendship returned by the county medical officers of health. He pinned his faith to the coming cause of preventive health services.

THE Far Eastern Conference of representatives of Red Cross Societies was held at Bangkok, Siam, from November 29th to December 7th, and was attended by delegates from Siam, India, China, Japan, the Philippine Islands, the East Indies, the Federated Malay States, French Indo-China, Australia, and New Zealand. The chief purpose of the Conference was to lay before the organizations in the East the peace programme of the Red Cross as adopted by the General Council of the League last March, and discussion ranged round the best methods of preventing disease through popular health instruction.

THE reference under the Safeguarding of Industries Act has decided that oxalic acid is properly included in the list of articles chargeable with duty under Part I of the Act.

AN interallied congress on cancer will be held at Strasbourg next spring, when the following subjects will be discussed: experimental production of cancer; spontaneous and provoked defensive reaction of the organism against cancer; irradiation treatment of mammary cancer.

THE number of schools for physically defective children certified in this country since April 1st, 1914, is 108. The total number is now 199.

THE number of lepers in the United States, which twenty years ago was estimated at 278, is now between 1,000 and 1,500.

A PAMPHLET, entitled *Shall the State throw away the Key?* has been published by the Association of British Chemical Manufacturers with the object of showing how wide are the ramifications of the fine chemical industry, and how much it means to the nation. Sir W. J. Pope, professor of chemistry at Cambridge, contributes a plea for national support for a young enterprise. Exactly what kind of support is expected is not stated there or elsewhere in the pamphlet, but the reader is left to draw his own conclusions from the remarks made about German competition; it is hinted that the goodwill felt towards a young enterprise should be coupled with a willingness to submit for a time to some inconvenience. Sir William Pope makes a reference to the trypanocidal drug "Bayer 205," the constitution and uses of which were described in our columns of September 23rd last (p. 569). Upon this drug the Germans found pretensions for the restoration of their tropical colonies. In our issue of December 16th (p. 1183) we referred to another drug obtained in America, and named "tryparsamide," having similar properties. Sir William Pope affirms that a well organized fine chemical industry in this country could undertake a scheme of work, routine-like in its simplicity, which would almost infallibly result in the discovery of a cure for sleeping sickness. The pamphlet deals briefly with fine chemicals as therapeutic agents in the treatment of tropical diseases, and as adjuncts to surgery and first aid. It then passes on to describe the various uses of fine chemicals in photography, in the making of solvents and varnishes, in the preparation of synthetic perfumes and flavouring agents, and as analytical reagents in various industries. Thousands of different chemicals are now available as the result of the recent development of the fine chemical industry in this country, and the British chemist, academic or industrial, has proved himself in no way behind the chemist of any other nation; the argument of the pamphlet is, however, that without national assistance the enterprise will have to be abandoned because it cannot quickly become self-supporting. Copies of the pamphlet may be obtained on application from the Association of British Chemical Manufacturers (166, Piccadilly, W.1).

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

Authors desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

For postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Atiology*, Westrand, London; telephone, 2630, Gerrard.

2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.

3. MEDICAL SECRETARY, *Medical*, Westrand, London; telephone, 2630, Gerrard. The Address Medical Association is 16, South F. Belfield, Dublin; telephone, 4737. 6, Rutland Square, Edinburgh; telephone, 4361, Central.

QUERIES AND ANSWERS.

X RAYS IN HYPERTRICHOSIS OF FACE.

DR. LEO A. ROWDEN (Leeds) writes: I have taught for many years that the x-ray treatment of this condition is not justifiable.

PAINFUL VARICOSE ULCER.

"H." writes: I have a patient, a lady 73 years of age, with an old chronic varicose ulcer on the dorsum of the foot. The most troublesome symptom is very acute nocturnal pain, extending as far as the knee. The local condition is excessively tender, and this, combined with the pain, causes continued sleeplessness. I would be grateful for any suggestions as to treatment. All the better known remedies have been tried to alleviate the pain, including bromide, barbitone, aspirin, phenacetin, phenalgin, etc. Opium, or any of its alkaloids, are contraindicated, as even in minute doses they cause an exzematous rash. The local condition has been treated with various ointments and pastes, without any permanent effect. Complete rest for a period of months had no favourable effect on the pain complained of.

INCOME TAX.

"J. F. D. W.'s" car transactions have been as follows:

1917 bought 10-h.p. Austin for	£295
1920 sold	£350
bought 8-h.p. Morgan for	£234
sold	£195
bought 10-h.p. Riley for	£630

When the Riley was purchased a 10-h.p. Austin was not obtainable; these cars are considered to be of similar grade.

* The total cost of replacement allowable as an expense of 1920 appears to be:

Cost of replacing 10-h.p. Austin, £234 - £350	£-116
Cost of replacing 8-h.p. Morgan, £630 - £195	£435
Net total cost	£319

Or the allowance can be calculated as follows: Assuming the 10-h.p. Riley to be the equivalent of the 10-h.p. Austin, "J. F. D. W." has not improved his equipment, but to maintain it has spent £234 + £630 = £864, less his receipts of £350 + £195 = £545—that is, a net expenditure of £864 - £545 = £319.

"J. C. C." holds a public appointment from September, 1921, at £170 per annum, rising by £10 yearly.

* The liability for the year ending April 5th, 1923, is £175, the amount receivable for the year of assessment, less any expenses incurred wholly, exclusively, and necessarily in the performance of the duties. If there are any such expenses we recommend our correspondent to make an estimated statement now and lodge a definite statement after April 5th, 1923, and before the July instalment of tax becomes due.

"R. C." bought in 1913 a new Rover landaulette, 12-h.p., for £500. In 1922 he bought a Volesey landaulette, 15-h.p., for £900, less £100 allowed for the old car. The Rover Company do not now make a landaulette, the 12-h.p. saloon being priced at £775.

* We consider "R. C." to be entitled to treat £775 - £100 = £675 as a professional expense of the year 1922.

"R. L." bought a second-hand Ford coupé in 1921 for £220; in 1922 he sold it for £85, and bought a second-hand Maxwell for £225.

* The amount allowable as an expense is £220 - £85 = £135.

LETTERS, NOTES, ETC.

UNSUSPECTED PREGNANCY.

DR. W. B. HUNTER (Londonderry) writes: The following case may come under the above designation. A widow over 40 years of age had never been pregnant during her married life. One morning some fifty years ago I was called to visit her, and when asking her sisters, who were present, what was wrong, they told me she was passing some blood and thought she must be suffering from piles. I asked the patient to lie down on the bed. The abdomen then seemed to be rather prominent, and I examined her by the vagina and found a baby's head presenting. I then told the sisters that she was going to have a baby. That assertion was met with contemptuous and loud hysterical screams of unbelief—and "hoots man boots, n baby, a baby. We sometimes thought you were a wee bit daft, but now we know you're daft at thegither." So using n phrase that has become an every-day one now, "we shall wait and see," I went home for breakfast. In the meantime a somewhat exciting drama was being enacted before a few spectators. The brother of the patient had been consulting on the illness with a widower 60 years of age who was in the employment of this brother as a gardener, horse tender, and other odds and ends. The widower said, having been a married man once he knew more about women in consequence than the brother who was a bachelor, diagnosed the case as "a change in her courses." When my diagnosis at that moment was mentioned to them the brother immediately "went for" the widower, declaring he would change the courses for him and drown him in the adjacent mill lake (stream). The old boy bolted at once, and a most spirited sprit was seen down the bank of the mill lake. The pursuer being stiff with rheumatism was not able to catch up the pursued, who found safety after crossing a narrow plank placed over the lake, in the adjoining meadows. Early in the afternoon I returned to my patient, taking with me a pair of Simpson's forceps. I considered these would be necessary owing to the age of my patient and the fact that she was a primipara. When the baby came, squalling very vociferously, into the world, the sisters thought I was not quite so daft after all, but the mother completely denied the ownership of the baby, and told us all that I brought it with me rolled in a cloth, and placed it amongst the blankets. This declaration she persisted in for a long time; whether she ever gave it up I don't know. Though she kept her brother's house, and was visited daily or seen by her sisters, she was never suspected of being pregnant. The preceding drama occurred over fifty years ago.

THE PHYSICAL TRAINING OF THE SOLDIER.

DR. E. CLAUDE TAYLOR writes: It is of great interest and importance to note the growing emphasis laid by army instructors—for example, Colonel Campbell (December 16th, p. 1186)—on physical training of the non-combatative order for the development of the recruit. All the qualities that one would desire for the civilian citizen, he declares, are evolved by exercises of the gymnastic and "Swedish" type, by games such as net ball and running. He also states that the upward curve is sometimes spoilt by the military drill.

It is impossible to attach too much significance to this in view of the constant statement that military drill is required for the physical development of boys and lads while at school or college. If people want their sons to become efficiently destructive so as to exterminate any they may be set against, let them. But it ought not any longer to be possible for medical men to back them up by the argument that such teaching will best make them physically and vitally efficient. According to Colonel Campbell (and others) it simply is not true. Even "daring and pluck" were inculcated by gymnastics; and "the game quickened the team spirit." Surely nowadays it is a world-wide team spirit that we are needing,

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments in hospitals, will be found at pages 26, 27, 29, and 31 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 28 and 29.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 236.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 5 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive post restante letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

499. Myocardial Degeneration in Progressive Muscular Dystrophy.

JOSEPH H. GLOBUS (*Journ. of Nervous and Mental Disease*, September, 1922, p. 236), at the New York Neurological Society, described changes found in a number of cases of this disease, in which the patient's condition had remained apparently unchanged for a long period, when suddenly pulmonary oedema, hydrothorax, and hydropericardium occurred and terminated fatally within twenty-four hours of the onset. He does not accept the theory that in such cases death is due to paralysis of the diaphragm, but considers there is another cause—namely, cardio-vascular disturbance. He states that he has found definite changes in the heart muscle entirely similar to those in skeletal muscle. He discusses the views of Oppenheimer (who recorded these lesions as a disease of the central nervous system) and of many other observers, who interpreted them as myopathic in character. Clinical reports have described enlargement of the heart, irregularity, tachycardia, and palpitation on exertion. Of eleven cases since 1879 in which the heart was examined, the above described myocardial changes were found in eight, and in the remaining three there were changes in colour, consistence, and invasion of subepicardial fat. In the case of a boy, aged 10, the autopsy showed that the muscles, including the diaphragm, were infiltrated with fat; no hydrothorax; several small pneumonic areas in the lower lobes, which were oedematous. The heart was pale, yellowish-red, flabby, and friable; the left ventricular wall showed many irregular translucent patches, apparently of fibrosis, unconnected with blood vessels. The flynnus was large, solid, and rich in lymphoid tissue, and the liver showed marked fatty infiltration. Microscopically the heart showed many connective tissue scars, muscle fibres in various forms of degeneration, surrounded by large bundles of connective tissue containing fat, which also surrounded blood vessels. There was a small round-cell infiltration, and muscle fibres showed oedema, atrophy, hyaline changes, and fragmentation. Globus concludes that the changes are less marked than in skeletal muscles, but that the heart does not escape myopathic processes in progressive muscular dystrophy. The heart plays an important part in causing death from this disease, and he considers that it should be studied more systematically during life and after death. In the subsequent discussion several speakers described cases in which no myocardial disease was observed, others had found changes in the cells of the anterior cornua. One patient, aged 82, had no sign of myocardial disease, nor was it found in fourteen of his descendants (in three generations). The consensus of opinion appeared to be that there were various types of progressive muscular dystrophy.

500. Treatment of Leukæmia by Sodium Cinnamate.

R. LAUTIER (*Bull. Soc. de Thér.*, October 11th, 1922, p. 209) states that there is an increasing tendency to regard leukaemias as a group of morbid manifestations due to tuberculous infection. It therefore occurred to him to try if the action of sodium cinnamate, which he had found so beneficial in pulmonary tuberculosis, would not furnish a further proof of the tuberculous nature of leukaemias. He records two cases in which improvement in the blood picture and in the general condition, as well as a diminution in size of the spleen and the lymph glands, took place after treatment by sodium cinnamate, which was given intravenously three times a week. The dose, which was at first 1 mg., was increased by 1 mg. at each subsequent injection. A careful watch was kept on the patient's reaction to the drug, a sense of fatigue or a slight rise of temperature being an indication to reduce the dose by a few milligrams, and not to increase it until two or three more injections had been given. The highest dose should not exceed 20 to 25 mg. When this dose is reached, it should be continued for a few weeks and then a return should be made to the initial dose, which is subsequently progressively increased.

501. A Triad of Symptoms in Nervous Dyspepsia.

I. BOAS (*Deut. med. Woch.*, October 20th, 1922, p. 1405) draws attention to a triad of symptoms which are commonly found in nervous dyspepsia. They are (1) a sense of pressure in the abdomen; (2) globus (not the so-called globus hystericus; and (3) nausea. With regard to (1) it is often more

or less constant, and it possesses certain well-defined characteristics. It is independent of extraneous factors such as the quality and quantity of the food. The sense of pressure often begins early in the morning, when the stomach is empty, and it usually lasts throughout the day. It is unaccompanied by pain, but as patients are apt to confuse a sense of pressure in the abdomen with actual pain when they are describing their symptoms it is well to interrogate them closely as to whether the sensation is painful or not. With regard to (2) the author distinguishes it from ordinary globus hystericus because his patients showed no other sign of hysteria. Nausea—the third symptom of the triad—is, like (1), independent of extraneous factors such as the quality and quantity of the food. The subjects of this condition are usually women between the ages of 30 and 50, but men also suffer from it, and the author has found it to be very common in Germany as the result of the extra physical and mental strain thrown on the nation by the war. When other diseases can be eliminated, the treatment for this condition is to discard every dietetic restriction and to encourage the patient to thrust her symptoms into the background. To save her from operative meddling is also an important task.

502.

Factors in Dyspepsia.

F. W. PALFREY (*Boston Med. and Surg. Journ.*, October 12th, 1922, p. 527) classifies five common types of dyspepsia, the first due to an irritable hyperæmic mænsa resulting from improper diet, drugs, alcohol, or catarrhal inflammations, with symptoms of mild pyrosis or vomiting on the ingestion of food. In the second type there is depression or inhibition of the secretory and motor functions from reflex or psychic influences, in which the main symptoms are anorexia, epigastric weight, nausea and vomiting of undigested food proportionate to the duration of retention in the stomach. A third type, with symptoms of fullness, pain, and vomiting of an acid fluid, is due to hypersecretion or gastro-succorrhœa, with probably pylorospasm. The fourth type includes those cases usually attributed to hyperacidity, but in reality due to the rate of pyloric discharge into the duodenum not keeping pace with the acid secretion of the stomach, whether this latter is increased or merely normal, such insufficiency in the rate of discharge being due possibly to deficiency in the neutralizing fluids of the duodenum. Symptomatically heartburn, acid regurgitation, a sense of prolonged retention, and vomiting which relieves are present, due to irritation, hyperæmia, erosion, or ulceration at the pyloric end of the stomach. The fifth group is evidenced by a sense of epigastric pressure, not easily relieved by belching, and due probably to the fact that the œsophagus, by approaching the stomach obliquely behind rather than above the fundus, is liable to lateral pressure or kinking. Treatment of the first type consists in allaying irritation by rest and starvation, with, if necessary, a preliminary washing out or encouragement of vomiting. In the second type change of air and mental and physical improvement are needed, with regular, moderate meals preceded by a mixture containing nux vomica and dilute hydrochloric acid. In hypersecretion with pylorospasm slow moderate eating is essential, with avoidance of special articles which stimulate acid secretion. In hyperacidity with suspicions of ulceration, rest and special dietary are needed, and preparations of ox bile to increase the flow of bile are indicated. In cases of valvular cardiac orifice with difficult eructation attempts theret should be restrained, while the diet should aim at smallness in bulk, the day's total being divided between six meals instead of only three.

503.

Umbilical Colic in Children.

H. L. COOPMAN (*Nederl. Tijdschr. v. Geneesk.*, October 21st, 1922, p. 1825) states that the medical profession in Holland is not so familiar with umbilical colic in children as it should be. On the other hand, there is a considerable foreign literature on the subject, especially in Germany. The condition consists in repeated attacks of colic at longer or shorter intervals, usually accompanied by vomiting. Physicians and surgeons differ widely from each other in the interpretation of the symptoms; the former, of whom Moro and Friedjung are representatives, regard it as a neurosis, while the latter, especially Kuttner and Mülhsam, who operated on their own children, consider that it is almost always due to masked appendicitis. Coopman records a case in a girl aged 8 in whom the symptoms were at first attributed to neurosis, and subsequently found to be due to a faecal concretion in the appendix, on removal of which they

disappeared. Coopman states that the only objective sign of umbilical colic is a pressure point 1 or 2 cm. below and to the right of the navel, and known as "Künimoll's point," from the surgeon who described it in 1921. On the other hand, if no pressure point is present, and the pain is equally severe on both sides, and the temperature is normal, the condition may be regarded as a neurosis and treated accordingly.

504. Pernicious Anæmia due to Stricture of the Intestines.

E. MEULENGRACHT (*Ugeskrift for Læger*, October 19th, 1922, p. 1401) regards stricture of the intestines as a very important cause of pernicious anæmia, on a level with bothrioccephalus anæmia in importance. In both cases the anæmia is probably induced by the absorption through the injured gut of toxic bodies which normally pass through the gastrointestinal system without being absorbed. The relation of pernicious anæmia to strictures of the intestines could best be demonstrated if after resection of the intestine and restoration of its normal function the anæmia could be cured. The author records two cases of pernicious anæmia associated with strictures, and in one case he hoped to establish the relationship of the one condition to the other by resection of the gut. The patient was a woman, aged 64, whose blood picture was characteristic of pernicious anæmia. She also suffered from signs of intestinal obstruction, and laparotomy revealed three tuberculous strictures of the upper part of the ileum. Though intestinal anastomosis was successfully established after resection of the constricted portions death occurred within twelve hours of the operation. No amoebæ or worms were found in the intestines, the lining of which was much altered above the strictures.

505. Treatment of Coryza in Infants.

KOETTLITZ (*Le Scalpel*, September 23rd, 1922, p. 926) observes that common colds or influenzal coryza in young infants are particularly worthy of attention, as they are often the exciting cause of otitis, bronchitis, and even of bronchopneumonia; if not causing such serious results, coryza produces dyspnoea and serious interference with suckling. He recommends a 10 per cent. solution of argyrol as being palatable and non-irritant, introduced into the nasal fossæ by the lacrimal ducts. Half the contents of an eye-dropper pipette is allowed to fall into both eyes, in mild cases two or three times a day, every three hours in more serious cases. When the nose is blocked it is difficult to spray with oily solutions, while menthol is dangerous for very young children, in whom it sometimes causes fatal laryngeal spasm. In coryza the lacrimal ducts remain permeable and allow the argyrol solution to filter through drop by drop; it arrives thus in the nasal fossæ. Two or three days at the most suffice to dry up an acute coryza and to avoid infective complications—otitis, pneumonia, etc.

506. Classification of Pulmonary Tuberculosis.

E. MARCHIAFAVA (*Il Policlinico*, Sez. Prnt., September 25th, 1922, p. 1257) has adopted the following classification of the varieties of pulmonary tuberculosis: I. Acute and subacute tuberculosis with a duration of weeks or months: (a) Haematogenous military tuberculosis, the infection being conveyed directly by the blood vessels or indirectly by the thoracic duct from chronic tuberculous lesions in other organs, especially the lymphatic glands; (b) caseous tuberculous pneumonia—(i) lobar or pseudo-lobar type, sometimes ending in ulcerative phthisis and rarely in resolution; (ii) a disseminated bronchopneumonic type which may be nodular and ulcerative or mixed. The anatomical process in acute and subacute tuberculosis is the formation of nodular or diffuse tuberculous granulation tissue including epithelioid endoalveolar proliferation. These productive processes are associated in various degrees with exudative processes. II. Chronic tuberculosis, lasting for years, of variable extent, either unilateral or bilateral, with predominance in one lung; apical or lobar in distribution, and sclerotic, ulcerative, or mixed in character. The anatomical lesions in this group consist of a mixture of productive and exudative processes with a tendency to fibrous transformation and new formation of connective tissue which retards or arrests the progress of the tuberculous process. III. Tuberculosis of very chronic character lasting for many years, its distribution being the same as in the second group. The predominant anatomical feature is the new formation of sclerotic connective tissue containing tubercles. Hypertrophy of the right ventricle is a complication of this type of pulmonary tuberculosis.

SURGERY.

507. Tonsillectomy in Certain Systemic Diseases.

N. WHITTON (*Journ. Laryngol. and Otol.*, November, 1922, p. 552) reviews the results obtained by tonsillectomy in chorea, epilepsy, goitre, and rheumatism. While septal tonsils are sometimes undoubtedly a source of focal infection and marked improvement follows upon their removal, there is no doubt that the operation does not always effect a cure of the disease for which it is undertaken, and possibly too much importance is placed upon the tonsil as a focus of sepsis. In the diseases studied for which tonsillectomy was performed with a view to cure or relief an interval of seven years was allowed to elapse after operation in order better to ascertain the results. Of 11 cases of chorea 3 were quite cured, and in the remaining 8 the disease was still present, though 4 have improved, so that the results, while too small for any general deductions to be made, are not very encouraging. In 6 cases of genuine epilepsy 4 became entirely free from fits, and the attacks in the other 2 were less frequent and severe. Five of these were under 12 years of age, and the only adult, though improved, was not cured. Of 15 cases of goitre 7 were simple, and 8 showed exophthalmic symptoms. Of the 7 simple cases 1 was cured, 2 were improved, and 4 showed no improvement, so that as a curative measure tonsillectomy does not afford good results in such cases. Of the 8 ophthalmic cases, 2 were improved, 4 were unchanged, but 2 severe "toxic" ones were cured, showing that in this variety the operation may be useful. The results in rheumatism were more encouraging, since of 23 cases, including acute, chronic, muscular, and rheumatoid arthritis, 14 were cured, 3 improved, and 6 unimproved. The three that showed improvement only had been cases of rheumatic fever, and in these there was no recurrence of acute symptoms, though pains were complained of in wet weather. In one case in which the rheumatism was complicated by flat-foot cure of both conditions resulted, the cure of the latter probably being due to the toning up of the muscles and ligaments consequent on using the foot freely again.

508. Frequency of Congenital Club-foot and Dislocation of the Hip.

QUIRIN (*Zentralbl. f. Chir.*, September 22nd, 1922, p. 1414) states that Proppé and Blencke and Schanz (see EPITOME, November 12th, 1921, No. 451) found that congenital club-foot had decidedly increased in frequency since the war, while the frequency of congenital dislocation of the hip had diminished. Quirin has drawn up the following statistics of cases treated at the Orthopaedic Institute at Zwickau in Saxony. From 1906 to 1921 inclusive there were 914 cases of congenital dislocation of the hip and 495 of congenital club-foot among 18,965 patients; from 1906 to 1914 inclusive there were 372 cases of congenital dislocation of the hip (4 per cent.) and 221 of congenital club-foot (2.3 per cent.) among 9,772 patients; from 1915 to 1921 there were 542 cases of congenital dislocation of the hip (5.88 per cent.) and 274 of club-foot (2.98 per cent.) among 9,193 patients. These figures show a distinct increase in the percentage of congenital dislocation of the hip, and to less extent of congenital club-foot. During the last year 52 cases of congenital dislocation of the hip have been reduced at the Zwickau orthopaedic clinic, 24 being bilateral and 28 unilateral; 43 were in girls and 9 in boys; 8 children were over 4 years of age. Twelve cases of congenital dislocation of the hip were also treated in the cripples' home at Zwickau. Successful results were obtained in almost all cases.

509. Sarcoma of the Clavicle.

LUSSANA (*Archiv. Ital. di Chirurg.*, August, 1922, p. 621) publishes two cases of sarcoma of the clavicle. (1) A man, aged 66, without any syphilitic or tuberculous history, while undressing five days previously noticed a creaking in his right collar-bone, accompanied by severe pain and inability to raise the arm. On admission an irregular fusiform swelling was noted in the external third of the right clavicle, and on moving crepitus could be felt; the skin over the swelling was normal and freely movable; no enlarged glands were felt. The Wassermann and tuberculin reactions were negative. The radiogram showed spontaneous fracture of the bone. There was no history of injury. The clavicle and growth were removed on October 30th, and on November 20th the patient left the hospital in good condition, but unfortunately died of bronchopneumonia a few months later. Examination of the growth showed it to be a central round-celled sarcoma. (2) A woman, aged 64, accustomed to carrying heavy weights, had complained for about two months of wandering pains in the right shoulder, and a month before admission noticed a painless swelling in the

clavicle; the skin over the swelling was normal; pressure caused pain but no appreciable movement or crepitus. The radiogram showed a fracture of the middle third. The clavicle was excised on January 19th, 1921, and when last seen, in January, 1922, the woman was quite well and showed no sign of return of the growth. Examination of the growth showed it to be a spindle-celled periosteal sarcoma.

510. Primary Tumours of the Spleen.

F. VIGI (*Pathologica*, October 15th, 1922, p. 639) states that primary tumours of the spleen are of special interest, not only on account of their rarity but also on account of the relative frequency of metastases due to the structure and situation of the organ. Apart from the rare cases of benign tumours of the spleen, such as fibroma, chondroma, and osteoma, and a few of sarcoma and endothelioma (Buntig, Foix-Rocmello, Guyot, Moppert, Risel, and Simon), it may be said that the only splenic tumours which remain to be considered are cysts and angiomata. The nosological entity of the cysts varies, because they are sometimes not really tumours, but simple serous cavities invested with peritoneum and sometimes blood cysts following trauma, or mere dilatation of the lymphatic system or true lymphangiomas. Haemangiomas, and especially the cavernous variety, are of special interest, both clinically and pathologically—clinically because the increase in size of the spleen may render an operation necessary, and pathologically because the question has arisen whether the term "tumour" is applicable to these forms, or whether they should not be regarded as malformations or hamartomas. Vigì records a case in a man, aged 53, whose death was due to apoplexy, in whom at the autopsy a large solitary nodule was found in the spleen which on naked-eye examination presented all the characteristics of a primary tumour, but differed from it by its microscopical features, which were those of an hamartoma.

511. Meningitis following Spinal Anaesthesia.

SERIOUS complications following spinal anaesthesia are of somewhat rare occurrence. E. WERTHEIMER (*Lyon Chirurgica*, July-August, 1922, p. 387) records a case of acute aseptic meningitis occurring twenty-four hours after spinal anaesthesia, which was induced for an operation for acute appendicitis. The anaesthesia was satisfactory and the appendix was removed. The following day the patient had a raised temperature, rapid pulse, and severe headache; Kernig's sign was positive. Lumbar puncture was performed, but no bacilli were found. Antimeningococcal serum was administered. The patient later exhibited all the signs of acute meningitis, but the spinal fluid contained no organisms. He subsequently made a slow but satisfactory recovery. This case was one of several to whom a spinal anaesthetic was administered, and alone showed any ill effects. In this patient intravenous injections of a 30 per cent. glucose solution relieved the symptoms, and the patient felt considerably improved, whereas lumbar puncture did not produce any result. It is therefore suggested that the injections provide a sure means of reducing the tension of the cerebro spinal fluid.

512. Renal Calculus.

QUIGNON (*Le Scalpel*, September 9th, 1922, p. 881) reports (with photograph) the case of a woman, aged 44, who had suffered for the last fifteen or sixteen months from wandering pains in the loins, more marked on the right side. In 1917 she had haematuria lasting three days but no colic, no passage of stones or gravel. For the last few months she had complained of frequent micturition, every quarter of an hour during the day and twelve or fifteen times at night. The urine was fetid and occasionally bloody. Owing to the stoutness of the patient it was impossible to make out the size of the kidney. Cystoscopy showed the bladder to be healthy, of weak capacity (holding only 100 c.cm.), and the right ureteral orifice red and swollen. Radiography showed calculus shadows on the right side. The right kidney was removed and found to contain no less than 360 calculi (besides some lost) composed of tricalcic phosphate. The patient did well.

513. Effect of Hyperpyrexia upon Early Gonorrhoea.

K. SCHREIBER (*Deut. med. Woch.*, September 29th, 1922, p. 1313) has observed that intercurrent inflammatory processes may profoundly influence the course of early gonorrhoea, forcing it to assume an abortive and comparatively benign character. With a view to exploiting this phenomenon, and on the assumption that it is the element of hyperpyrexia in intercurrent inflammatory processes which exerts a beneficial action on gonorrhoea, the author recommends the intraglandular injection of 10 c.cm. of sterilized

milk. The ease with which he illustrates his thesis was that of a man whose last sexual intercourse with a woman, suffering from gonorrhoea, was on January 26th. On February 1st he developed an acute staphylococcal infection of the tonsils, and it was not till February 10th that urethral symptoms appeared. Gonococci were found the next day in the urethral discharge. On February 17th the sterilized milk was injected; the temperature rose rapidly, and after February 19th no gonococci could be found in spite of repeated and careful search. Even provocative injections of milk and arthogen could not induce a reappearance of the gonococci.

514. Scapular Crepitation.

P. JACOBY (*Ugeskrift for Læger*, August 24th, 1922, p. 1071) has examined 100 men at a surgical hospital, and, though none of them suffered from disease of the shoulders, as many as 23 exhibited scapular crepitation. In most cases this was slight, but in some it was fairly loud. It was demonstrable on both sides in 7 cases, in 8 on the right side, and in the remaining 8 on the left. In extreme cases the crepitation may be audible more than a metro away, as well as being palpable. Its genesis depends on a variety of factors, including bony changes in the scapula and ribs, and abnormalities of the muscles and bursae. Being about twice as common in men as in women, it is probably often an occupational condition, and the author has found scapular crepitation in 5 healthy young adults, all of whom had led athletic lives. In some cases operative interference may be necessary owing to the pain and disability provoked, but in none of the 23 cases referred to had the condition given rise to pain or other symptoms. In such cases scapular crepitation may yet be of importance because it may be mistaken for adventitious sounds in the lungs. To avoid this mistake, the hand belonging to the side examined by auscultation should be laid on the shoulder of the opposite side so as to immobilize the scapula. The frequency of this condition is great, according to Bassompierre, who found it in 52 out of 72 muscular and healthy young men. But Lotheisen found it only once among 47,000 persons in whom this condition was specifically sought.

OBSTETRICS AND GYNAECOLOGY.

515. Treatment of Hydatidiform Mole.

E. A. SCHUMANN (*Amer. Journ. Obstet. and Gynec.*, October, 1922) points out that various observers have recorded a mortality following hydatidiform mole of 15 to 25 per cent. The treatment conducted in the cases concerned has been on the usual lines of curettage of the uterus, with particular care against perforation, and packing in the event of severe haemorrhage, the patient being subsequently observed for from two to three years in order to guard against the development of chorion-epithelioma. The causes of death are given as sepsis, haemorrhage, peritonitis, and chorion-epithelioma. Extremely divergent views have been advanced with regard to the frequency of the last named, and according to Sympers considerable reserve should be exercised in forming a diagnosis of chorion-epithelioma even as a result of microscopic examination of tissues removed at operation, for placental remnants may live in the uterus for a considerable time after termination of pregnancy, syncytial cells may wander widely in normal circumstances, and mechanically displaced chorionic villi may sometimes be found in the uterine, pelvic, and vaginal veins after severe labour. In view of the high mortality mentioned above—the highest death rate following any obstetric complication except puerperal sepsis and premature placental detachment—Schumann advocates that every hydatidiform mole should be regarded clinically as a malignant tumour calling for radical treatment. Diagnosis being made, the abdomen is opened, and after the uterus has been isolated by gauze packs the mole is inspected *in situ* after hysterotomy. If it is limited in attachment to the decidua the tumour may be shelled out and the uterine wound closed after the cavity has been disinfected with iodine. Should, however, invasion of the uterine muscle be present, showing macroscopically as little haemorrhagic areas (and this is found in the majority of cases), supravaginal hysterectomy is performed; an exception may be made in the case of a primipara to whom the risks of conservative treatment have been explained. Treatment on somewhat less radical lines has been recommended by other authors, especially when the bleeding is profuse, the cervix rigid, and the patient near the climacteric. Schumann records three illustrative cases treated by hysterectomy, in which macroscopic (confirmed by the microscope) examination of the mole and uterus showed that curettage would probably have failed to eradicate syncytial elements which had already deeply invaded the uterine muscle.

516. Treatment of Perineal Tears.

F. LEXNEN (*Arch. méd. Belges*, October, 1922, p. 983) draws attention to the important part played by the levator ani muscles in supporting the pelvic organs, and says that in the treatment of perineal tears produced at labour it is necessary (1) to coapt the torn muscular fibres of this muscle; (2) to prescribe, after suture, exercises for its preservation in good condition. The two halves of the levator ani are felt as cord-like structures, passing downwards and backwards one on each side; when they have been identified by outward pressure of a finger introduced two-thirds of the way in the vagina, they are sutured to each other by catgut before the skin edges are united. Exercise of the levator ani is secured by instructing the patient to make voluntary contractions of the sphincter an twenty times daily for fifteen days after labour; a contraction of the levator accompanies each movement of the sphincter, as may be verified by vaginal examination.

517. Prevention of Puerperal Sepsis.

LOUROS (*Zentralbl. f. Gynäk.*, October 21st, 1922, p. 1681) advocates, on the following lines, immunization of expectant mothers against streptococcus infection. Those treated during the ninth month of pregnancy are given a polyvalent streptococcus vaccine (750 million killed organisms). Those coming to treatment immediately before or shortly after the onset of labour are given a combined treatment, endeavour being made (1) to induce active immunity by injection of 500 million dead streptococci, (2) at the same time to confer a passive immunity by injection of 50 c.cm. of anti-streptococcus serum. The combined treatment is essential for protecting at term: the serum contains antibodies which compensate for the negative phase ensuing on administration of the vaccine. Three hundred and fifty cases immunized on these lines showed a minimal incidence of blood infection. P. ZWEIFEL (*Deut. med. Woch.*, 1922, 23), as the result of thirty-four years' experience at the Leipzig clinic, concludes that the most important factor in prevention of puerperal fever is the avoidance of contamination by pus, either (1) from wounds or fistulae of the patient (which should be carefully bound up during labour) or (2) by reason of those attending or conducting the labour having been in contact with other sources of infection. Patients having a purulent discharge during pregnancy should be systematically douches with lactic acid. In the material of the clinic the introduction of rubber gloves led to no diminution of the mortality from puerperal fever; this, however, was notably reduced when protection by gloves was combined with strong antiseptic measures. Zweifel recommends that it should be made compulsory for midwives to wear thick rubber gloves.

PATHOLOGY.

518. The Wassermann Reaction in Non-luetic Cases.

T. MCKEAN DOWNS (*Amer. Journ. Med. Sci.*, October, 1922, p. 514) records the case of a seaman, aged 19, who contracted malaria five months prior to admission to hospital for a relapse of tertian malaria; he denied any venereal disease, and no symptoms of syphilis were observed; the blood was loaded with tertian parasites and the Wassermann reaction was weakly positive. The author quotes numerous authorities. Osler and Churchman (*Modern Medicine*, 1914) say that the reaction is positive in syphilis, tubercular leprosy, and fresh malaria. Lepinasso states that the reaction is not absolutely specific, but may occur in yaws, tubercular leprosy, some cases of relapsing fever, malaria (in the febrile stage), some cases of trypanosomiasis, and beri-beri. Connor confirms this, and says that false positives may occur in diabetes with acidosis. Downs comments on the absence of any standardized technique for the test and the large possibilities of error. Müller found a positive reaction in 88 per cent. of cases of yaws. Bohn found it in 35 per cent. of cases of malaria, the reaction disappearing when the malaria was cured. Müller found positive reactions in 3 per cent. of cases of advanced tuberculosis and 19 per cent. in cases of tubercular leprosy, but the anaesthetic form was always negative. Kolmer states that the cerebro-spinal fluid is much less subject to error than blood serum. He found it positive only in yaws and leprosy, in addition to syphilis. Craig observes that tuberculosis is more commonly associated with syphilis than any other disease, and that syphilis of the lung is not infrequently called tuberculosis. "If syphilis be excluded tuberculosis does not give a positive reaction. If the positive Wassermann in malaria persists after disappearance of all fever syphilis is a complication." Downs details the experience of the Philadelphia General Hospital and of the Pennsylvania Hospital in cases of malaria and of tuberculosis subjected to

the test, including six cases of advanced tuberculosis in which the reaction was positive with cholesterylized antigen but negative with all others. He concludes as follows: (1) The Wassermann reaction is invariably positive at some time during the course of syphilis. (2) It is but rarely positive in non-luetic diseases. (3) It is unusual for it to be positive in malaria; if so it is only weak or doubtful (Craig) while fever is rising, becoming negative between paroxysms. (4) It is rarely positive in tuberculosis, and is then weak or doubtful (that is, not diagnostic of lues in absence of history or signs). Downs has found it positive only in far advanced cases. (5) It is not positive in uncomplicated hyperthyroidism. (6) The cholesterylized antigen is probably too delicate to be of value alone in diagnosing lues in the absence of history and symptoms. It is invaluable in following the course of known syphilis under treatment by reason of its delicacy.

519.

Experimental Rickets.

A GOOD summary is given by PAUZAT (*Gaz. hebdom. des Sci. méd. de Bordeaux*, November 26th, 1922, p. 567) of the work which has been carried out during the past two years by Pappenheimer and his associates on the production of rickets in animals. Rats 4 weeks old were chosen, and a diet was found which was uniformly successful in giving rise to rickets. This consisted of purified flour, calcium lactate, sodium chloride, and iron citrate. After four weeks on this regimen the animals had developed definite rickets, characterized macroscopically by costal nodes and typhosis, and microscopically by decalcification of the ribs. Now this dietary, though high in its calcium content, was poor in phosphorus, and it was discovered that the simple addition of 3 or 4 per cent. potassium phosphate sufficed to prevent the appearance of rickets. The elimination of calcium from the diet did not lead to the development of rickets, so long as plenty of phosphorus was given, though troubles in osteogenesis of non-rachitic nature did arise. The importance of vitamin A was now investigated. In the original dietary 5 per cent. of the flour was replaced by fresh butter, which is rich in this principle. The results showed that though the rats were protected from xerophthalmia they still developed rickets. He therefore inclines to the belief that rickets cannot be considered as an avitaminosis at all. In this connexion, however, it is difficult to understand, from the data given, exactly where he draws the dividing line between rickets and xerophthalmia, for in the latter disease he finds definite lesions in the bones, which he considers as non-rachitic. With regard to the cure of his rats, he states that the administration of cod-liver oil brought about a progressive recalcification of the ribs, as was expected. Further, however, by submitting the oil to a process of continuous oxidation he succeeded in destroying the antixerophthalmic properties while leaving the antirachitic properties intact. From this he concludes that the antirachitic principle in cod-liver oil is not identical with the vitamin A encountered in food. Finally, he showed that a rat which had developed rickets could be cured by exposure to the sun for fifteen minutes a day, or to a quartz lamp for one and a half minutes. That the ultraviolet rays were responsible for this action was proved by filtering them off by a glass screen—a procedure which deprived the light of its therapeutic effect.

520.

Influence of Antityphoid Vaccination on the Enteric Fevers.

AN interesting analysis is given by P. HÉBERT and M. BLOCH (*Rev. d'Hygiène*, November, 1922, p. 969) relating to the condition with regard to antityphoid vaccination of 2,334 cases of enteric fever from whom a positive blood culture was obtained. The study was conducted at a military hospital and lasted from July, 1916, to January, 1919. Altogether there were 431 cases of typhoid, 1,598 of paratyphoid A, and 305 of paratyphoid B. Of the typhoid cases 91 per cent. occurred amongst patients who had either not been vaccinated or who had been insufficiently vaccinated; of the paratyphoid A cases 75.9 per cent. belonged to these two classes, and of the paratyphoid B cases 85 per cent. Of the total 2,334 cases it may therefore be said that only 20.1 per cent. occurred amongst patients who had been fully vaccinated with T.A.B. within the previous year, or who had been revaccinated within that period. Studying the period elapsing between the last injection and the development of the disease, it was found that the majority of the cases of paratyphoid A and B occurred from six to nine months after vaccination, while the greater number of cases of typhoid fell between the fifteenth and twenty-first months. From this it would appear that during the first year following vaccination immunity is strongest against typhoid, while during the second year it is stronger against paratyphoid A and B. With regard to mortality, 77 per cent. of the fatal cases were contributed by patients who had not been vaccinated or whose vaccination was incomplete, while 23 per cent. were furnished by the fully vaccinated. Several other interesting points are dealt with which will repay study.

Motoring all the year round.

THE graceful lines, exquisite finish and luxurious upholstery of the Wolseley covered carriages, render them particularly attractive to those to whom motoring refinement appeals.

Their remarkably effective suspension, their economy in running cost and high road efficiency make them equally suitable for touring or for town work.

THE ROVER COMPANY, LIMITED, COVENTRY,
59a, New Oxford Street, London and Lord Edward Street, Dublin.

THE 12 h.p. ROVER Limousine Coupe illustrated, is acknowledged to be the most handsome car of its type, eminently suitable for social and town use. It is warm and draught proof when closed, and with the top ventilator, adjustable front and sliding side windows can be arranged for any degree of comfort in the hottest or coldest weather.

The full range of Rover Models includes: 12 h.p. Chassis £415, 12 h.p. Two-Seater £525, 12 h.p. Four-Seater £550, 12 h.p. Limousine Coupe £650, 12 h.p. Coupe (Drop Head) £675, 12 h.p. Saloon £775, 8 h.p. Two-Seater £480, 8 h.p. Four-Seater £490, 8 h.p. Two-Seater De Luxe £200, 8 h.p. Four-Seater De Luxe £210, 8 h.p. Coupe with self-starter, £240. Self-starter on 8 h.p. Models £15 extra. So far as can be foreseen at present there is not likely to be any further reduction in the prices of Rover cars during the 1923 season.
